where PH is the realized cash price of hogs at time t as defined above, $({}_{t-i}FP)_t$ is the futures price for t observed at time $t - i$ and $({}_{t-i}PPH)_t$ is the predicted cash price for t made at time

$t - i$ and generated from our above econometric model. The assumption about unbiased predictors simplifies, but is not critical to, our analysis. Theoretically, if both forecasts are equally efficient, β should equal 0.5. The coefficients reflect the weights of individual predictors and their marginal contribution to the composite predictor. The composite model is estimated by ordinary least squares, with the β restricted to lie between zero and one.

Evaluation of Results

Interpretation of the futures price being an estimate of subsequent spot prices applies only to the delivery months and not to nondelivery months. Hence, we test the two forecasts against the cash price only during the months of contract maturity, which are February, April, June, July, August, October, and December. For academic interests we also tested the models for all twelve months of the year and found no significant difference in results from those presented. The procedure followed is to compare the econometric forecast i months forward with a corresponding futures price i months prior to delivery.

Table 1 gives for annual forecast periods and the combined seven-year period the *RMSE* and composite regression weights when actual sow farrowings are used in the supply equation. The seven-year period results on the bottom line of the table show the *RMSE* for the futures market being smaller than the econometric model, and the futures market having a larger composite weight. These results would indicate the futures market is the more efficient predictor.

Table 1. Summary Measures of Forecasting Accuracy When Using Actual Sow Farrowings

	RMSE		Composite Regression Weights[b]	
Time Period[a]	*FP*	*PPH*	*FP*	*PPH*
1971(4)–72(2)	2.18	2.75	.41 (2.19)	.51 (3.01)
1972(4)–73(2)	2.95	3.35	.45 (3.10)	.70 (5.05)
1973(4)–74(2)	9.48	15.14	.64 (2.84)	.45 (1.38)
1974(4)–75(2)	7.86	3.17	.13 (.80)	.80 (4.65)
1975(4)–76(2)	10.94	5.90	.001 (.004)	1.00 (3.64)
1976(4)–77(2)	5.63	10.09	.52 (2.03)	.42 (1.99)
1977(4)–78(2)	7.09	5.07	.71 (3.36)	.35 (2.05)
1971(4)–78(2)	7.30	7.67	.57 (6.56)	.44 (5.50)

Note: *FP* is futures price; *PPH* is predicted cash price from the econometric model.

[a] The number in parentheses following the year indicates the month of the year.

[b] The number in parentheses below the coefficient is the t-ratio.

However, examination of the results year-by-year casts doubts on that conclusion. The econometric model has a smaller *RMSE* in three of the seven individual years, and it has the larger composite weight in four of the seven years. (Because of the potential multicollinearity problems, the t-test may be distorted, but, other things equal, the larger weights always have higher t-ratios.) Hence, when disaggregating the evaluative measures, the econometric model, by both measures, demonstrates periods of being the more efficient predictor. During the highly volatile period of 1974–75, both measures indicate the econometric model as the more efficient.

The evaluation measures demonstrate quite similar results when sow-farrowing intentions are used in the supply equation. (The statistical results are available from the authors.) Forecasts in this case are for the three months further out than when actual sow farrowings are used. Over the full seven years, both forecasting techniques have a *RMSE* equal to 8.9, while the futures market has a larger composite weight. The year-by-year results conform fairly closely to those just noted above; namely, that the econometric model on occasion provides more accurate estimates of subsequent spot prices than the futures market, even when forecasting as far as six to eight months forward.

Three evaluative tests were performed to validate whether in fact the econometric model itself uses information to generate improved forecasts. The model was tested year-by-year against a naive model which used last-month's cash price as the predictor of the subsequent cash price. Using *RMSE* as the evaluative technique, the naive model performed slightly better than the econometric model, while the econometric model performed slightly better under the composite prediction evaluator. However, when comparing which model indicates more accurately the correct direction of future price changes, the econometric model did substantially better. Hence, the econometric model does provide modest improved forecast information. Fur-

thermore, to rely solely upon a naive or time-series model instead of an econometric model as a performance norm would reduce our tests of the futures market to the weak-form type, contrary to the goal of conducting a semi-strong form test of market efficiency. Note throughout this analysis that the composite predictor credits the econometric model as being relatively more accurate than does *RMSE*, the standard measure in many earlier market tests.

Finally, using the econometric model to indicate the direction of futures market price changes, and utilizing the naive trading strategy of buy-and-hold if the predicted price exceeds the futures price (if opposite, sell-and-hold), substantial trading profits could have been generated between 1971 and 1978 in the hog futures market. These profits were much larger than what would be expected in an efficient market and indicate that changes in futures prices can be predicted by our econometric model. Thus, objectionable inaccuracies are present.

Implications

The semi-strong form test of marketing efficiency examines if the market employs all publicly available information in forming expectations about future spot prices. This test establishes a performance norm for comparing alternative forecasts, thereby determining if objectionable inaccuracies exist. Previously cited tests were unable to distinguish whether forward-pricing errors were due to information or judgment.

The live-hog futures market has not consistently utilized all the available market information. It appears to react slowly. The price changes in the futures market have at times been predictable, indicating the presence of objectionable inaccuracy. Hence, the futures prices for hogs are not reliable estimates of subsequent cash prices. These results hold both when using actual sow farrowings and farrowing intentions.

One institutional rule that could be blamed for this inefficiency is the daily limit in price moves which prevents the market from adjusting fully within one day to new information. Because we used monthly observations, this rule seems unlikely to be the cause for forward-pricing inefficiency. The more likely cause is poor quality speculation. This can come from inexperienced and unknowledgeable traders, poorly specified forecasting models, and/or the lack of available trading capital to take advantage of the errors.

Research cited above demonstrated that producers utilize futures prices in making production and marketing decisions. This reopens the issue that a futures market cannot act as a forecasting agency and as a medium for rational price formation (Gray, pp. 323–28), which relates to our conclusions. A good price forecast from the futures market could elicit a response (in the cobweb context) that would defeat the forecast. But with the sow-farrowing and farrowing intentions reports, producer production decisions have been made and are being reported. With this information on supply response known, futures prices should then be reflecting expected subsequent spot prices. The potential sources of inaccuracies from that point of time, such as farrowing sampling errors, production uncertainty, demand response shifts, or altering market weights and rates of gain, cannot in our judgment fully account for the magnitude of the futures market errors noted.

Whether these errors cause resources to be misallocated from production decisions cannot be ascertained specifically from this analysis due to the time horizon being shorter than the biological lag. Related research questions suggested for examination are the extent to which expectations affect cash and futures prices simultaneously, and the direction of causality between cash and futures prices and their relative impacts. However, using poor-quality futures prices in marketing- and feeding-rate decisions may cause bad timing for producers, potentially creating financial losses. Reliance by producers on inaccurate futures prices as expected prices may cause them to lose confidence in the market and ignore its potential in risk management. The relationship between trader commitments and forward-pricing accuracy needs investigation.

How can the quality or accuracy of hog futures prices as expected prices be improved? Very few people foresaw the volatile prices of the 1970s, but close examination of the data for hogs indicates the warning signs were present. Certainly, more or better informed traders could improve the forward-pricing accuracy of the futures market. One can observe from this study that few economic variables need to be examined for effective trading decisions. Because few producers ac-

tually use the market, educational programs designed to inform producers of the market's benefits might encourage a well-informed group of traders into the market. A reason for poor performance may be the lack of a sufficient proportion of producers and firms forward pricing. Active trading by commercial firms may aid in rational price formation. If lack of financial capital causes the market to react slowly to information, either reducing margin requirements or contract size may encourage additional traders to the market, thereby improving forward-pricing efficiency.

Finally, further research on market performance may find this technique applicable to other commodities. Subsequent models might identify moving-average and autoregressive components of the time series within the econometric forecasting scheme. Such expansions and improvements will gradually increase the rigor of testing the efficiency of a market or the expectations hypothesis in a semi-strong form context.

Summary

Using a semi-strong form test, we have found that on occasion the live-hog futures market has not performed efficiently. Using an econometric forecasting model as a performance norm, the futures market by comparison has not at all times fully reflected the available information. This has allowed us to observe the presence of objectionable inaccuracies. The hog futures prices cannot consistently be relied upon to reflect accurately subsequent spot prices, and thereby the market is not considered efficient.

Risk Preferences and Flood Insurance

E. D. Attanasi and M. R. Karlinger

A detailed theoretical model characterizing the individual's decision to purchase flood insurance is specified and the magnitude of the risk parameter is estimated using data based on transactions of flood insurance purchases. Empirical results for several samples of this subset of the general population indicated that consumers exhibited a relatively uniform degree of risk aversion across various localities where different hydrologic and economic conditions prevailed. While the estimates presented should not be directly extrapolated to the entire population located in a flood prone area, they provide evidence that parameters determining an individual's and/or community's willingness to pay for flood protection can be measured.

Key words: disaster insurance, floods, risk aversion.

In this paper, a model characterizing the individual's decision to purchase flood insurance is specified and empirically parameterized. The model conforms to the Von-Neumann Morgenstern expected-utility hypothesis. Data used for estimating the model parameters are based on transactions of insurance purchases and also include detailed hydrologic and economic information. Recent studies (Kunreuther, Kunreuther and Slovic) appear to suggest that potential consumers of natural disaster insurance have difficulty comprehending consequences of events which cause severe losses but which occur with relatively low frequency, resulting in behavior that is inconsistent with the Von-Neumann Morgenstern expected-utility hypothesis. Results presented here for samples of insurance purchasers located in various areas subject to different hydrologic and economic conditions indicate risk-averse behavior and parameter estimates that are somewhat similar.

The plan of the paper is as follows: in the next section, a consumer decision model is presented along with assumptions relating to the form of the flood distribution, damage function, and consumer utility function. After deriving a partial equilibrium solution to the consumer optimization problem, the data are discussed. Empirical results are presented, as well as tests for the validity of the underlying model. In the concluding section, the interpretation and implications of the findings for public policy are discussed.

Consumer Decision Model

The motivation for this analysis rests largely on the failure of previous studies to characterize adequately the consumers' decision to purchase flood insurance. Among the components of a "complete," although specialized, model are assumptions relating to the level and form of the physical damage function, the probability distribution associated with flood occurrence, and a form for the consumers' utility function. In the following discussion, specifics relating to these components are considered and integrated into a decision model which can be solved to yield the optimal coverage as a function of risk preferences, premium structure, the damage function, and parameters of the probability distribution governing the occurrence of floods. Inasmuch as an explicit form of the utility function must be specified in order to estimate the model, the analysis is limited and should be interpreted as being somewhat exploratory.

In accordance with the expected-utility theory of behavior under conditions of uncertainty (Arrow), the consumer is assumed to maximize expected utility of wealth where

E. D. Attanasi is an economist with the U.S. Geological Survey, Reston, Virginia, and M. R. Karlinger is a hydrologist with the U.S. Geological Survey in Tacoma, Washington.

The authors wish to express their appreciation to the referees for helpful comments and to the National Flood Insurors Association for the data used in this study.

properties of the utility function follow the Von-Neumann Morgenstern axioms (Mossin). The utility function is assumed to be bounded, monotone increasing, and concave, with increments to wealth. With these assumptions, it may be shown that the individual's utility function exhibits risk aversion. A utility function that conforms to these assumptions and which has been used in applied studies (Gould, Friedman) is the exponential utility function of the form

(1) $$U(Y) = 1 - \exp(-\alpha Y),$$

where Y is final wealth and the parameter α is the Arrow-Pratt measure of absolute risk aversion (Arrow); that is, $\alpha = -U''(Y)/U'(Y)$. Because observed behavior seems to suggest that individual's utility functions should be characterized by decreasing absolute risk aversion, the use of the exponential utility function (exhibiting constant absolute risk aversion) in applied situations is regarded frequently with some disfavor (Arrow). The exponential utility function was used here because it allowed the algebraic separation of the individual's total wealth from that part of wealth subject to flood hazards, thus making it possible to use transactions data to estimate the risk-aversion parameter.

For the specification of the consumer's decision problem, the wealth function will take several forms, depending on damages. Flood insurance deductible provisions specify that damage reimbursements do not include the first \$200 or 2% of the amount of losses (whichever is greater) (Vaut). The argument of the wealth function includes: A, the value of the individual's assets not subject to loss; L, the maximum value of assets which are subject to flood losses; C, the amount of coverage; P, the premium rate; and X, (random) damages associated with a hazard event. In particular, if coverage and maximum liability are greater than \$10,000, expressions for final wealth are

(2a) $$W_0 = A + L - PC, X = 0,$$

(2b) $$W_1 = A + L - PC - X, 0 < X < 200,$$

(2c) $$W_2 = A + L - PC - 200, \quad 200 < X \le 10{,}000,$$

(2d) $$W_3 = A + L - PC - .02X, \quad 10{,}000 < X < C < L, \text{ and}$$

(2e) $$W_4 = A + L - PC - .02X - (X - C), \quad 10{,}000 < C \le X \le L.$$

A somewhat similar set of expressions would result if coverage were less than \$10,000. The definition of a flood used here is the instantaneous annual peak flow at a given location.

Damages generated, X, are assumed to be a monotone nondecreasing function of the particular peak discharge (McCrory, James, Jones). That is, the probability distribution associated with damages, X, is directly related to the flood discharge probability distribution through the damage function. When a particular flood is discussed, it is frequently referred to in terms of its recurrence intervals. The recurrence interval in years is defined as the reciprocal of the probability of a particular flood discharge being exceeded in any given year. Given the form and parameters of a particular probability distribution associated with floods, the discharge magnitude of a specific recurrence interval can thus be determined. For less than some minimum flood, Q_0, for example, the ten-year flood, damages are assumed to be zero (negligible). For floods greater than some catastrophic flood, Q_T, damages are set equal to the value of assets subject to flood losses. Even for small increments beyond Q_0 which result in a flood depth as small as 0.1 feet, damages average about 5% of the total value of the structure (McCrory, James, Jones). Therefore, the probability associated with the interval where W_1 holds in the wealth function is quite small. For computational convenience the respective intervals for W_1 and W_2 were combined and W_2 was employed as the relevant wealth function. This is equivalent to stating that any flood greater than Q_0 results in damages of at least \$200. In addition, in all cases 2% of maximum liability represented a small percentage of the individuals' coverage. Consequently, for computational purposes the expected utility may be written as

(3) $$\begin{aligned} E[U(Y)] &= \left(1 - \exp\{-\alpha W_0[X(Q_0)]\}\right)k_1 \\ &+ \int_{Q_a}^{Q_b} \left(1 - \exp\{\alpha W_2[X(Q)]\}\right) f(Q)\,dQ \\ &+ \int_{Q_b}^{Q_c} \left(1 - \exp\{-\alpha W_3[X(Q)]\}\right) f(Q)\,dQ \\ &+ \int_{Q_c}^{Q_T} \left(1 - \exp\{-\alpha W_4[X(Q)]\}\right) f(Q)\,dQ \end{aligned}$$

$$+ \left(1 - \exp\{-\alpha W_4[X(Q_T)]\}\right)k_2,$$

with the damages X specified according to

$$(4) \qquad X = \begin{cases} 0, \; Q \leq Q_0 \\ g(Q), \; Q_0 < Q < Q_T, \\ L, \; Q_T \leq Q \end{cases}$$

and where k_1 and k_2 are probabilities associated with flood discharges less than Q_0 and events with discharges greater than Q_T, respectively, and $f(Q)$ is the flood discharge probability density. Limits of integration Q_a, Q_b, and Q_c correspond to damage intervals defined by the relevant wealth function in equation (2). For example, Q_b and Q_c define the floods between which damages are greater than \$10,000 but less than coverage and are used in (2d). These are calculated using the inverse of the analytical form of the damage function, which was assumed to be linear between Q_0 and Q_T (fig. 1). That is $g(Q)$ has the form $a(Q - Q_0)$, where a is the slope of the damage function.[1] To complete the specification of the model, it is assumed that flood events, that is discharges, Q, follow a two-parameter log normal distribution (Aitchison and Brown).

Given a premium, the consumer is assumed to choose coverage so as to maximize expected utility. To obtain coverage the integrated form of equation (3) may be differentiated with respect to C, with the solution to the first order condition providing optimal coverage. The distribution function of damage levels is well-behaved and the utility function is concave. Because of the complexity of the resulting expectation expression, individual's optimal coverage could not be solved in closed form but was done numerically.[2] Using transactions data associated with the purchases of flood insurance, the risk parameter, α was estimated from the first order condition yielding the consumer's optimal choice of coverage. After differentiating equation (3) with respect to C, the expression, $\exp[-\alpha(A)]$, was factored from all the terms. The remaining integrand expressions containing exponential terms with the damage variable were subsequently expanded using a fourth order Maclauren's series. Estimation of α was carried out using the equation which results from the first-order condition and data for L, P, C, $g(Q)$, and $f(Q)$.

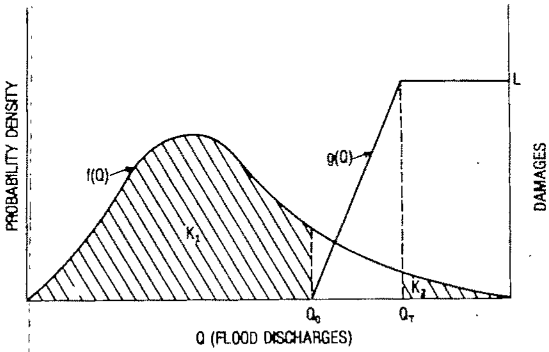

Figure 1. Damage function with weighting function

Data

The economic data are based, in part, on a sample of individual insurance contracts from four preselected towns (Clark, Cranford, Plainfield, and Elizabeth) in New Jersey. Each town was enrolled under regular provisions of the National Flood Insurance program. To be admitted on a regular basis a jurisdiction must have had a topographic and hydrologic study carried out for the development of technical information to be used in the preparation of a Flood Insurance Rate Map (National Flood Insurance Act, 1968). Once a community is admitted to the regular program, new policies are subject to actuarial rates rather than the very highly subsidized emergency program

[1] Engineering studies indicate that the relationship between economic damages and the flood discharge approximates a square root function (McCrory, James, Jones) sensitivity studies for the two alternative functional forms for an idealized situation suggested that the use of the empirically estimated linear function may have produced a slight downward bias in estimates of the risk aversion parameter.

[2] After differentiating equation (3) with respect to C (using Leibnitz's rule) and factoring out the term $\exp(-\alpha A)$, the first order condition (for the insurance purchaser with greater than \$10,000 coverage) becomes:

$$0 = (\alpha P)^{k_1} + (\alpha P)[\exp(200\alpha)]k_3 + (\alpha P - \alpha)[\exp(1.02\alpha L - \alpha C)]k_2 + \alpha P \int_{Q_b}^{Q_c} \{\exp[.02\alpha g(Q)]\}f(Q)dQ + (\alpha P - \alpha) \int_{Q_c}^{Q_T} \{\exp[1.02\alpha g(Q) - \alpha C]\}f(Q)dQ,$$

where k_3 is the probability associated with the discharge causing damages between zero and \$10,000 and the other variables are defined as above. The integral terms in the equation above were evaluated by applying Maclauren's expansion to the exponential variable terms (to the fourth order term). A similar process could be carried out to obtain the first order conditions for individuals who purchased less than \$10,000 coverage. Applying an iterative numerical procedures the value of α was estimated using the above expression.

rates. Other reasons these four towns were chosen are that only one dominant river was located in each and the localities were not subject to tidal or coastal flooding. The residences sampled were located in the AO and C flood hazard zone. Zone AO is defined to be in the one hundred-year floodplain but subject to shallow flooding (up to three feet) at the hundred-year flood. The zone C hazard area was defined as an area subject to damage beginning with the occurrence of a flood of the magnitude of the five hundred-year flood.

These zone definitions and the historic hydrologic data provided the basic information upon which the damage function was positioned. Using the hydrologic records of the individual town, estimates of the mean (μ) and standard deviation (σ) of the flood distribution were obtained. For AO zone, the flood whose estimated stage was three feet below the hundred-year flood stage was chosen to be the maximum zero damage flood, Q_0. Actual values of the hundred-year flood discharge were determined from the information provided in the topographic and hydrologic information report carried out for each town prior to entering the National Flood Insurance Program under the regular provisions. Estimated flood distribution parameters, μ and σ, were used to determine the frequency (or relatedly the cumulative probability) associated with Q_0. By definition, the exceedance probability for Q_0 in zone C is 0.002. For the AO and C zones the discharge, Q_T, which was assumed to assure maximum damage (or a catastrophic event) was chosen to be the ten thousand-year flood. In order to determine the slope of the damage function, $g(Q)$, damages were estimated for the discharge level Q_T, using engineering damage stage functions (McCrory, James, Jones).[3]

In contrast to other studies, the sample data are based on actual transactions. The information obtained from the insurance policies included a structural description of the dwelling, insurance coverage, and the premium amount. Because the exact locations of individual properties were not identified, the values of the insured buildings were estimated. Information on current market prices (less the estimated value of the typical residential lot) for houses in the same town and with similar structural characteristics was used in deriving the estimated maximum liability. The range of market prices for similar types of houses within each town was not more than 15% of the town's average value for that type of dwelling. No attempt was made to obtain data on nonpurchasers of insurance living in areas subject to the same flood risks who own buildings of the same value with similar structural characteristics. There were two reasons for this. The fact that individuals and street addresses were not identified made it difficult to design a survey to obtain information on nonpurchasers. Second, before the decision to purchase insurance can be made rationally, it is assumed that the individual has all the relevant information. Survey studies (Kunreuther) suggest that nonpurchasers are frequently ignorant not only of the potential hazard risks in the areas in which they live but also have little or no knowledge of the terms or existence of the insurance program. Consequently, the results obtained are valid only for a subset of the general population.

The insurance contract information also included data on the current premiums and the amount of coverage that the individual was carrying. As mentioned earlier, the variable, A, defined as the value of the individual's wealth was not subject to the flood hazard was eliminated after differentiation of equation (3). Given the estimated damage function, premiums, along with the procedure for adjusting premiums, coverage, and the maximum liability, individual risk aversion parameters were estimated using the procedure described in the second section.

Results and Interpretation

Estimates of the risk-aversion parameter and their sample standard deviations (table 1) across all townships are reasonably consistent. Moreover, the ratios of the coefficient estimates to their sample standard deviations for the larger samples indicate the quality of the estimates to be relatively good. While risk

[3] According to the damage table presented in McCrory, James, and Jones, stage levels greater than fifteen feet are necessary to cause maximum damage. For the AO zone market values (exclusive of land) were used as the maximum damages. Although it might be argued that floods rarely totally destroy a dwelling, it was felt that estimated market prices understated expected replacement costs of the dwelling. Alternatively, for residents of the C flood zone (a much less hazardous zone), maximum damage was set at 60% of the market value. Parameters of the flood discharge distribution (μ and σ) in cubic feet per second are for Clark, 1053 and 466; Cranford, 1053 and 466; Elizabeth, 4700 and 1689; Plainfield, 882 and 773. For the AO zones, the respective values for k_1 are .67, .67, .98, and .50 while the value for k_2 was .0001 in all cases (see fig. 1). By definition for all the C zone residents k_1 was .998 and k_2 was .0001.

Table 1. Estimated Risk Aversion Parameters

Towns	N^a	I	N	II	N	III	N	IV	N	Pooled
AO zone	4	.000355	13	.000355	9	.000347	16	.000310	42	.000336
		(.000192)		(.000164)		(.000120)		(.000131)		(.000140)
C zone	5	.000236	1	.000100		—		—	6	.000213
		(.000171)		—		—		—		(.000162)
Pooled data	9	.000289	14	.000333	9	.000347	16	.000310	48	.000319
		(.000180)		(.000186)		(.000120)		(.000131)		(.000152)

Note: Numbers in parentheses are standard deviations.
[a] N is the sample size. Towns are I, Clark; II, Cranford; III, Plainfield; and IV, Elizabeth.

parameter estimates for C zone residents were lower, this may be the result of a small sample size. The relative uniformity in the estimated levels of risk aversion is worth noting. In most cases the market value of housing for township IV was estimated to be about three-fourths the market value of similar housing in townships I and II. Income levels for township IV were also relatively lower. Uniformity in the estimates of the risk parameter across townships is consistent with constant absolute risk aversion.

In order to examine how the individual's demand, i.e., premium versus coverage, changes as the risk-aversion parameter changes, the consumer model was used to obtain reservation price as a function of coverage. The hydrologic assumptions corresponded to the case for a resident in the AO zone in township I or Clark, New Jersey, with the maximum liability set at $40,000. Results indicate that the individual's demand for insurance becomes more price inelastic and shifts to the right (for any given premium the optimal insurance coverage increases) as the risk parameter value increases. An example of the shift is shown by figure 2 for risk parameters equal to .00030 and .00035.

Conclusions

The results of this analysis have several implications. Estimated risk coefficients were all positive and different from zero. Behavior of the sampled individuals who purchased insurance was not inconsistent with the expected utility hypothesis. The uniformity in the values of the estimated risk parameters across townships may suggest a broader applicability of the estimated utility function. Estimates of the risk parameters and the results of the numerical experiments applying these estimates appear to be reasonable.

The federal flood insurance program was instituted to avoid the inefficiency of society as a whole bearing the cost of flood protection in the form of structural flood control measures (reservoirs, levees, etc.) while benefits accrue to relatively few individuals (Dacy and Kunreuther). Community participation in the regular program requires that some floodplain landuse-planning measures be instituted. Estimates of a community's willingness to pay for flood protection might enable officials to structure premiums to generate sufficient rev-

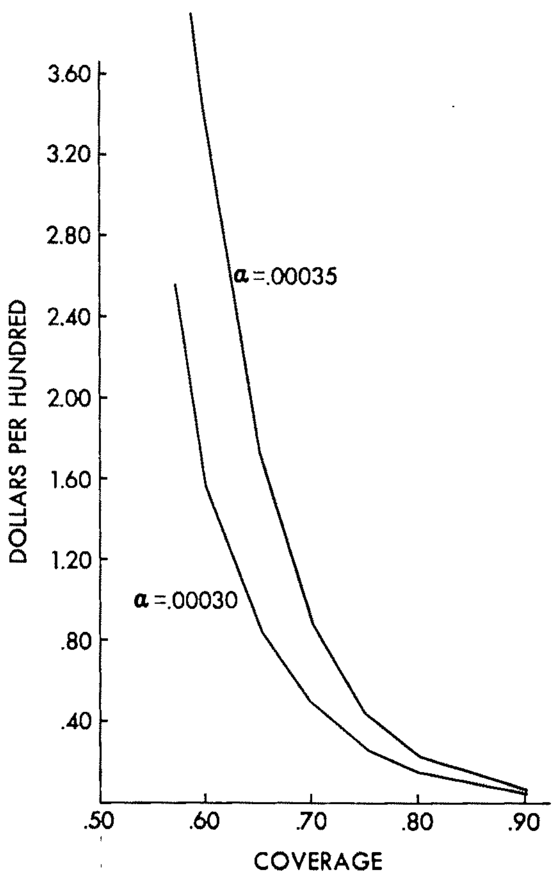

Figure 2. Price vs. coverage

enue to pay for structural flood protection measures or induce abandonment of the floodplain (if insurance is mandatory). Estimates might also be employed in the design of multipurpose (flood control, recreational, hydroelectric) water resource projects (Maass et al.).

When considering the direction of future research, these results should be placed in perspective with other studies relating to individual behavior and natural hazard events. First, although other forms of the utility function might yield different results, use of the lognormal distribution to describe flood events severely limited forms that were analytically tractable. Second, the sample used in this study was restricted to those purchasing insurance. Presumably, these individuals were relatively well-informed about the nature of the natural hazard event. Kunreuther, on the basis of the results of survey studies, has suggested that there is a positive and perhaps significant cost associated with becoming informed about the nature of the flood hazard. These explanations may in part account for the seeming inconsistencies in observed behavior with economic theories that have been reported. It appears that more needs to be known about individuals who did not purchase insurance. Perhaps the decision to purchase insurance should be modeled using a threshold approach (Kunreuther). It has also been argued that flood insurance marketing efforts have been less than vigorous. The nature of risks associated with residing in the floodplain must be communicated in a manner that can be understood by the general population. Efforts appear to be underway to remedy the problem of nonparticipation (Vaut). While the empirical estimates presented here should not be directly extrapolated to the entire population located in a flood prone area, they provide evidence that critical parameters determining the individual's demand for insurance can be measured. If greater levels of participation are brought about by efforts to inform residents of the damages of floods and through increased marketing efforts, the methodology presented and type of information used in this study provide a means for estimating a community's willingness to pay for flood protection.

Flood Insurance or Disaster Loans: An Economic Evaluation

Michael J. Rettger and Richard N. Boisvert

Alternative federal flood disaster assistance programs are evaluated through an economic comparison of flood insurance and disaster loan programs. The distribution of costs, benefits, and program transfers, both private and public, are simulated over time and are analyzed to determine the sensitivity of program performance to specific program parameters. Empirical results demonstrate that both programs provide adequate levels of protection at approximately equivalent costs. Variations in premium and interest rate subsidies have major effects on the distribution of total costs between the public and private sectors.

Key words: disaster loans, flood insurance.

Since the 1950s, the Small Business Administration (SBA) and the Farmer's Home Administration (FmHA) have been the primary sources of federal aid to flood victims (Dacy and Kunreuther). Recent sharp criticism has been directed at these and other loan programs which, through interest rate subsidies and liberal forgiveness provisions, have contributed to increased federal relief costs for every major flood disaster since 1960 (Kunreuther). Critics argue that by shifting costs to the federal government, these programs subsidize the development of the nation's floodplains and are responsible in part for the growth in average annual flood damages from $250 million in 1950 to $1.5 billion in 1975 (U.S. Congress).

As an alternative, the federal government has established the National Flood Insurance Program (NFIP). The program provides some subsidies to the insurance rates paid on existing floodplain properties, but it is intended to operate ultimately on a sound financial basis, with the major burden of flood losses to be paid by those exposed to the hazard. The program seeks to control future flood losses by requiring communities to adopt strict regulations governing new and renovated buildings in flood hazard areas.

Research evaluating these alternative relief and insurance programs is beginning to appear. Schaake and Fiering and Friedman and Roy derived countrywide estimates of program performance, costs, and benefits from temporal simulations of a flood insurance fund, but neither study estimated similar results for alternative relief programs. Kunreuther, on the other hand, compared the impacts of flood insurance and the SBA loan program on hypothetical victims of a single major flood disaster.

The study on which this article is based involves a more comprehensive economic comparison of emergency and regular flood insurance programs and SBA-type disaster loan programs (Rettger). The distributions of costs and benefits among participating groups, both public and private, are simulated over time and are analyzed to determine the sensitivity of program performance to specific program parameters. Although the empirical results are based on a case study of the Binghamton, New York, metropolitan area, the simulation methodology could be adapted to other areas.

Flood Insurance and Loan Programs

Established in 1968, the NFIP provides federally subsidized insurance against flood losses to properties in flood hazard areas. In order to provide for both immediate and longer-term needs for insurance coverage of flood-prone

---

Michael J. Rettger is an economist with the Michigan State Insurance Department; Richard N. Boisvert is an associate professor of agricultural economics, Cornell University.

Funds for this research were provided in part by the Center for Environmental Research, Cornell University, through the Annual Allotment Project No. A-074-NY from the Office of Water Research and Technology, U.S. Department of the Interior.

communities, the NFIP is designed to operate at two levels (Flood Disaster Protection Act, P.L. 93-234). Initially, usually after the issuance of a Flood Hazard Boundary Map (FHBM), a community can qualify for the "emergency" flood insurance program by adopting and enforcing minimum land-use standards. After a flood insurance study of the community has been prepared to determine flood profiles, actuarial insurance rates, and floodplain boundaries, the community becomes qualified for the "regular" flood insurance program. To enroll a town must, within six months of qualification, adopt strict land-use regulations establishing minimum building elevation and floodproofing standards and floodway encroachment boundaries.

Emergency program insurance rates are legislatively established and apply to first-layer coverage (e.g., single-family residential coverage is limited to \$35,000 structure and \$10,000 contents coverage) on all properties constructed in a community prior to the determination of actuarial insurance rates. Actuarial rates, once specified, apply to all new construction and substantial improvements begun after the actuarial rates become effective, to all properties for which actuarial rates are less than emergency program rates, and to "additional" coverage in excess of emergency program limits.

To encourage participation by communities in the flood insurance program, the Flood Disaster Protection Act of 1973 provides that failure by a community to join the program within one year of being formally identified as flood-prone will result in the prohibition of all direct federal financial aid for purposes of acquisition or construction in identified flood hazard areas [P.L. 93-234]. Under amendments in the Housing and Community Development Act of 1977, conventional mortgage funding remains available in nonparticipating communities [P.L. 95-128].

The SBA disaster loan program also was chosen for comparative evaluation because it has been the major source of federal aid for nonagricultural flood damages since its inception in 1953 (Dacy and Kunreuther). The analysis focuses on physical-loss disaster loans, which are made available to finance repairs of damaged buildings and personal property.

Under this program, a property owner may obtain a disaster loan for an amount equal to the replacement cost of damaged property. Repayment regulations now and in the past have provided for substantial interest rate subsidies. At the time this study was made, however, such subsidies were prohibited, and interest rates were set at the U.S. Treasury cost of borrowing, plus an additional 0.25% to cover administrative costs. The length of the loan may extend up to thirty years and initial repayment may be deferred up to three years in hardship cases.

Although not under SBA control, Internal Revenue Service (IRS) regulations also affect loan program costs. Unreimbursed losses may be deducted from taxable income as casualty losses, and additional deductions may be taken for loan interest payments in calculating individual and business tax liabilities. Because these tax deductions are not allowed if losses are indemnified, they must be considered when comparing disaster loans with disaster insurance.

Evaluation Methodology

Alternative relief programs were evaluated by comparing the private and government costs of providing equivalent levels of disaster assistance to flood victims. Private costs to individuals can be measured directly by the cost of payable insurance premiums. Government costs arise when subsidies are introduced to reduce premiums paid by individuals below actuarial insurance costs. Benefits to the individual depend on levels of reimbursement for future flood losses.

Loans differ from "pure" insurance because there is no expense prior to a loss. Operation of a loan program permits the individual to shift the burden of loss to the government at the time of the disaster, and thereby to defer reassumption of the loss until repayment of the loan. A loan program does not reduce the uncertainty of experiencing a loss, but may reduce the magnitude of costs incurred for a loss which does occur.

Evaluation of the loan program centers on the cost of repayment which, discounted on the basis of annual payments, is equal to

$$(1) \qquad C^* = (LN)\left[\frac{i}{1-(1+i)^{-N}}\right]\left[\sum_{k=1}^{N}\frac{1}{(1+r)^k}\right],$$

where N is the term to maturity, i is the loan borrowing rate, r is the individual's cost of

borrowing, and LN is the amount of the loan principal equal to the amount of loss incurred (Selby). If $i = r$, the present value of repayment costs equals the loan principal. In cases of imperfect capital markets, $i < r$, the present value of loan cost is less than the original loan principal. This difference (an implicit subsidy) allows a loan to function as an alternative to flood insurance.

Given a fixed repayment principal net of forgiveness grants, the benefit of a loan program is determined by the differential between the actual loan interest rate and the individual's opportunity cost of borrowing [see equation (1)]. If the loan rate is just equal to the government's borrowing cost, this loan benefit is provided at no explicit cost to the government; rather the loan subsidy is created by the elimination of inequities in existing financial markets. If the loan rate is set below the government's cost of borrowing, however, explicit costs to the government are created. The additional rate subsidy requires that the government pay the cost differential between the borrower's annual cost at the actual loan rate (i), and the amount the borrower would have paid at the government rate, defined by (g). Discounted over the life of the loan, this government loan subsidy cost may be expressed mathematically as

$$(2) \qquad S_G = LN\left\{1 - \left[\frac{i}{1-(1+i)^{-N}}\right]\left[\sum_{k=1}^{N}\frac{1}{(1+g)^k}\right]\right\}.$$

A second subsidy involved in the loan program is the reduction in tax liabilities for casualty losses and interest payments. If the individual has an effective tax rate (t), the casualty loss element of this transfer is simply

$$(3) \qquad S_{CL} = (LN)(t),$$

where LN is the amount of unreimbursed loss, as assumed earlier. The present value of the tax transfer for loan interest payments is calculated as

$$(4) \qquad S_{IP} = (LN)(t)(i)\sum_{k=1}^{N}\left[\frac{1-(1+i)^{-N+k-1}}{1-(1+i)^{-N}}\right]\left[\frac{1}{(1+g)^k}\right],$$

where the first bracketed quantity is the proportion of the loan balance outstanding in period k and discounting is calculated at the lower borrowing rate g to assure equal evaluation of the subsidy by both the government and individuals. Combining these expressions, the total value of the tax transfer subsidy becomes

$$(5) \qquad S_T = (LN)(t)\left\{1 + (i)\sum_{k=1}^{N}\left[\frac{1-(1+i)^{-N+k-1}}{1-(1+i)^{-N}}\right]\left[\frac{1}{(1+g)^k}\right]\right\}$$

A third form of subsidy involves government forgiveness grants (F) to reduce the amount of principal subject to repayment. The availability of such grants generally varies with political concern about the magnitude and severity of disaster losses.

Overall, the cost of the loan program to the individual is determined by the loan interest rate, the individual's borrowing cost, and the individual's tax rate. As a single expression, this cost is $C' = C^* - S_T$ (Rettger and Boisvert). Similar factors determine the cost of the loan program to the government which is calculated as $S' = S_G + S_T$. If forgiveness grants were available, the basis of the loan cost calculation would be $(LN - F)$, with the change affecting both the individual and government costs of the loan program.

A straightforward evaluation of these alternative programs is difficult because flood damages vary from year to year and cannot be predicted with certainty. Therefore, empirical estimates of program costs and reimbursements are determined using a simulation model.

Empirical Model Specification

The primary study area is the City of Binghamton, New York, a community of 80,000 population at the confluence of the Chenango and Susquehanna Rivers. The city is an established commercial center which has experienced a major shift in its employment base from industrial to administrative and light manufacturing activities. The housing stock is relatively old; only 15% of all units have been constructed since 1950.

The balance of the study area is Endwell, New York, a community of about 16,000 people located on the main branch of the Susquehanna about three miles downstrean from

Binghamton. Endwell is a residential community and has experienced recent gains in population. The housing stock is somewhat newer than that of Binghamton; nearly 40% of all units have been built in the last twenty-five years (Rettger).

Floodwalls protect most of Binghamton along the Susquehanna from smaller floods, but many areas along the Chenango remain exposed to low-level inundation. Much of Endwell is also exposed to flooding, although a railroad embankment does protect part of the community from minor floods.

To evaluate the loan and insurance programs, property value data were obtained from surveys of existing residential and commercial properties conducted by the Corps of Engineers (Robillard). Each property in the study area was classified according to the size and condition of building, the value of interior furnishings, and the existence or absence of a basement. With these data and stage-damage information from the Susquehanna River Basin Commission (SRBC), it was possible to estimate damage potential based on the actual cash value of each property.

Several adjustments to these data were needed. For example, the aggregate damage estimates presented in the SRBC report had to be separated into structure and contents components; this was achieved by relating asset holdings to relative annual expenditures in each of these categories (U.S. Department of Labor). The estimates also were adjusted to current price levels by use of appropriate construction and consumer price indices (Rettger).

Flood profiles for the study area were calculated from information about floodplain topography and floodwall heights, using the HEC-II Water Surface Profile Program (Hydrologic Engineering Center). This program translates specified stream discharge levels into flood stage elevations, both within the channel and across the adjacent floodplain. It shows water elevations for an entire length of the river, as well as elevation differences for different flood levels. The information is plotted on local topographic maps to determine the boundaries of floodwaters for specific flood events. These maps, prepared for Robillard's earlier study, were used to delineate the heights of the 100- and 500-year floods along individual reaches of the Susquehanna and Chenango Rivers and to allocate the properties among three floodplain categories on the basis of each building's first floor elevation.

The diversity of flood exposure is seen in the distribution of properties among hazard areas (table 1). Within the study area there were nearly 4,700 residential structures with a total value of $234 million. About 28% of these properties were located in the 100-year floodplain, with another 27% situated outside the 100-year floodplain, but within the 500-year floodplain. This distribution varied considerably among property-value classes. Only 11% of high-valued properties, for example, were located in the 100-year floodplain, compared with 24% and 34% of the middle- and

Source: Estimated from U.S. Army Corps of Engineers unpublished data (Rettger).

[a] Because a structure's contents also can be insured, the value figures reported in the table include repair and replacement costs of building contents less normal depreciation for furnishings and equipment. This explains why the average value of property in a particular property class may be higher than the value range indicated. The value of "durable" contents was estimated to range from 48% of the low value structures to 35% of the high value structures (Rettger).

[b] These value ranges are the "cash values" for the structures only (e.g., the costs of repair or replacement of structural components such as walls, flooring, and foundation).

low-valued properties, respectively. The adjacent 100- to 500-year floodplain contained approximately one-third of the high- and medium-value properties, but contained approximately one-fourth of properties in the lowest-value group.

The study area also contained 1,280 commercial properties with an aggregate value of $72 million. These properties showed somewhat greater loss exposure, with 35% located in the 100-year floodplain, and another 29% located in the 100- to 500-year flood fringe.

The property damage and hydrologic characteristics of this study area were combined with simulated flood losses to evaluate insurance and loan programs. The general operation of the simulation model, displayed in figure 1, may be divided into three distinct functions: physical damage estimation, financial impact calculation, and relocation adjustment.

In the physical damage portion of the model, simulated random flood events are specified to establish floodwater elevations for each year of a simulation flood profile.[1] Stage-damage curves for the Susquehanna Basin (SRBC) are used to translate floodwater

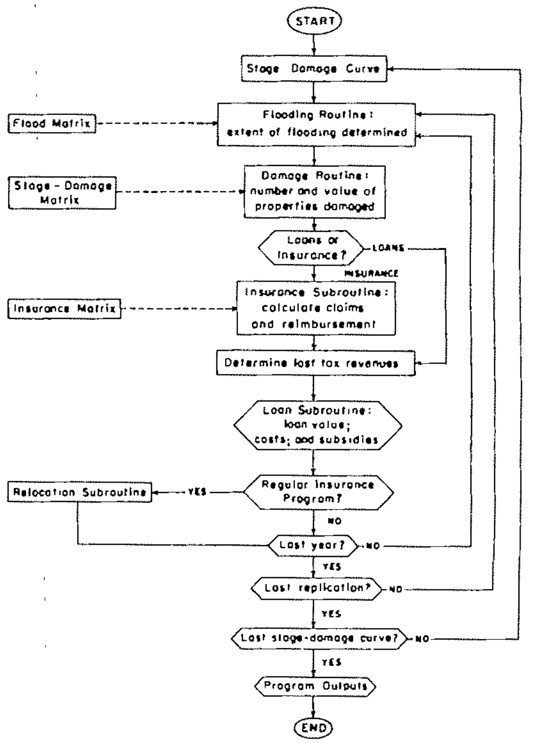

Figure 1. Flow chart of the flood relief simulator

elevations into specific damage estimates for sets of individual properties, which are grouped by property elevation and by various structural characteristics related to damage potential. Although properties are handled as groups in this and other portions of the model, parameter estimates are equal to those which would be measured if each property were evaluated individually by the simulator.

Property damage estimates initiate operation of the financial impact portion of the simulator. For simulation runs involving insurance alternatives, insurance premiums and premium subsidies are recorded, and damages are reimbursed up to coverage limits, net of deductibles. If the model specification involves a loan program, loans are granted for any damages not reimbursed by insurance (except deductibles) and loan costs and loan subsidies are calculated according to equations (1) and (2). Finally, according to equations (3) through (5), the simulator determines tax transfers based on unreimbursed losses and loan payments, and on implied income levels estimated from ratios of median income levels to median property values for various income categories (U.S. Department of Com-

[1] Each simulated flood event was selected randomly from an estimated probability distribution of peak discharges. Historic discharges from a gauging station near Binghamton were used to estimate the parameters of this Log-Pearson Type III frequency distribution:

$$\bar{X} = \frac{1}{N}\sum_{i=1}^{N} X_i;\; S = \left[\frac{1}{N-1}\sum_{i=1}^{N}(X_i - \bar{X})^2\right]^{\frac{1}{2}};\text{ and}$$

$$G = \frac{N}{(N-1)(N-2)S^3}\sum_{i=1}^{N}(X_i - \bar{X})^3;$$

where X_i is logarithm (Base 10) of annual peak flow in cubic feet/second (cfs) in year i; and N is the number of events in the sample record. Using this information and Log $D = \bar{X} + KS$, where D is the estimated annual peak discharge and K is a deviation factor calculated on the basis of a selected exceedence probability $[P(D \geq D^*)]$ and the computed skew coefficient (G), one can define "flood potentials in terms of peak discharge and exceedence probability at locations where a systematic record of peak flow is available" (U.S. Water Resources Council, p. 9). The K values for various exceedence probabilities and skew coefficients are tabulated by the U.S. Water Resources Council (pp. 3-1–3-27).

The estimated values of the parameters for the study area are $\bar{X} = 4.697$; $S = 0.12575$; and $G = 0.27166$. Discharges for each of the simulated flood events were randomly selected according to this frequency distribution. Using these discharges and the flood profiles from Robillard, the floodstage (mean sea level) was calculated using the following polynomial function of discharge (estimated by least squares on the basis of twenty-eight years of gauge station data):

$$\text{Flood Stage} = \underset{(7.69)}{805.66} + \underset{(7.87)}{3.24\text{X}10^{-4}D} - \underset{(1.72)}{1.12\text{X}10^{-8}D^2} + \underset{(0.77)}{2.78\text{X}10^{-9}D^3};$$

$$\bar{R}^2 = 0.99; \quad (\quad) = t\text{-ratio.}$$

merce). Effective federal tax rates were assigned from data in Musgrave and Musgrave.

Under insurance program regulations, properties receiving substantial flood damages do not qualify for premium subsidies in the future. The third portion of the simulator estimates the impact of these higher insurance costs on decisions to relocate out of the floodplain, based on the present value of future insurance costs and the existing relationship of property value to household income. If the total housing costs rise above 2.5 times estimated household income, the homeowner is assumed to relocate outside the floodplain. This estimate is made only for residential properties because of difficulties involved in establishing appropriate relocation standards for commercial properties.

Analysis of Alternative Programs

Simulation results were averaged over 30 years and 25 replications for evaluation purposes. For each year, 25 individual peak discharges were selected according to the Log-Pearson Type III discharge frequency distribution. This resulted in a matrix of 750 peak discharges, only some of which were sufficiently large to result in flooding and/or flood damages. To facilitate comparison and evaluation, each of the loan and insurance alternatives was examined using this same matrix of flood events to generate physical damage estimates.

On average, 226 residential properties receive over $660,000 in flood damages each year; about 33 commercial properties receive damages amounting to over $400,000 (table 2). Over 95% of average residential losses are borne by the middle- and low-value property classes. This result is explained primarily by the fact that the majority of floodprone properties are in these classes.

Substantial year-to-year variability was present in the damage estimates, as evidenced by the tremendous range of flood damages seen in the data for selected high and low probability flood events (table 2). Total damages range from $197,000 for the 2-year flood to over $57 million for the 500-year event. The number of structures damaged range from 132 in the 2-year flood to 4,260 in the 500-year flood.

In general, the 1977 insurance coverage limits evaluated in this study for both the emergency and the regular flood insurance programs appear adequate relative to potential exposure, except in the case of the high-value residential class, where low limits for contents coverage produce low overall protection levels for both programs (table 3). This result may have been different if recent increases in coverage limits allowed by the Housing and Community Development Act of 1977 (P.L. 95-128) had been used. Despite these apparent inadequacies, however, simulation results revealed the specified amounts of insurance to be adequate to cover losses.

Data from tables 1 and 3 indicate payable insurance costs per dollar of coverage vary substantially between programs. In moving from the emergency to the regular insurance

Note: An *n*-year flood has a probability of 1/*n* of being equaled or exceeded in any year.

[a] See table 1 for property class definitions.

[b] These averages are the mean number and value of damaged properties over all 750 sample flood events used in the simulation model. The numbers in parentheses are standard deviations.

Table 3. Initial Insurance Costs and Coverage (Beginning of Simulation)

		Emergency Program		Regular Program				
Property Class	No. of Insured Properties	Payable Premiums[a] ($)	Protection Level[b] (%)	Payable Premiums ($)	Actuarial Premiums[c] ($)	Protection Level[b] (%)	Average Subsidy[d] ($)	No. of Subsidized Properties
Residential[e]								
High value	59	7,228	39	8,902	11,023	67	193	11
Middle value	1,337	154,840	66	173,415	248,204	82	172	434
Low value	1,197	80,677	82	82,169	184,488	97	171	599
Subtotal	2,593	242,745	69	264,486	443,715	86	172	1,044
Commercial								
Subtotal	804	296,940	99	218,787	1,006,211	100	2,415	326

[a] Emergency program insurance rates are $0.25 ($0.40) and $0.35 ($0.75) per $100 of residential (nonresidential) structure and contents coverage, respectively.
[b] Ratio of total coverage to total exposure. Coverage is equal to the lesser of program limits or actual property value (table 1).
[c] Actuarial insurance rates are based on the type of structure, the elevation of the first floor, and the flood hazard factor (FHF). The FHF is defined as the difference in flood elevation between a 10-year and a 100-year flood. For reaches along the river, these FHF's were calculated using the HEC-II flood profiles reported in Robillard. Once this was accomplished, actuarial rates were determined from NFIP rate tables (National Flood Insurers Association, pp. B3-B4). The difference between actuarial and payable premiums is the premium subsidy.
[d] Per subsidized property.
[e] See table 1 for property class definitions.

program, payable residential premiums increase 9%, but coverage rises by 25%; for commercial properties, payable premiums actually fall by 26% as coverage increases slightly. These changes suggest that although emergency program rates may be highly subsidized in specific instances, they are higher for many properties in the study area than the average actuarial rates. Only 40% of the residential properties qualify for a premium subsidy, which averages $172 per property; over 57% of the subsidized residential properties are in the low-value property class (table 3). The same proportion of commercial properties (40%) receives an average subsidy of $2,415 each.

The simulation model focuses on the two insurance programs and two loan program alternatives (table 4). In the "regular" insurance program, all properties are assumed to be insured to either property value or to program coverage limits (if less), at actuarial or emergency insurance rates, whichever is lower.[2] Flood damages are reimbursed first from insurance coverage, with any remaining losses (net of insurance deductibles) qualifying for twenty-year disaster loans at a 6⅝% annual interest rate. Properties with structural losses in excess of 50% of total value are assumed to need "substantial improvement" and are excluded from future insurance subsidies.

With an average claim of $2,500 per residential property, this program is able to reimburse over 99% of all allowable claims from insurance funds and over 85% of losses. The average claim cost is much higher for commercial properties ($12,000), but insurance reimbursement is still over 99% of claims and 95% of losses. Average supplemental loan requests are quite small, never exceeding 10% of property damage.

Overall, the actuarial premiums for residential properties (paid premiums plus subsidy) are below reimbursement costs (e.g., 78% of claims). Commercial payable premiums are slightly less than reimbursement costs (e.g., 97% of claims), although total actuarial premiums exceed insurance claims by 150%.[3] Thus, while the regular program provides high levels of insurance coverage at relatively low costs to program participants, these results are an initial indication that nationwide insurance rates, as set by NFIP, may not be especially accurate for specific flood-prone areas.

[2] It was beyond the scope of this research to estimate insurance program participation rates. Also, it was not possible to estimate the flood damage threshold at which a presidential disaster declaration would be issued and disaster loans would become available or the proportion of eligible property owners that would apply for the loans. Thus, 100% participation in all programs was assumed to facilitate consistent evaluation.

[3] The payable premiums reported for this model differ slightly from the insurance parameters reported in table 3 because of the impact of the "substantial improvement" provision. The change is not significant for residential properties, but in the case of commercial properties, payable premiums are 80% higher than they would have been without this provision. As a measure of sensitivity, this same program was modeled using an 80% substantial damage limit; changes in payable premiums were not significant for either commercial or residential properties (Rettger and Boisvert).

Table 4. Comparison of Average Annual Costs for Alternative Relief Programs

	Participant Cost				Government Cost						
	Paid Premiums	Loan Cost[a]	Tax Transfer[b]	Participant Cost[c]	Premium Subsidy	Loan Subsidy[d]	Tax Transfer[b]	Government Cost	Program Cost	Insurance Claims[e]	Loans for Unreimbursed Losses[e]
	$										
Residential											
Regular insurance program	265,218	3,666	978	267,906	177,976	374	978	179,328	447,234	568,133	4,127
Emergency insurance program	242,744	7,573	2,179	248,138	179,230	764	2,179	182,173	430,311	568,133	8,439
Unsubsidized loans	0	572,277	171,493	400,784	0	59,859	171,493	231,352	632,136	0	661,039

Modified insurance program, corrected rates[f]	276,502	7,573	2,179	281,896	205,438	764	2,179	208,381	490,277		
Commercial											
Regular insurance program	392,061	1,127	927	392,261	614,169	120	927	615,216	1,007,477	402,325	1,327
Emergency insurance program	296,939	1,246	1,025	297,160	793,106	133	1,025	794,264	1,091,424	402,325	1,467
Unsubsidized loans	0	356,311	292,977	63,334	0	37,985	292,977	330,962	394,296	0	419,472
Subsidized loans	0	146,960	143,320	3,640	0	262,134	143,320	405,454	409,094	0	286,155
Modified insurance program, corrected rates[f]	89,714	1,246	1,025	89,935	237,902	133	1,025	239,060	328,995		

[a] Based on equation (1). Based on a procedure by Haveman, discount rates (r) varied among property classes. Average rates were set at 9%.
[b] Based on equation (1). Tax rates (t) are 23.6%, 20.3 and 16.3 for the high-, middle- and low-value property owners (Musgrave and Musgrave). Tax rates for commercial properties were estimated at 47%.
[c] Adjusted for out-of-pocket costs, such as deductibles which are not covered by insurance or loans.
[d] Assumes interest rate of 1%, forgiveness of first $5,000 of principal.
[e] The difference between property damages and the combined total of claims and loans is equal to insurance deductibles.
[f] The rates are corrected for differences between current rates and rates that would cover expected losses from the simulated runs (Rettger).

The emergency flood insurance program currently governs over 90% of the NFIP communities. This program differs from the regular program in that insurance rates are legislated to be uniform, regardless of exposure, and coverage limits are half of those in the regular program.

Coverage under this program remains adequate despite the lower coverage limits. Although average loan requests double and triple for high- and middle-value residential property classes, respectively, the total loan requests remain under $10,000. Payable residential premiums fall by about 9%. This is the primary explanation for the 4% reduction in residential program costs. Payable commercial premiums fall by 24%, but this occurs primarily because the "substantial improvement" rule is not operational; when properties are substantially damaged while a community is in the emergency program, there is no basis for charging actuarial rates. Total commercial program costs rise by 8%.

The third model program is based on the SBA disaster loan regulations which were in effect at the time of this study. All property losses are assumed to qualify for twenty-year loans at 6⅝% annual interest. Under this program, residential participant costs amount to 63.4% of total program costs. Unlike the case of the insurance models, tax transfers play a significant role in determining loan program costs; nearly 75% of government costs go for such transfers to residential properties.

Tax transfers also play a significant rule in the commercial case. Average participant loan costs amount to $10,797 per property, but because of transfers, the net cost per property is

only $1,919. Nearly 84% of total program costs are paid by government tax transfers or interest rate subsidies.

The final program alternative is designed to reflect loan program regulations which were in effect following the 1972 tropical storm Agnes disaster. Loan interest rates are reduced to 1% and the first $5,000 of each loan request is "forgiven" as an outright grant. Loan maturities remain at twenty years.

Under this program, there is a major shift of disaster costs to the federal government. Compared with the unsubsidized loan program, residential participant costs fall by $347,632, or 87%. The government portion of total costs amounts to 92%. For commercial properties, participant costs are reduced from $63,334 to $3,640, a drop of 94%. Government costs account for 99.1% of the program total. A substantial portion of this change is attributable to the loan forgiveness grants, which account for 87% and 51% of total loan subsidy costs to residential and commercial properties, respectively.

In addition to the four programs already described, table 4 contains a special modified insurance program. The model approximates the operation of a program with emergency program coverage limits and with insurance rates corrected for differences between current actuarial rates and rates that would just cover expected losses as calculated in the simulation runs. Because one would ultimately expect rates to reflect expected losses in the long run, these adjustments to premium costs make this model most directly comparable to the loan program results.

When insurance rates are modified to reflect the expected level of damages over time, total insurance costs are approximately 20% less than total costs of the unsubsidized loan program. These adjustments, however, do little to affect the proportion of insurance program costs borne by property owners and the government.

Policy Conclusions

Although it is difficult to generalize from the results of one case study, this analysis does suggest several important aspects of current disaster relief policy which merit careful examination. For the individual, the simulation results present several important implications. Participant costs for both the emergency and regular insurance programs are about five times the participant costs of the subsidized loan program. Because this subsidized loan model is characteristic of past disaster assistance strategy, these results may partially explain other research findings that voluntary purchases of flood insurance have been relatively infrequent in the past (Kunreuther, Kunreuther et al.).

In the simulation model, care was taken to calculate correctly flood insurance premiums based on flood hazard studies and the NFIP rate manual. Nevertheless, the model results showed annual premiums to be much below and much above average claim costs for residential and commercial properties, respectively. While the evidence does not prove conclusively that current NFIP rates are actuarially unsound, it does suggest the possibility that the rates may be quite inaccurate for certain areas because they ignore specific local hydrologic factors. If insurance rates could be specialized to regional geographic and flooding conditions, serious inequities in premiums might be avoided. Insurance rates that reflect flood risk adequately are essential for sound floodplain management and increased program participation.

The study also demonstrated that, in general, the coverage provided under the emergency flood insurance program appeared sufficient to reimburse most flood losses up to the 100-year flood level; thus, the individual faces less than a 1% chance of ever needing the additional coverage available under the regular program. Currently, the extra coverage is sold at a fixed rate, so that the ratio of premium cost to expected loss increases with coverage. From the individual's perspective, this also makes the choice of insurance relatively less favorable to other alternatives. Thus, it may be necessary to reduce the cost of higher amounts of coverage in order to encourage property owners to insure their property at a high percentage of its value. Because actuarial rates for many properties in the study area were found to be less than emergency program rates, movement toward this goal might be facilitated by the conversion of similar communities from the emergency to the regular flood insurance program as soon as possible.

From a public perspective, these programs must be evaluated on the basis of both total program costs and distributional impacts. Once insurance rates are adjusted to reflect

expected annual losses, total insurance program costs are somewhat lower than the total costs of the loan programs. For the insurance alternatives studied, variations in premium subsidies change the distribution of costs between individuals and the government without affecting the total. In the loan programs, benefits and costs are not evaluated equally by both parties because of differentials in public and private opportunity-borrowing costs. Thus, loan subsidies can potentially increase total program costs, as well as affect their distribution.

In the study area, for example, the level of subsidy for residential properties is influenced tremendously by the size of the forgiveness grants and is relatively insensitive to changes in interest rates. The opposite is true for commercial properties: interest subsidies and the tax deductions are quite large. To achieve any desired level of subsidy to property owners, within a given tax structure, two policy instruments, interest rates and grants, must be manipulated simultaneously. An insurance subsidy, if one were desirable, could be achieved more directly by changing insurance premiums.

In conclusion, only a few of the policy issues involving disaster assistance programs have been examined; even for these it is difficult to generalize on the basis of case study research. Despite these limitations, the methodology developed here can be applied elsewhere and the study does highlight the economic variables built into present disaster assistance programs. Several potential sources of inequity have been suggested, thus providing topics for additional research in this area.

Notes

Sensitivity of Efficient Frontiers Developed for Farm Enterprise Choice Decisions

Bryan Schurle and Bernard L. Erven

An efficient frontier provides information concerning the tradeoff between risk and return in farm enterprise choice decisions. If mean-variance analysis is used, the frontier is efficient in the sense that it represents a series of farm enterprise combinations, each enterprise combination having minimum risk (variance of returns) for a specified level of return. Anderson, Dillon, and Hardaker provide a discussion of the different types of frontiers and the different methods of deriving them.

Development of efficient frontiers is particularly helpful when the risk among enterprises varies substantially (Schurle and Erven). However, efficient frontiers do not provide information about near-optimal enterprise combinations. According to Heady and Candler the optimum solutions in linear programming need not be optimum for other criteria. Since farmer's utility functions cannot be completely specified in terms of risk and returns, decision makers and researchers should be interested in farm plans slightly different from those on the frontier in terms of risk and return levels. The usefulness and uniqueness of frontiers as a decision aid would be reduced substantially if these near optimal solutions included substantially different enterprise combinations. Other considerations of the manager may overshadow the differences in risk between near-optimal enterprise combinations off the frontier and the optimum plan on the frontier.

Related work of an experimental nature has been done previously on the impacts of estimation error on the development of efficient frontiers. Frankfurter, Phillips, and Seagle found that the impacts of errors in estimating the mean, variance, and covariance are so strong that the usefulness of some mean-variance approaches to portfolio selection is brought into question. The model used in this analysis is somewhat related to other mean-variance approaches; thus, the possibility of carryover of these results to the model used here does exist. In this article an empirical approach to the sensitivity issue similar to a procedure used by Levy and Sarnat is employed.

The issue of frontier sensitivity, indicating how greatly farm plans just off the frontier differ from the minimum risk farm plans on the frontier, needs to be analyzed. In this paper, we report on the sensitivity of efficient frontiers developed in a farm enterprise choice study. Specifically, we address the question of how much change in risk accompanies an enterprise combination change when expected return is held constant.

Problem Setting

The problem involves choices between cash grain crops (corn, soybeans, and wheat) and specialty crops (processing tomatoes and cucumbers) in Ohio. The budgeted net returns in table 1 show the relatively high returns associated with tomatoes and cucumbers. However, farmers considering adding these enterprises or expanding current acreage have a major concern with risk. Yields may vary substantially due to interactions of complex production technology, seasonal labor supply, and weather. Substantial yield variation results in much greater annual variation in returns for specialty crops than for grain crops (see table 1).

Risk is an important factor in farmers' decisions because of the trade-offs between the higher returns and higher risk of the specialty crops and the lower returns and lower risk of the grain crops. The coefficient of variation allows a comparison of the risk associated with different enterprises. Table 1 shows that the coefficients for the grain crops are substantially below those for tomatoes and cucumbers. It is these differences among the crops which cause risk to be a major concern for farmers.

Farmers can reduce risk by diversifying among these enterprises. The correlation coefficients between returns for different enterprises indicate that only hand and mechanically harvested tomatoes are significantly correlated. Wheat returns tend to be negatively correlated with other returns, but not at a significant level. All correlations between enterprises are built into the model.

Bryan W. Schurle is an assistant agricultural economist with the Kansas Agricultural Experiment Station, Kansas State University, and Bernard L. Erven is a professor, Department of Agricultural Economics and Rural Sociology, Ohio Agricultural Research and Development Center and the Ohio State University.

Table 1. Descriptive Statistics for Alternative Enterprises

Enterprise	Return above Variable Cost Per Acre	Standard Deviation of Return	Coefficient of Variation
	($)	($)	
Corn	172	50	.29
Soybeans	122	39	.32
Wheat	90	28	.31
Mechanically harvested tomatoes	593	344	.58
Hand-harvested tomatoes	335	268	.80
Cucumbers	250	272	1.09

Model Formulation

Given the characteristics of this problem, an operational procedure was needed which permitted the handling of a complex set of enterprise alternatives, explicit treatment of risk and the development of practical farm enterprise choice guidelines. The modified linear-programming alternative, the MOTAD model proposed by Hazell, was chosen. The MOTAD model minimizes a measure of dispersion which can be converted to a variable comparable to the variance used in quadratic programming. The results provide data for an EA frontier very similar to the EV frontier from quadratic programming (Thompson and Hazell). The MOTAD model has been used previously in attempts to reflect accurately producer behavior (Simmons and Pomareda, Brink and McCarl).

The basic linear-programming matrix models a 600-acre representative farm with the resources to produce corn, soybeans, wheat, mechanically harvested tomatoes, hand-harvested tomatoes, and hard-harvested cucumbers. Additional activities also were included for hiring labor, land preparation, and other support services. The constraints of the model included land, and the limiting factors of labor, machinery capacity, and field time associated with critical spring planting and fall harvesting periods.

Several activities were used to represent each enterprise in the model. For example, corn and soybeans could be planted in any of six spring time periods and harvested in any of the three fall time periods. This resulted in eighteen activities to represent corn and eighteen to represent soybeans. A portion of the Ohio Crop Model, a modified version of the Purdue Top Farmer Model, was used for the corn, soybeans, and wheat components of this model. Other enterprises were handled in a similar manner. Tomatoes harvested by machine were represented by thirteen activities and tomatoes harvested by hand were represented by ten activities. The returns associated with activities varied depending on the estimated yield for each planting and harvesting period combination.

Formulation of the MOTAD model was accomplished by adding eight years of historical product price and yield data to the basic linear-programming matrix (Schurle). These historical data were collected from three farms. The farms were similar in that they were located near each other, they had similar soil types, and the managers had reputations of being excellent. Homogeneity of these three farms was necessary because data for different enterprises were taken from each farm. One farm provided data on mechanically harvested tomatoes and soybeans, one farm provided data on hand-harvested tomatoes and cucumbers, and one provided data on corn and wheat. These historical data provided an eight-year series for all enterprises. The series was constructed from three farms because not all the farms had all the enterprises in each of the eight years. Detailed cost data for each of the years were not available from these farms. Therefore, product price trends were removed and costs were assumed to be constant over the eight-year period. The presence of a trend in yields was not verified, so no yield trends were removed. Consequently, the gross margin deviations measure the dispersion around a trend line for year-to-year product price but not year-to-year cost or yield variation (Chen). This was justified because the sources of risk of importance in this study are yields and product prices.

The data allowed development of gross margin deviations for each enterprise. However, time-series data on yields were not available for each activity (representing different planting and harvesting dates) in the model. Consequently, the same gross margin data were used for each activity of an enterprise. This caused each activity of an enterprise to have the same variance of returns even though some activities representing an enterprise were less profitable than others due to less than optimal planting and harvesting dates.

These data were included in the following MOTAD model formulation:

(1) $$\text{Minimize } \sum_{h=1}^{s} y_{\bar{h}},$$

such that

(2) $$\sum_{j=1}^{n} (c_{hj} - g_j)x_j + y_{\bar{h}} \geq 0$$

(for $h = 1, 2, \ldots, s$), and

$$(3) \quad \sum_{j=1}^{n} f_j x_j = I \qquad (\text{for } I = 0 \text{ to unbounded}),$$

$$(4) \quad \sum_{j=1}^{n} a_{ij} x_j \leq b_i \qquad (\text{for } i = 1, 2, \ldots, m), \text{ and}$$

$$(5) \qquad x_j, y_{\bar{h}} \geq 0 \qquad (\text{for all } h, j),$$

where $y_{\bar{h}}$ is the absolute value of the sum of the negative gross margin deviations in observation h; c_{hj} is the gross margin (gross revenue per acre—variable costs per acre) for the jth activity on the hth observation; g_j, the average gross margin for the jth activity; x_j, the level of the jth activity (usually in acres); f_j, the expected net return of the jth activity; I, the expected net return; a_{ij}, the technical requirements of the jth activity in the ith constraint; b_i, the ith constraint level; s, the number of years; n, the number of activities in the basic LP model; and m, the number of constraints in the basic LP model.

This model minimizes risk for each level of I (total returns above variable costs) specified in equation (3). The model minimizes risk as measured by the sum of the absolute values of the negative total gross margin deviations. Essentially this minimizes the standard deviation of returns to the farm measured by the estimator

$$D\left[\frac{\pi s}{2(s-1)}\right]^{\frac{1}{2}},$$

where s is the number of years in the sample and D is the estimated mean absolute deviation in returns to the farm (Hazell). In order to minimize risk while achieving a specified return level, the model selects enterprise combinations that are least risky (as measured by variance in annual returns) and/or that have negatively (or less positively) correlated returns. Return to the farm (I) is parameterized, resulting in a minimum risk farm organization for each specified level of return. The return, risk coordinates can be graphed as in figure 1 (the solid curve) to show the efficient frontier facing a farm manager with a given resource base. The decision maker can then choose an enterprise combination and return-risk situation which is consistent with his risk preference and goals. If the farm plan chosen is off the frontier, there is an increase in risk with no compensating increase in returns.

Results

In the first phase of the analysis, all cash grain and specialty crop enterprises were allowed to enter the model. The resulting efficient frontier is illustrated in figure 1 as a solid curve. Net return above variable costs was varied in $5,000 intervals. There is a specific farm plan associated with each point on the frontier. However, for purposes of brevity, only selected farm plans for the frontier are shown in table 2. This table also shows the coefficient of variation and the standard deviation of net return for the farm.

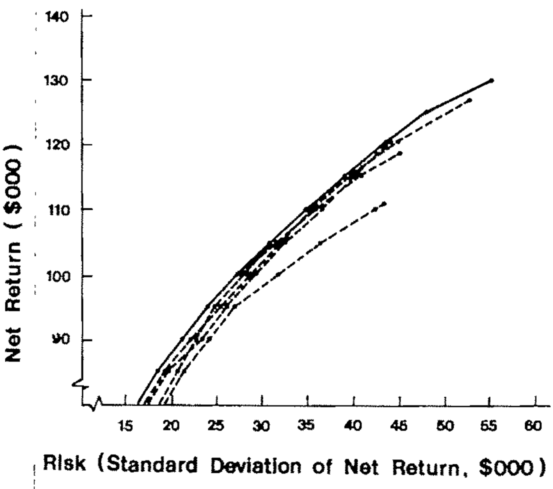

Figure 1. Minimum risk-efficient frontier (solid curve), and near optimal frontiers (dashed curves)

It can be observed readily from table 2 that diversification has a major impact on risk and net return. The more diversified farm plans have lower levels of net return and risk. The trade-off between returns and risk is captured by the coefficient of variation. As net return decreases, the coefficient of variation is reduced which shows that risk per dollar of expected return is reduced.

Farm plans change considerably along the frontier. Table 2 shows that most acreage is committed to grain crops at lower return-risk levels and that specialty crops become increasingly important at higher return-risk levels.

Sensitivity of Frontier

We have shown the impacts of changes in enterprise combinations on both return and risk. We turn now to the sensitivity of the frontier which has been generated. Are there enterprise combinations substantially different from those in table 2 for each level of return which have inconsequential increases in risk? If there are, the approach we used for investigating enterprise choice under risk has not identified all the enterprise combinations of interest to decision makers.

The sensitivity question was investigated by restricting the model to the selection of enterprises in different subsets of all the enterprises considered. This method has been used previously in analyzing the effects of international diversification on investment portfolio risk (Levy and Sarnat). Each subset, formed by excluding one enterprise, resulted in a separate frontier. Each new frontier falls to the right of the original frontier, indicating increased risk due to the different enterprise combi-

Table 2. Enterprise Combinations of Grain and Specialty Crops

[a] Return above variable costs. The estimated fixed cost of land and machinery for this representative farm is $97,000.

nation on the new frontier. These new frontiers are represented as dashed lines in figure 1. All frontiers remain relatively close together with the exception of the frontier derived for no corn. The no corn frontier drifts away from others. The other frontiers tend to converge as returns increase.

Table 3 shows the enterprise combinations for each of the frontiers at the $95,000 return level. The results in table 3 show that substantial differences exist among the enterprise combinations. Corn varies from 114 to 442 acres, soybeans from 142 to 453 acres, wheat from 60 to 158 acres and hand-harvested tomatoes and cucumbers from 0 to 67 acres in the plans where each is allowed. These differences should be important to a farmer. For example, the "no soybeans" farm plan in the table consists of corn and wheat only, while the "minimum risk" farm plan includes corn, soybeans, wheat, and a substantial amount of hand-harvested tomatoes. These two farm plans are different from a farmer's viewpoint because tomatoes are included in one combination and not the other. Most important, these significant enterprise combination changes resulted in little additional risk at this return level. The next to last column in table 3 shows that the increase in standard deviation of net return varied from $690 to $3,500. These are relatively small increases (3%–15%) when compared to the level of standard deviation, which ranged from $23,910 to $27,410.

The sensitivity of risk was also investigated at other return levels. However, for the higher return portion of the frontier, enterprise specialization sometimes caused one of three results when risk sensitivity was investigated. First, a frontier developed with a certain restriction may not reach the high return levels under consideration. As an example, table 4 shows that the "no corn" frontier does not reach the $115,000 return level. A second result occurring in some situations was that the restriction placed on an enterprise did not change the farm plan from the "minimum risk" farm plan.

Table 3. Enterprise Combinations Which Result in a Net Return of $95,000

Enterprise Restriction	Corn	Soybeans	Wheat	Mechanically Harvested Tomatoes	Hand-Harvested Tomatoes & Cucumbers	Standard Deviation of Net Return	Change in Standard Deviation	Percentage Change in Standard Deviation
	(acres)					($000)		
None (minimum risk)	186	274	99	0	41	23.91	—	—
No corn	0 (−186)[b]	453 (+179)	60 (−39)	21 (+21)	66 (+25)	27.41	3.50	14.6
No soybeans	442 (+256)	0 (−274)	158 (+59)	0	0 (−41)	25.58	1.67	7.0
No wheat[a]	114 (−72)	362 (+88)	0 (−99)	0	67 (+26)	25.12	1.21	5.1
No hand-harvested tomatoes	311 (+125)	142 (−132)	137 (+38)	9 (+9)	0 (−41)	24.60	.69	2.9
No machine-harvested tomatoes	186 (0)	274 (0)	99 (0)	0 (0)	41 (0)	23.91	0	0

[a] 56 acres were rented out.
[b] Numbers in parentheses are changes in acres from minimum-risk enterprise combination.

Table 4. Enterprise Combinations Which Result in a Net Return of $115,000

Enterprise Restriction	Corn	Soybeans	Wheat	Mechanically Harvested Tomatoes	Hand-Harvested Tomatoes & Cucumbers	Standard Deviation of Net Return	Change in Standard Deviation	Percentage Change in Standard Deviation
	(acres)					($000)		
None (minimum risk)	341	171	0	27	60	38.99	—	—
No corn[a]	—	—	—	—	—	—	—	—
No soybeans	476 (+135)[b]	0 (−171)	60 (+60)	30 (+3)	35 (−25)	39.57	.58	1.5
No wheat	341 (0)	171 (0)	0 (0)	27 (0)	60 (0)	38.99	0	0
No hand-harvested tomatoes	318 (−23)	225 (+54)	0 (0)	57 (+20)	0 (−60)	39.34	.35	.9
No machine-harvested tomatoes	487 (+146)	22 (−149)	0 (0)	0 (−27)	92 (+32)	40.17	1.18	3.0

[a] The frontier derived for no corn did not reach $115,000 return level.
[b] Numbers in parentheses are changes in acres from minimum-risk enterprise combination.

Thus, risk comparisons could not be made. As an example, the "minimum risk" farm plan at the $115,000 return level in table 4 contains no wheat. So when wheat is not allowed in the farm plan, the new farm plan is the same as the "minimum risk" farm plan. A third result was that the enterprise restriction caused relatively smaller changes in farm plan, resulting in a correspondingly small increase in risk. As an example, the "no hand-harvested tomato" frontier in table 4 shows that corn acreage changed 23 acres; soybeans, 54 acres; wheat, 0 acres, mechanically harvested tomatoes, 20 acres; hand-harvested tomatoes and cucumbers, 60 acres; and the resulting change in standard deviation was $350. These results, as well as the results at other return levels reinforce the conclusion that major farm plan changes often are accompanied by relatively small risk changes for a fixed return level.

The ultimate determination of the significance of these increases in risk depends on the utility function of the producer. Utility functions presumably contain a number of variables in addition to profit and risk, both of which are analyzed in this model. Profit always has been of paramount importance, and risk in many instances, including this one, must be considered. However, the increases in risk as one moves from the frontier may be less important in this case than other considerations such as management requirements, need to manage migrant labor for specialty crops, or the prestige of producing certain crops.

Comparisons can also be made between non-optimal farm plans. There are even greater differences among these farm plans with extremely small differences in risk. Comparisons between the "no soybeans" farm plan and the "no hand-harvested tomato" farm plan in table 4 shows extreme differences in farm plan and only a $.23 difference in standard deviation. This indicates that once off the frontier, farmers may have many different farm plans to choose from with nearly negligible differences in risk.

Summary and Conclusions

The sensitivity of the efficient frontier for a particular farm enterprise choice problem has been examined. These results point out the need for not blindly using the farm organizations prescribed by the model. It appears appropriate to investigate only the more general trends in return, risk, and enterprise combinations within this model.

The results also cause concern about the usefulness of the model in predicting farmer behavior. How sophisticated can farmers be in choosing least-risk farm plans without the aid of these models? They probably cannot be very sophisticated and thus, in many cases, can only come close to the least-risk farm plan by some intuitive feel. If the farmers only come "close," and such wide differences in farm plans occur "close" to the frontier, how accurate can models of this type be in predicting farmer behavior?

We cannot be conclusive about the extent to which our findings can be generalized to choice problems involving other enterprises or other similar models. Much additional work needs to be done investigating the problems reported here and the causes of these problems. The problems may stem from the complexity of the model, the lack of data for each activity representing an enterprise, or the

length of the time-series data. However, the problems also may be a result of more basic difficulties with models of this type. Although not conclusive, the results presented here may add empirical strength to the conclusions of Frankfurter, Phillips, and Seagle that the usefulness of such techniques may be in doubt. Although the results do not indicate where the weakness in the method lies, with the available data in this study, there is basis to question the quality of decisions made using the efficient frontier.

The Effects of Trade Intervention on International Price Instability

Malcolm D. Bale and Ernst Lutz

Price instability has been an issue of long concern to economists and recently has received increased attention, mainly because of economic events taking place in the world during the 1970s. Much of the discussion has occurred in relation to agricultural commodities where random prices, reflecting stochastic fluctuations in supply and demand, are often of major significance. At different phases of price fluctuations, different groups become more vocal and more concerned about price movements—rising prices affect consumers and importing nations, whereas falling prices are of vital interest to producers and exporting countries. It is, perhaps, from such interactions and competing interests that the demands of developing countries for an international buffer fund to stabilize major export commodities have arisen.

Instability originates basically from two sources: real and policy-induced ones. Natural random factors influence both supply and demand of commodities. Production is affected by weather, disease, technological change, and input availability, while demand varies due to fluctuating income and taste changes. Stochastic demand and supply, in turn, cause prices to fluctuate. Price variability can be decreased through stabilization policies via buffer stocks and price forecasting, or it can be increased via policy measures affecting foreign trade. While it has long been recognized that international trade distortions which partially or totally insulate an importing country from the rest of the world have the effect of throwing the total price adjustment burden onto the rest of the world—often increasing the amount of price instability compared to that which would prevail under free trade—there has been little formal analysis of this phenomenon. Both Johnson and Schultz have stated recently that trade barriers increase price instability in world markets, while Shei and Thompson have simulated the impact of United States export controls and a change in Soviet import policy on world wheat prices in a quadratic wheat trade model under alternative trade policy assumptions.

The question of price instability induced by trade restrictions is particularly topical. Recently several international organizations (UNCTAD, IWC, FAO) have discussed the effects of price instability on export receipts in developing countries and its consequent effect on development. Many countries are studying commodity buffer stock plans in order to stabilize prices, and GATT members currently are attempting to liberalize trade at the Geneva multilateral trade negotiations. Thus, gaining insights into the causal effect of trade restrictions on price instability has considerable pragmatic appeal.

The purpose of this paper is to examine formally the effects of different trade intervention policies on international price instability. Our results show that some trade barriers have no impact on world price instability, while other types of restrictions transfer different degrees of instability from one country to the other. The paper uses a two-country, one-commodity, equilibrium model of trade to show that price instability generated by random supply fluctuations in the importing country can be amplified by various trade restrictions. The analysis is general, so that stochastic disturbances of supply and demand functions in both exporting and importing countries are considered simultaneously in order to demonstrate how and to what extent distortions affect price instability under constant exchange rates. Finally, some concluding comments are offered. (See Bale and Lutz for an expanded version of this paper and a simplified diagrammatic analysis.)

Mathematical Framework

Consider the following linear two-country model where demand in countries 1 and 2 is given by

$$(1)\qquad d_i = a_i - b_i P + \delta_i,$$

$i = 1, 2$, and supply is given by

$$(2)\qquad s_i = \alpha_i + \beta_i P + \epsilon_i,$$

$i = 1, 2$, where: d_i is demand in country i; s_i, the supply in country i; and P is price. The terms a_i, b_i, α_i, β_i are fixed parameters, and δ_i and ϵ_i denote random variables distributed as $N\ (O, \sigma_{\delta_i})$ and $N\ (O, \sigma_{\epsilon_i})$, respectively.

Free Trade

Under free trade, aggregate excess demand is zero, i.e.,

$$(3)\qquad \sum_i d_i - \sum_i s_i = 0,$$

Malcolm D. Bale and Ernst Lutz are economists at the World Bank.

The views expressed are those of the authors and not necessarily those of the World Bank.

The authors wish to thank an anonymous referee for constructive and detailed comments, and Debbie Kreamer for skilled typing. Any remaining errors are the responsibility of the authors.

$i = 1, 2$. From equation (3), the equilibrium price can be found to be

$$P_w = \sum_i \frac{a_i - \alpha_i + \delta_i - \epsilon_i}{b_i + \beta_i}, \tag{4}$$

$i = 1, 2$, and hence the variance of the free trade world market price is

$$\sigma_{P_w} = \sum_i \frac{\sigma_{\delta_i} + \sigma_{\epsilon_i}}{(b_i + \beta_i)^2}, \tag{5}$$

$i = 1, 2$, provided that s_i and ϵ_i are independently distributed.

Specific Tariff

The price P_2 in country 2 (the importing country) is equal to the price P_1 in country 1 (the exporting country) plus t, i.e.,

$$P_2 = P_1 + t. \tag{6}$$

Equation (6) is based on the assumption that the elasticity of supply of imports is infinite. Inserting into (3), and solving for P_1, P_2, we obtain

$$P_1 = P_w - t\frac{(b_2 + \beta_2)}{b_1 + b_2 + \beta_1 + \beta_2}, \tag{7}$$

$$P_2 = P_w + t\frac{(b_1 + \beta_1)}{b_1 + b_2 + \beta_1 + \beta_2}. \tag{8}$$

From (7) and (8) it can be seen that the price variance in both countries is equal to that in (5), i.e., equal to the free trade variance. The introduction of a specific tariff does not change the degree of price instability, or, in other words, a specific tariff transmits fluctuations so that a shock in one part of the system is absorbed by the whole system (table 1).

Ad Valorem Tariff

An ad valorem tariff is proportional to the export price and can be described by the following conditions:

$$P_2 = P_1\,(1 + t), \tag{9}$$

where t in this case is the tariff rate. Inserting (9) into (3), the price in the exporting country is found to be

$$P_1 = \sum_i \frac{a_i - \alpha_i + \delta_i - \epsilon_i}{b_i + \beta_i + t(b_2 + \beta_2)}, \tag{10}$$

$i = 1, 2$, and hence

$$\sigma_{P_1} = \sum_i \frac{\sigma_{\delta_i} + \sigma_{\epsilon_i}}{[b_i + \beta_i + t(b_2 + \beta_2)]^2}, \tag{11}$$

From equation (11) we see that for $t > 0$, $\sigma_{P_1} < \sigma_{P_w}$. That is, the imposition of an ad valorem (by an importing country) reduces the price variability in the exporting country. This is the case because the ad valorem tariff discourages imports when the export price is rising, and thus it has a stabilizing effect.

The price variance in country 2 is

$$\sigma_{P_2} = \sigma_{P_1}\,(1 + t)^2. \tag{12}$$

Comparing σ_{P_2} with the variance of price prevailing under free trade, we find

Table 1. The Effects of Trade Policies on Price Instability in Exporting and Importing Countries

	Degree of Price Instability in Comparison with the Instability under Free Trade[a]	
Trade Policy of Importing Country	Exporting Country	Importing Country
Specific tariff	same	same
Ad valorem tariff	smaller	larger
Fixed quota	generally larger	generally larger
Proportional quota	generally larger	generally larger
No trade	generally larger	generally larger
Price fixing	larger	smaller (= 0)
Variable levy	larger	smaller
Trade Policy of Exporting Country		
Specific tariff	same	same
Ad valorem tariff	smaller	larger
Fixed quota	generally larger	generally larger
Proportional quota	generally larger	generally larger
No trade	generally larger	generally larger
Price fixing	smaller (= 0)	larger
Export controls	smaller	larger

[a] By using the degree of price instability under free trade as a basis for comparison, we do not intend to imply that the free-trade price variance is necessarily optimal in a welfare sense.

$$(13) \qquad \frac{\sigma_{P_2}}{\sigma_{P_w}} = \frac{[k + t(b_1 + \beta_1)]^2}{k^2} > 1,$$

where, for convenience, k equals $b_1 + b_2 + \beta_1 + \beta_2 + t(b_2 + \beta_2)$. Thus, an ad valorem tariff increases the price instability in the (importing) country which imposes the tariff. Also, the variance of price increases with an increasing tariff rate and with increasing slopes of the supply and demand function in the exporting country.

Fixed Quota

The imposition of a quota, $\bar{q}$, in a two-country trading world results in the following equilibrium prices and price variances.

$$(14) \qquad P_1 = \frac{a_1 - \alpha_1 + \delta_1 - \epsilon_1 + \bar{q}}{b_1 + \beta_1},$$

$$\sigma_{P_1} = \frac{\sigma_{\delta_1} + \sigma_{\epsilon_1}}{(b_1 + \beta_1)^2}, \text{ and}$$

$$(15) \qquad P_2 = \frac{a_2 - \alpha_2 + \delta_2 - \epsilon_2 - \bar{q}}{b_2 + \beta_2}, \text{ with}$$

$$\sigma_{P_2} = \frac{\sigma_{\delta_2} + \sigma_{\epsilon_2}}{(b_2 + \beta_2)^2}.$$

Thus, it is clear that under a quota system no instability is transmitted and that all disturbances are absorbed in the country where they originated as in the no trade case.

Comparing the variance of price in the exporting country under a quota system with that under free trade, it is found that

$$(16) \qquad \sigma_{P_1} > \sigma_{P_w},$$

since

$$(\sigma_{\delta_1} + \sigma_{\epsilon_1})[(b_2 + \beta_2)^2 + 2(b_1 + \beta_1)(b_2 + \beta_2)] - (\sigma_{\delta_2} + \sigma_{\epsilon_2})(b_1 + \beta_1)^2 > 0.$$

From equation (16) we see that σ_{P_1} is larger than the free-trade price variance when the slopes of the supply and demand functions as well as the variances in both countries are of equal size (or similar in magnitudes). The reason for this is that in a system where disturbances are not correlated, free trade tends to even out fluctuations. The variance of price σ_{P_1} would be smaller than σ_{P_w} only where the demand and supply variances in the importing country are much larger than those in the exporting nation or where supply and demand elasticities in the exporting country are much larger than those in the importing country. Similar arguments can be made for a comparison of σ_{P_2} and σ_{P_w}.

Equivalence of Tariffs and Quotas

The notion of equivalence between tariffs and quotas is widespread in the literature on trade theory. Bhagwati (1965) showed that for the equivalence to hold, the assumption of universal competitiveness must be used and that equivalence characteristics break down when monopoly elements are introduced. Further refinements followed in later papers by Bhagwati (1968) and McCulloch, and the nonequivalence of tariffs and quotas assuming retaliation was analyzed by Rodriguez using a general equilibrium approach. Within the partial equilibrium framework, Fishelson and Flatters, Pelcovits, and, more recently, Dasgupta and Stiglitz have extended the analysis to uncertainty. They each found and analyzed cases in which the widely held equivalence of tariffs and quotas collapses. Our analysis presents yet another example of the nonequivalence of tariffs and quotas. From equations (5) and (16), we demonstrate that with a pure tariff, instability is transmitted freely among countries; whereas, under a pure quota, it is not transmitted at all.

Proportional Quota

A proportional quota is a system in which import rights are assigned to producers or consumers in proportion to their individual production or consumption of the restricted goods. For the analysis of the effects of a proportionally distributed quota and a comparison with a tariff or equivalent quota see McCulloch and Johnson. For our analysis we assume here a system that guarantees domestic producers in the importing country a constant market share. The quota is, therefore, defined as

$$(17) \qquad Q = cd_2,$$

where $o < c < 1$.[1] An equivalent proportional quota policy for the exporting country would determine a constant share of production to be exported. Using (17) the equilibrium price for the importing country is found to be

$$(18) \quad P_2 = \frac{a_2(1 - c) - \alpha_2 + \delta_2(1 - c) - \epsilon_2}{b_2(1 - c) + \beta_2},$$

and, hence, the variance is

$$(19) \qquad \sigma_{P_2} = \frac{\sigma_{\delta_2}(1 - c)^2 + \sigma_{\epsilon_2}}{[\beta_2 + b_2(1 - c)]^2}.$$

The price variance for a proportional quota policy is larger than the price variance under a fixed quota if

$$(20) \quad \beta_2 \sigma_{\delta_2} [\beta_2(c - 2) + 2b_2(1 - c)] + b_2 \sigma_{\epsilon_2} [b_2(2 - c) + 2\beta_2] > 0.$$

The algebraic expression in (20) increases for increasing b_2 and σ_{ϵ_2} and for decreasing β_2 and σ_{δ_2}.

[1] Sometimes a policy is defined such that $Q \leq cd_2$, i.e., domestic producers not only have a guaranteed share of the domestic market, but their share can be increased through a reduction of the quota as dictated by the policy environment. Note also that for the cases where Q is less than cd_2, it is necessary to set Q equal to cd_2 in order to obtain an equilibrium solution.

From condition (20), we conclude that a proportional quota as defined above generally would increase the price variance in the importing country as compared to the free trade or the fixed-quota case. The reason is the quota introduces an additional disturbance into the system.

The imposition of a proportional quota in the importing country affects the exporting country such that

$$(21)\quad P_1 = \frac{a_1 + ca_2 - \alpha_1 + \delta_1 + c\delta_2 - \epsilon_1}{b_1 + cb_2 + \beta_1}, \text{ and}$$

$$(22)\quad \sigma_{P_1} = \frac{\sigma_{\delta_1} + c^2 \sigma_{\delta_2} \sigma_{\epsilon_1}}{(b_1 + cb_2 + \beta_1)^2}.$$

It can be shown that a proportional quota results in a reduction of the price variance in the exporting country as compared to the cases of no trade or the fixed quota for

$$(23)\quad b_2(\sigma_{\delta_1} + \sigma_{\sigma_1})(cb_2 + 2b_1 + 2\beta_1) - c\sigma_{\delta_2}(b_1 + \beta_1)^2 > 0.$$

From condition (23) we obtain the interesting result that the imposition of a proportional quota by the importing country generally results in the transmission of instability from the exporting to the importing country.

Price Fixing

In most state trading nations, but also in some other countries, internal prices are fixed by government policy. Trade is strictly controlled by the government, which allows only specific quantities to be imported, quantities which vary from year to year. For the cases where external prices rise above the internal price, a ban on exports coupled with import subsidies is needed to maintain the policy. If the price in the importing country is fixed at $\bar{P}_2$, the equilibrium price in the exporting country is

$$(24)\quad P_1 = \frac{\sum_i a_i + \alpha_i + \delta_i + \epsilon_i - \bar{P}_2(b_2 + \beta_2)}{b_1 + \beta_1},$$

$i = 1, 2$, and the price variance is

$$(25)\quad \sigma_{P_1} = \frac{\sigma_{\delta_1} + \sigma_{\delta_2} + \sigma_{\epsilon_1} + \sigma_{\epsilon_2}}{(b_1 + \beta_1)^2}.$$

From (25) we can see that all instability in the importing country has been exported to the exporting nation. Comparing σ_{P_1} with the variance of price under free trade, we obtain

$$(26)\quad \frac{\sigma_{P_1}}{\sigma_{P_{1C}}} = \frac{(b_1 + b_2 + \beta_1 + \beta_2)^2}{(b_1 + \beta_1)^2} > 1.$$

It is clear that this ratio increases when supply and demand in the importing country become more inelastic.

Variable Levy

As long as the export price is below the price in the importing country, the imposition of a variable levy has the same effect on instability as in a pure case of price fixing. In a case where the export price rises above the price determined by the importing country, the latter would import the commodity as in the free trade case up to the self-sufficiency price. Because the export price usually can be assumed to be below the price in the importing country, the latter can shift almost all internally created instability onto the external market.

Concluding Comments

In this paper we have demonstrated that various trade intervention policies have a very different effect in altering instability in one country and transmitting it to the rest of the world. The purpose of the note is to present a comprehensive analysis of different trade restrictions and to show how, and to what extent, they affect price instability.[2] For each of the trade intervention measures the resulting price variances are derived for both the exporting and the importing country.

What is the practical importance of this work? Governments seem interested in price stability, particularly for agricultural commodities. Yet they are interested primarily in internal stability rather than in global stability. In achieving internal price stability by various means governments throw adjustment onto the rest of the world. We have quantified the impact such actions will have on world and domestic price stability. Empirical calculations of these effects should be an important issue in trade negotiations. Not only may it be possible to appeal to a barrier-imposing country's international responsibility; but it is possible to demonstrate that for a given level of protection, some trade intervention policies generate a smaller impact on instability in the international community than others. There are other uses of the model. It also can be used to determine a mix of trade-restricting measures by different countries simultaneously. Thus, retaliation also could be analyzed and the resulting equilibrium price levels (if any) and the degrees of instability could be determined.

[Received September 1978; revision accepted November 1978.]

[2] An extension of this work, not considered here, involves a determination of the welfare consequences of each of these actions. Some cases are already discussed in the literature. Bieri and Schmitz have analyzed a case of tariffs and marketing boards; Hueth and Schmitz determined the welfare gains from price stabilization for free trade within a linear framework; Just et al. (1978) used a general nonlinear analysis for the free trade case; and Just et al. (1977) developed the distribution of the welfare gains from price stabilization with price fixing. For a review of the price stabilization literature, the reader is referred to Turnovsky's excellent survey.

Import Tariffs and Price Formation in the World Wheat Market

Colin Carter and Andrew Schmitz

A theoretical analysis of price formation in the world wheat market has been presented by McCalla; Taplin; and Alaouze, Watson, and Sturgess. McCalla and Taplin based their models on a duopoly arrangement between the United States and Canada. These models were extended by Alaouze, Watson, and Sturgess to include Australia, and a theoretical model of triopoly pricing in the world wheat market was developed. Canada is assumed to act as a price leader in the triopoly, and it is concluded that producer prices in wheat-exporting countries will be higher under triopoly as opposed to duopoly pricing. The major thrust of these papers is that price formation in the world wheat market is largely determined by the major exporters.

The purpose of this paper is to suggest and empirically test an alternative hypothesis; namely, that world wheat prices are essentially determined by the major wheat importers. Two major importers—Japan and the European Economic Community (EEC)—are used as the focal point for the analysis. The authors believe the world wheat market is usually a buyer's rather than a seller's market. By arguing the market is usually dominated by buyers, it is recognized that there are periodical exceptions to the argument over time, the major one being the commodity boom period of 1973–74.

It is well known that the major importers are restricting trade in wheat. This paper suggests that the restrictive policies of the importers (whether consciously or not) are likely to result in a welfare gain to importing nations greater than that under free trade. This suggests that perhaps importing countries are using tariffs in an optimal sense (where all sectors of society are taken into account) rather than merely using them to protect domestic producers from low-priced competitive imports. This is not to argue that a duopoly or triopoly structure does not exist among the United States, Canada, and Australia but rather that the effect of such arrangements is minor relative to the buying power exerted by importers. Although this paper focuses on the world wheat market, the framework of analysis has application to other agricultural markets as well.

In light of the trade restrictions that have been set up by the major wheat importers in the international market, the effect of a duopoly or triopoly arrangement seems relatively minor. As an example of one such restriction, the Common Agricultural Policy (CAP) of the European Economic Community establishes a variable import levy on wheat (Riesenfeld). The levy ensures that wheat imports never sell below a target price which is set for Duisburg, in the Ruhr Valley, where wheat is in short supply. The variable levy serves to restrict severely the entry of wheat into the European market. A recent study by Cline et al. (p. 157) has estimated that in 1972 the tariff equivalent of the EEC variable levy on wheat was 109.5%. On the other hand, Japan has import quotas on wheat. As a result of the quota, Cline et al. (p. 167) have reported that in 1970 the import price of wheat was 24.5 yen per kilogram, while, at the same time, the Japanese domestic price was 60.2 yen per kilogram. These prices correspond to \$3.34 per bushel and \$8.20 per bushel, respectively.

Framework of Analysis

To study the structure of the international wheat market, the "optimal tariff" model is used as a framework. The optimal import tariff solution is given in figure 1 (see Enke). The supply schedule in the exporting country is given by S_f with MC_f being the marginal cost of importation when the importing country exerts monopsony power. In the importing country, S_d and D_d are the supply and demand schedules, respectively. Under free trade, imports are *BA*. However, the importing country can do better by imposing an optimum tariff. This solution is derived by summing $S_d + MC_f$. Imports are reduced to *JK*. In the importing country, producers gain *BCIJ*, consumers lose *IKAC*, and there is a gain in tariff revenue of *JKNM*. The gain in tariff revenue plus the producer gain more than offsets the consumer loss.

The model, as presented in figure 1, is used as a reference point for the hypothesized structure of the international wheat market in this study. That

Figure 1. The optimum tariff solution

is, the optimal tariff solution (i.e., what the world wheat prices would be if, in fact, importers pursued monopsony pricing) is computed. The results are then compared to the prices which actually prevail in the market.

Note that with the optimal tariff solution benefits accrue to more than just producers in the importing country; if the tariff revenue is redistributed to consumers, the country as a whole gains from the tariff. Thus, while a government may use tariffs primarily for the purpose of protecting producers, the net result may be an overall improvement in society's welfare if the tariff imposed is close to being optimal.

A Test of the Optimal Tariff Hypothesis

To test the model presented in figure 1, estimates of national supply and demand equations for wheat were obtained from an econometric study of the world wheat economy by the U.S. Department of Agriculture's Economic Research Service (ERS). From the estimates, aggregate supply and demand functions were computed for the major wheat exporters and importers. The estimated slope coefficients and elasticities provided by the ERS are not too dissimilar to those reported by Schmitz and Bawden. Because of the amount of time devoted to these studies, their estimates are likely as good as one can derive realistically for the world wheat economy using currently available econometric tools. The aggregate supply and demand curves were obtained by a horizontal summation of the countries' individual supply and demand curves. The intercept term of the importers' aggregate demand function was adjusted by the equivalent of a ten-year average of Russian and Chinese imports (approximately 10 million metric tons per annum) because it is difficult to estimate supply and demand functions for these countries due to a lack of data.

The aggregate empirical model is presented in figure 2 where D_E and S_E represent the empirical demand and supply functions of the major wheat exporters. The amount of excess supply of the major exporters is ES_E $(= S_E - D_E)$. The function marginal to ES_E is labeled MO_E. On the other side of the market, D_I and S_I represent the demand and supply functions of the major importers.

To integrate transportation costs into the analysis, the horizontal axis of the major exporters is shifted upward. The prices in figure 2 are in 1964–66 dollars.[1]

[1] Figures on transportation costs were obtained from the International Wheat Council. Freight rates for the 1964–66 period averaged between 15¢ and 40¢ per bushel for wheat for shipments from

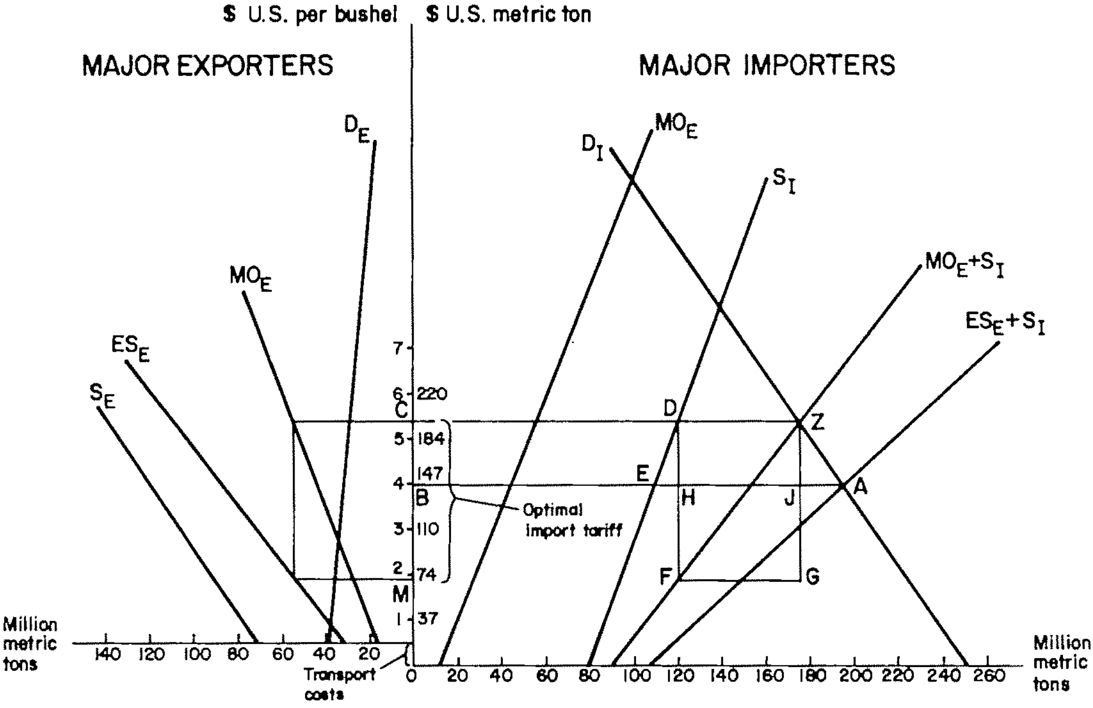

Figure 2. Empirical estimate of the optimal import tariff solution (1964–1966 prices)

From figure 2, free trade imports of wheat would equal *EA*, and the free trade price of wheat would be approximately *OB* per bushel. However, if, as hypothesized, the importers are exerting monopsony power in trade and, at the extreme, are imposing an optimum tariff, wheat imports would be restricted to *DZ*. Relative to the free trade position, the price in the importing countries would be raised from *OB* to *OC*, and the price of wheat in the exporting countries would be reduced from *OB* to *OM*. The world price of wheat would be *OM*. It is a depressed price due to the influence the importers have in the market.

To test informally the hypothesis that importers are exerting monopsony-like power in trade, one can compare actual prices (table 1) with the empirical estimates of the optimal tariff solution (figure 2). The export prices of Argentina, Australia, Canada, and the United States (table 1) should be compared for equivalence with the estimated price of *OM* (figure 2). Similarly, the support levels in Japan and in the EEC should be compared with the estimated *OC*. Because it is not argued that the "buyer's market" hypothesis in this study is completely robust over time, figures from table 1 should be compared with those from figure 2 for the period 1966–73 and 1976–77. This comparison abstracts from the 1973–74 to 1975–76 period as the "power" in the market temporarily reverted to the sellers as a consequence of the general commodity boom at the time.

Interestingly enough, the export prices for the 1966–73 and 1976–77 periods are very similar in table 1 and figure 2. The actual average export price for this period is $72 per tonne (average of the first four entries in the last row of table 2), while the estimated export (world) price is $70 per tonne (*OM*). The estimated and actual prices in the importing nations do not compare quite so favorably. The estimated price in the importing nations is approximately $198 per tonne. The average support price in Japan, $193, is very near the optimal $198 figure, but the support price in the EEC is less and is approximately equal to $113. The results suggest that perhaps, relative to Japan, the EEC is not taking full advantage of its position as a major wheat importer.

Because the actual prices in some cases are reasonably similar to the empirical estimates (figure 2), there is reason to argue that the major importers of wheat could be acting in a fashion similar to tacit collusive behavior and that they are effectively imposing close to an optimal import tariff on wheat. Even though there seems to be no formal collusive arrangement, it is conceivable that one of the major importers of wheat (e.g., Japan or the EEC) acts as a price leader in setting an optimal or nearly optimal tariff. Perhaps a mechanism used to achieve this is

Canada, Australia, and the United States to Rotterdam, India, and Japan. The authors chose to adjust the model in this study for transportation costs by assuming freight rates are set at 50¢ per bushel for all international shipments. This rate is likely an overestimate of actual rates but, in any case, does not adversely affect the results obtained.

Table 1. World Wheat Prices, 1966–67 to 1976–77

Crop year	Export Prices				Basic Support Levels[d]

the variable levy or the equivalent quota. Even though there is no evidence that overt collusion among importers exists, one could argue, as does Scherer, that collusion without formal agreement is both feasible and tempting.

The EEC, China, the USSR, and Japan account for between 30% and 40% of the world wheat imports, and they directly influence the world price of wheat. Table 1 and figure 2 suggest that the major importers are regulating consumption, production, and imports so that the least possible marginal cost to the group of obtaining wheat (shown by $MO_E + S_I$) is equal to its marginal value in consumption (shown by D_I) at point Z. As shown in figure 2, consumption of wheat in the importing countries under the optimal tariff is reduced to approximately 174 million metric tons per annum (CZ) with production of 119 million metric tons (CD). Imports of wheat to the group are approximately 55 million metric tons annually (DZ). The importers would set the optimum import tariff at close to $3.50 per bushel, and the exporting countries would receive approximately $1.90 per bushel net of transport costs. Under this solution, producers in the importing countries receive slightly over $5.00 per bushel.

The results generated from the model (figure 2) pertaining to volumes of wheat traded are very close to actual world wheat statistics. *World Wheat Statistics* reports that, for the period 1966–73 and 1976–77, the major wheat importers restricted their purchases to an average of 55.1 million metric tons per year. The model in this study predicted that, with an optimal tariff solution, imports of wheat to the group would be approximately 55 million metric tons annually.

Table 2. Welfare Gains to Wheat-Importing Nations with the Imposition of the Optimal Import Tariff

Welfare Effect	Net Gain
	$U.S. millions
1. Loss in consumers' surplus	−9,439
2. Gain in producers' surplus	5,971
3. Import tariff revenue	7,202
4. Net gain (3 + 2 − 1)	3,734

Source: Calculated.

Welfare Effects

Empirical estimates of the welfare gain accruing to the importing group as a result of the optimal tariff are shown in figure 2. Consumers in the importing countries lose a surplus equivalent to the area $CZAB$. On the other hand, producers in these countries gain a surplus equal to the area $CDEB$. Government revenue from the import tariff is equal to $DZGF$. Therefore, the total net gain to the importing nations is equal to the area $(HJGF) - [(DHE) +$

$(ZAJ)] > 0$. This estimated net welfare gain accumulated per annum by the wheat importers is shown in table 2 to be approximately $3.7 billion. These welfare estimates of the effects of trade restriction seem consistent with earlier studies by Johnson and by Cline et al.

Changing Structure of the Market

It has become apparent within the past ten years that the world wheat market is increasingly becoming a buyer's market. This trend lends credence to the hypothesis presented above. Recently, the production of wheat by the major exporters has been increasing faster than world demand for it. This production increase has been due mainly to increased yields and has been most predominant in Australia and the United States (table 3). Also, the USSR and East Europe are expected to considerably reduce wheat imports because there have been substantial production improvements in the USSR grain economy. Since the early 1960s, the Russian grain harvest has climbed from an average of 130 million tonnes to over 200 million tonnes in the mid-1970s. Also, the development of high-yielding varieties of both rice and wheat in the less developed countries as part of the "Green Revolution" has reduced their potential demand for wheat.

It has been argued above that the wheat market is a buyer's market and that the major importers impose close to an optimal tariff on wheat. However, because the world does experience periodical food grain shortages, this argument is not entirely robust over time. For example, during the 1973–74 commodity boom, the market power obviously reverted to the sellers, and the optimal import tariff argument had less validity. However, even though the degree of power the importers yield may change from year to year, in general, they tend to determine world wheat prices.

Alaouze, Watson, and Sturgess suggest that surplus carryover stocks serve to maintain market shares in the exporters' triopoly. It is suggested further that the stocks provide market power for the exporters. We are somewhat skeptical of this latter suggestion and believe that stocks do not necessarily detract from the market power of the importers, especially when stocks are "excessive," as is often the case. Stockholding on the part of exporters is usually not used for optimal export pricing but, rather, is a result of excess supply. They are seldom used as a weapon against importers! If they were, importers could also hold stocks to offset any market power exporters may have (see Feder, Just, and Schmitz). In most years it appears that the cost of holding stocks is borne by exporters, not importers.

Table 3. Wheat: Average Production, 1954–55 to 1976–77

	1954–55 to 1958–59	1964–65 to 1968–69	1974–75 to 1976–77[a]
	------ 1,000 metric tons ------

[a] 1976–77 data are provisional.

Conclusion

This paper has emphasized, using a rather naive model, that market power on the part of importers of wheat is perhaps greater than the power attributed to exporters by previous researchers. If this is true, price formation on the world wheat market may rest largely in the hands of wheat importers. However, because of the importance of this topic and because the structure of the wheat market is more complex than depicted in this paper, further research is needed to integrate the role of both exporters and importers in price formation. Also, in this paper only, consumers, producers, and governments were considered. To make a structural model of the world wheat market complete, market intermediaries (e.g., Canadian Wheat Board and Cargill) should also be included. One approach might follow a model recently developed by Just, Schmitz, and Zilberman, where intermediaries are assigned different objective functions.

The arguments presented in this paper are directly related to recent and ongoing discussions on the feasibility of exporters forming a cartel in wheat. If, as hypothesized by others, exporting nations currently have market power, a major question (left unaddressed by the literature) is whether or not these exporters can use their power optimally in the form of an "optimal export tax." However, in view of our discussion above, it appears that the cartel argument runs the other way. That is, the wheat exporting nations may want to form an export cartel, but the most they can hope for is a removal of the buying power of importers and perhaps a movement closer to the free-trade solution (from the direction of the optimum import tax solution). The task of the exporters setting the optimal export tax (cartel solution) is a difficult and perhaps impossible one.

Capital-Surplus, Labor-Short Economies: Yemen as a Challenge to Rural Development Strategies

John M. Cohen and David B. Lewis

If the test of a development model is its capacity to yield strategies that deal effectively with new and different situations, then the Yemen Arab Republic will be a good proving ground for contemporary theoretical approaches to agricultural and rural development. Until the early 1970s Yemen's annual gross national income was less than US$100 per capita; the country had a shortage of capital and a surplus of labor—characteristics shared by many developing countries. Within the last five years, however, employment opportunities in Saudi Arabia have attracted some 40% of Yemen's male labor force, and the remittance of earnings by these workers has increased Yemen's gross national income per capita by a factor of six. Policy makers now face the problem of planning for national development under conditions of capital surplus and labor shortage. There is a growing concern that the dominant models of agricultural and rural development cannot generate strategies responsive to their needs.

Paradigms and Anomalies

In any science at a given point in time, there is generally a fundamental image defining the agenda of topics to be studied, the concepts used in inquiry, the validity of propositions that emerge, the essential elements of the model or framework that integrates them, and appropriateness of policy actions based on the accumulated research (Kuhn). Such an image constitutes a paradigm. Typically, while science operates within the paradigm, forward thinking scientists explore its boundaries and seek to expand it. This effort inevitably uncovers anomalies which cannot be explained or dealt with by the dominant perspective. These problems lead supporters of the paradigm to develop it further so that the anomalies can be resolved. If anomalies grow in number and remain intransigently unresolvable, a crisis is reached. Usually this results in the emergence of a new paradigm.

The work of Johnston and Kilby, Mellor and Lele, and others has been fundamental in defining what is today a major paradigm in international agricultural economics and the conceptual basis for much of the contemporary work on rural development strategies. The question we wish to raise is whether the problems of rural-based, capital-surplus, and labor-short economies constitute an anomaly to this general perspective. Specifically, we propose to describe the interesting case of the Yemen Arab Republic, in order to alert rural development specialists to a situation which appears to be an anomaly needing additional theoretical work. We hope this research note will lead agricultural economists to a particularly careful study of countries like Yemen, because we believe that the focus on such unique cases may lead to significant improvements in development theory and strategy.

Rural Development Paradigm

Since the mid-1960s, a new strategy of rural development has emerged. Increasingly national leaders, policy makers, and development experts are looking beyond the industry-led, capital investment-based strategy that dominated development theory during the first two decades of the post World War II era (Johnston and Mellor, Mellor, Johnston and Kilby, Hunter, Owens and Shaw). Growing attention is being devoted to rural development with efforts concentrated not only on increasing food production to accommodate population growth, but also on improving income levels of rural inhabitants—the majority of the population in many countries. This increase in income for a substantial portion of the population is expected to generate increased demand for domestic industrial products (Mellor and Lele). Past experience suggests that increasing agricultural output and improving income distribution in the rural sector may be the only effective way to stimulate sustained development.

The shift toward rural-led development strategies was accelerated by the appearance of high-yielding varieties of wheat, rice, and corn (Brown, Streeter). When combined with fertilizer, water, and the proper production practices under favorable conditions, these hybrids typically yield more than traditional varieties. The technology of the new high-yielding varieties has been effectively used on both

Work from which this note was developed was funded under a cooperative agreement between Cornell University's Rural Development Committee and the Office of Rural Development of USAID focused on "Rural Development Participation."

large and small holdings. After initial experiences with the tendency of large farmers to adopt capital-intensive, labor-displacing practices, however, many governments and international agencies now seek to raise yields through small farm strategies. The choice has been made easier by the increasing evidence that small farms can be as productive with food crops and some nonfoods as the larger-scale commercial farms. For example, the highest yields of food grains per land unit in the world are found on small-scale holdings in Taiwan, South Korea, China, and Japan (Owen, pp. 31–6).

The effectiveness of small farm policies depends on the development and maintenance of a progressive rural structure (Mosher). This includes elements such as agricultural research and production incentives that are effective in serving the needs of the small farmers; commercial centers through which farmers can obtain supplies and sell their production output; rural roads to increase flows of supplies, goods, information and services; extension activities; credit facilities; group action by farmers, and so on. Much of the growth of a progressive rural structure is a private sector response to the stimuli resulting from increased rural income, but the government must also follow land, tax, pricing and monetary policies supportive of economic growth with equity.

Until the mid-1970s this small-scale farm strategy seemed to fit the needs of the Yemen Arab Republic. Its physical, social, economic and political characteristics were compatible with the basic assumptions underlying the new agriculture-led development model. However, because of some very unusual economic events the comprehensiveness of the model in general, and its appropriateness for Yemen in particular, now seem challenged.

Rural Economy of Yemen Arab Republic

Yemen is located at the southern corner of the Arabian peninsula. Aside from some general introductions (Wenner; Nyrop; Stookey; Tutwiler, Murdock and Horowitz; economic details and a summary of the rural economy can be found in Cohen and Lewis) little information is available on the country or its development opportunities and problems. It is composed of areas that vary greatly with regard to their ecological, agricultural, and societal characteristics, ranging from the dry but productive coastal lowlands of the Tihama, through the agriculturally rich waddis of foothills and fertile highlands bordered by rugged mountain peaks, to the arid deserts of the interior of the peninsula. For centuries this Islamic country was a nominal dependency of the Ottoman Empire. After gaining independence at the end of the First World War, it was ruled by an Iman who kept the country largely isolated from the West and closed to external economic forces and technological innovations. This absolutism ended in 1962 with a coup that only partially succeeded. For the next several years, civil war between nationalistic republican army officers and royalists prevented much development progress in rural or urban areas. By 1969 the republicans gained the dominant position and the war ended. Attempted coups d'etat, assassinations of top political leaders, and tribal conflict, however, have continued to threaten national stability. Even today, the central government has only limited authority in the hinterland. The functions of local government are performed largely by the village sheikhs—traditionally independent men for whom tribal allegiances are often paramount to national concerns. While the larger towns and southern and western parts of the country are more integrated with the national government, few government officials go into the remoter regions of the north without apprehension.

On the basis of data from the early 1970s, we know that Yemen has some six million people and an area of 145,000 square kilometers. Nearly 90% of the population traditionally has earned its livelihood from agriculture or animal husbandry. The rural sector is divided into highland, waddi, coastal plain, and arid regions. The major crops of the highlands are sorghum, wheat, millet, barley, fruits, tomatoes, potatoes, and a variety of lentils. The seasonally heavy flowing rivers of the foothill waddis permit the cultivation of most cereals, corn, sugar cane, and tropical fruits such as mangoes or bananas. Dates, tobacco, cotton, millet, and sorghum are widely grown on the hot Tihama plain along the coast. Most farmers also raise a large variety of livestock, and pastoralists work their herds on the arid fringes of the cultivated areas.

Overall, some 90% of agricultural crop production is made up of cereals, with the northern parts of the country dominated by sorghum, millet, and barley, and the south by sorghum and maize. A total of some 1.8 million hectares are thought to be in production. In 1972 agriculture accounted for 70% of gross national product, with coffee being the major export product, followed by cotton, salt, and hides. Despite this well-established agrarian base, by 1970, food production was lagging behind population growth. The problem has since been exacerbated by recurring periods of drought.

Most rural people live on small farms using traditional production techniques and working the soil either by hand or with oxen. Rural land ownership patterns vary from region to region, but the country does not seem to be plagued by the kinds of concentrated holdings that make rural development difficult in countries like the Philippines. While irrigation has increased since the end of the civil war, most farmers are still limited to dry farming practices. They have, however, developed a high degree of sophistication in the management of runoff rain water. On the terraced hillsides and in the waddis, it is efficiently channeled from field to field with minimal losses.

In 1972 industry accounted for only 3% of Yemen's gross domestic product, and it employed less than 1% of the labor force. Despite a 1969 law designed to attract foreign capital investment, the country still has only one textile mill, a small aluminum plant, and a cement factory—all representing foreign aid. The use of mechanical power is limited. The country has no known oil, and other mineral resources are both limited and largely untapped. Aside from agriculture, the country's greatest asset is its manpower. Yemen historically has supplemented income from domestic production with income earned and repatriated by its emigrants working abroad.

In 1972 the country stood at the bottom of most lists for demographic, development and quality of life indicators. Per capita income was US$80 per year, illiteracy rates ran more than 90%, and such pervasive diseases as tuberculosis and malaria, as well as chronic malnutrition, kept life expectancy at the low level of thirty-six years. Few public services reached the towns, much less the villages, and amenities such as potable water systems, health clinics, or schools were available only in a few of the larger towns. Sanitary public sewers were unknown in most towns and paved streets rare. Moreover, there was an acute shortage of trained manpower to staff clinics, schools, or public welfare organizations. Indeed, the government had few of the technical or middle-level managerial people so necessary to get development moving. And, in the agricultural sector, there was little agricultural research, no production credit programs, and few extension agents. Poor road and communication networks held back the development of efficient markets and storage systems were scarcely developed.

Despite this dismal description, the situation is changing and Yemen has the potential for a productive and profitable rural sector. The country contains some of the most fertile land on the Arabian Peninsula and its people are hard working, energetic, and entrepreneurial. Moreover, the ruling military coalition has a political and economic philosophy centered on Islam, pragmatism, and free enterprise.

Given the situation in Yemen in the early 1970s, the policy prescriptions of the new rural development model (described earlier) would seem to be as appropriate as for such countries as Ethiopia, Kenya, Bangladesh, Peru, or Indonesia. However, the rapid increase in employment opportunities in Saudi Arabia has changed two critical characteristics of the situation in Yemen: capital is relatively more abundant and labor is in short supply.

The Changing Context in Yemen

Information on recent change in Yemen is difficult to acquire, though some helpful reports exist (Ross, Keyser, UNCWA). These indicate that the increased demand for labor in Saudi Arabia has attracted some 600,000 males from Yemen, roughly 40% of the labor force. Most are unskilled when they emigrate, but they typically earn wages four times the presently prevailing levels in Yemen. The 1977 remittances from these workers totaled US$ 1.5 billion. This inflow of funds has caused annual per capita income to increase from US$80 before the oil boom to present levels of more than US$ 500. The money supply in Yemen has increased by a factor of more than twelve since 1972. Incredibly, more than two-thirds of this money supply is held outside the formal banking system in the form of currency.

Yemen's change in fortunes is a direct result of the development boom in Saudi Arabia. Yemeni political leaders and policy makers are concerned, however, with how long the current situation will last. Yemen enjoys a special relationship with Saudi Arabia, but workers from other Islamic countries do represent an increasingly important alternative and competitive source of labor. Also the pace of construction, a key factor in current levels of labor demand, may slacken as Saudi Arabia completes its current phase of development. Finally, a change in the world energy supply structure or in relations between Saudi Arabia and Yemen could bring abrupt changes in employment opportunities for Yemenis.

Opinion varies greatly, but the consensus suggests it would be dangerous for Yemen to assume that it can count on its currently extraordinary remittances for more than twenty years. Indeed, the unpredictable politics of the Middle East could cut it off much sooner than most observers predict. Hence, it seems reasonable to suggest that Yemen view itself as being in a grace period, and use the time and resources to build rural institutions and infrastructure in anticipation of the day the migration opportunities decline.

The effects of these sudden changes are visible throughout Yemen. Migration is moving more women into agricultural roles and bringing new skills and resources back into the country. Structural changes are occurring in local transportation systems, consumption patterns, market prices, and foreign trade. New local or village level development associations have appeared which might be able to channel some of the new wealth into rural development projects. Unfortunately for policy makers seeking to devise strategies for rural development, there is little data available on the nature or trend of such changes.

Yemen: A Challenge to the Paradigm?

The theoretical guidelines proven useful in other poor, rural-based countries are not particularly helpful in the Yemen context. There are two main elements to this problem. First, although the country has agricultural potential, no progressive rural

structure, and potentially productive small-scale farms, the capital surplus/labor shortage situation appears to fall outside the accepted assumptions of the paradigm. Second, some of the functional relationships implied by the strategy do not seem to be borne out by the experience of Yemen over the last few years.

Assumptions

The model of Johnston, Mellor, and others generally assumes that rural families have low incomes and that rural poverty is a major problem. The rural population in Yemen, while not necessarily affluent, does not fit the assumption very well. By contrast with many developing countries, this increase in gross national income has been distributed rather equitably among the population. Coming primarily from the export of labor in the form of earnings of individual emigrants, the incomes do not appear to have been concentrated in the hands of owners of capital or land. The typical pattern seems to be for a family to release one son to go to Saudi Arabia. He works there for one or two years, sending home remittances regularly. He then returns, usually bringing appliances and consumer goods with him. While he is away, his brothers, and in some cases his wife, will look after the family's agricultural interests and activities. Commonly, as one brother returns another migrates—again for one or two years of work in Saudi Arabia.

The effect of this migration pattern and the associated remittances has been to place resources in the hands of a widely spread rural population. The government does not tax these remittances, and, hence, has very limited funds of its own. In contrast with other developing countries, the rural population is the principal holder of the liquid financial resources needed for development. With more than two-thirds of the money supply being privately held outside of the formal financial system of the country, the government has relatively little direct control over its allocation and expenditure. This puts the government in a substantially different position from its counterparts in other developing countries, where the discretionary financial resources are concentrated in the hands of the administration.

Another discrepancy between the assumptions of the general model and the situation in Yemen is that the rural labor force does have an opportunity for obtaining high-paying employment. Limited data suggest there is relatively low unemployment in the rural areas for reasons other than the "self-absorptive" ability of rural economies. This phenomenon varies from one region to another depending on the degree of emigration, but it is sufficiently widespread that individuals rarely have to accept unemployment involuntarily. The informal network for sending laborers to Saudi Arabia and placing them in employment there is well-established and apparently very effective.

As a result of the substantial remittances from abroad, the domestic economy enjoys an abundance of foreign exchange. Unlike the situation encountered in many developing countries, Yemen has a vigorous system of local commercial activity. It is virtually unconstrained by either high duties on imports or shortages of foreign exchange. Residents of local towns are served by stores featuring the latest in imported Japanese stereo tape cassette players and cameras. They can also buy four-wheel drive tractors from France and canned food from Eastern Europe. It should be noted that the network is primarily commercial in nature, and relatively undeveloped in terms of being able to service the products it sells or helping the consumer select equipment appropriate to his needs. This is particularly true in the area of agriculture machinery. Establishments selling tractors, for example, are often not in a position to advise customers on the appropriate selection of implements to be used with the tractor, nor are they organized to supply spare parts on a regular basis.

There seems to be minimal pressure on agricultural land. The Tihama region is under-utilized, with big sections lying vacant. In other areas, agricultural land is going out of use as rural people redirect their labor toward employment in Saudi Arabia. It should be noted that the lands falling into disuse tend to be of marginal quality. They often, however, represent a substantial past investment of capital in that they are, typically, terraced fields, and when neglected for several years, the supporting walls often deteriorate to the point that the terraces collapse and the top soil is washed away by the rain. Another perhaps even more significant indicator of the decreasing pressure on agriculture land is the shift of its use from essential food crops into luxury crops. This is especially true of *qat,* a mildly narcotic plant whose leaves are chewed to produce a sense of euphoria and alertness in the chewer. With the growing per capita income, people can now afford to import more food, grow less at home, and use the land to grow *qat*—an important element to the culture, but not nutritionally essential to life.

Finally, Yemen has an interesting system of local or village level development associations (Green). These are supported primarily by their local constituencies and undertake, in some cases, significant development projects, such as roads and water systems. In addition, there is increasing evidence that rural areas can mobilize marketing and production cooperatives that are successful. For example, the agricultural Cooperative Society of Al-Lawiah in the Tihama has in two years initiated a share-capital enterprise that supplies agricultural inputs to the community, owns a gas station, owns and rents a bulldozer for land reclamation, and markets substantial quantities of okra in Saudia Arabia (Gow). As information emerges on the rural sector, it becomes increasingly clear that local communities have shrewd, intelligent leaders, progressive community members, and a general instinct

for profitable rural development activities. The major question is what kinds of policies the government should follow to capitalize on this potential? Answering this question appears to raise difficult theoretical issues.

Functional Relationships

In effect, it appears that the remittances from abroad are a temporary but functional substitute for the increased income of Johnston and Mellor's highly productive small-scale farmers. Small towns are thriving commercially and a large percentage of the population has resources to spend on capital and consumer goods. The rural development strategy, however, is largely dependent on the viability of the small farm—the capacity of the small farmer to support himself through his efforts on his own land. Given the current price structure for imported food, the farmer in Yemen has difficulty competing. Imported food grains can be sold at a lower cost than those produced domestically. A typical store in the capital city will have frozen chickens imported from France selling at a lower price than domestic chickens. It is common to see fruit imported from the United States selling in rural areas.

The government would like to stimulate the development of institutions and infrastructure that would support development of the rural sector, but with the exception of requests for roads and water systems and occasionally a school or clinic, there is relatively little spontaneous demand. With the purchasing power that exists in the rural sector, there has been relatively little demand, for example, for agricultural credit. And the government has done little to mobilize rural savings. Similarly, there seems to be relatively little elasticity in the demand for traditional crops such as sorghum and millet. Families customarily produce only for their own needs, and government efforts to increase the output of these cereals have been only marginally effective.

The central tenet of the rural development paradigm tested here is the importance of increasing the income of the small farmer. In Yemen a significant proportion of the rural population already has substantially more money than it has ever had before. The rural commercial and manufacturing systems, however, do not seem to be serving the needs of a progressive rural structure. There does not appear to be a growing demand for locally produced agriculture implements, and there does not appear to be a supply of these implements which might stimulate a demand. A very sophisticated and effective marketing system has emerged for *qat*, and it demonstrates a capability for efficient economic response. Despite attractive price differentials, this type of response has not been widely duplicated, however, for other agricultural commodities. A box of tomatoes, which sells for 10 riyals (one riyal = US$0.21) at the farm gate, sells for 55 in a city less than two hours drive away.

In sum, one is left with a concern that although rural development is badly needed in Yemen, the contemporary model may not be helpful in offering effective policies or strategies. Many of the concerns of the model are already being addressed—people have a substantial increase in income; yet, the private sector element of a progressive rural structure which should be emerging has not begun to materialize. In this regard a fundamental question is how can the basic small-farm strategy be modified to create a modernizing agriculture that will be viable when out migration and high remittance levels are no longer possible and the economy has to rest on its potentially productive agrarian sector?

The Effect of Water Quality on Rural Nonfarm Residential Property Values

Donald J. Epp and K. S. Al-Ani

The past decade has seen a phenomenal increase in public awareness and concern over environmental quality. The desire to consume larger amounts of environmental quality has been difficult to satisfy because many of the natural resources involved do not lend themselves to market allocation. This failure of markets to solve the major environmental quality problems has been well documented (Bator, Mishan, Samuelson, Turvey), and generally can be attributed to externalities imposed by use of the environment and the public goods nature of many natural resources.

The failure of markets to perform the allocation function to the satisfaction of most people has caused us to turn to other institutions for solutions. Most frequently society has turned to legal processes, both the passage of new legislation and the interpretation or enforcement of existing legislation in the courts. While these activities affect many environmental areas, this paper is focused on water quality, where many state and federal laws have been passed in recent years. Typical of this legislative effort are the 1972 Amendments to the Water Pollution Control Act (P.L. 92-500) and the 1977 Clean Water Act (P.L. 95-217). These acts specify national goals and policies to eliminate the discharge of pollutants into surface waters, encourage policies that maintain a level of water quality sufficient to protect fish and wildlife, require local authorities to establish waste treatment projects, and finance the development of pollution abatement technology.

While there has been political support for these laws, economic analyses of their effects have concentrated largely on determining the costs of achieving the standards set through the political process (e.g., Nagadevara, Heady, Nicol; Pound, Crites, Griffes; Van Note, Hebert, Patel; Young). Very little evidence has been presented that measures the demand (in the economic sense) for environmental quality in general or water quality specifically. This article reports an attempt to determine one aspect of the demand for one kind of environmental quality—clean streams.

The study reported here used real estate prices to determine value of improvements in water quality in small rivers and streams in Pennsylvania. The specific objectives of the study were (*a*) to estimate the relationship between water quality and the value of residential properties adjacent to small rivers and streams; and (*b*) to estimate the effect of various components of water quality, such as acidity, dissolved oxygen, biochemical oxygen demand, and nitrate and phosphate levels, on the value of properties adjacent to small streams.

The second objective was included because various pollutants have different physical and biological effects in the streams, have very different costs for removing marginal increments, and usually are listed separately in quality standards established for specific streams.

The Model

Traditionally, the real estate market consists of at least four parts—residential, commercial, industrial, and agricultural—each of which may be divided into a market for rental of services and a market for purchase of stocks. The model developed in this study concentrates on the market for the purchase of housing stocks, but does not use the conventional supply and demand approach. Due to the wide variety of housing characteristics provided by units on the market at any one time, especially in the rural areas of particular interest to this study, it is inappropriate to represent these markets with a model that assumes homogenous products. Instead, a hedonic model based on property characteristics is developed. Using such a model, the economic analyst can determine the implicit price of various attributes of properties from observed prices of differential products and the specific amount of each attribute associated with them (Rosen, p. 34).

For this study, the characteristics of residential property are divided into four groups and related to market value as

$$V = f(\Sigma R_j, \Sigma S_j, \Sigma T_j, \Sigma U_j),$$

where V is the market value of the property; R_j is the value of physical housing characteristic j, such as number of rooms or age of the house; S_j is the value of neighborhood characteristic j, such as

Donald J. Epp is an associate professor of agricultural economics at Pennsylvania State University and K. S. Al-Ani is head of the Department of Cooperatives and Farm Management, University of Baghdad, Iraq.

community average income, average education level, or employment rate; T_j is the value of accessibility characteristic j, such as distance to major highways, to a metropolitan area, or to a waterway; and U_j is the value of amenity characteristic j, such as water quality or topography (Al-Ani).

Estimating the Model

Small rivers and streams in Pennsylvania (average discharge of 850 cubic feet per second or less) with documented levels of various water quality components were classified as clean if all components were within the normal range established for surface waters by the National Academy of Science and polluted if one or more components had levels outside the normal range. A paired sample, consisting of twelve clean streams which had not undergone recent quality improvement and thirteen polluted streams, was selected. On each stream a site was selected to consist mainly of rural, nonfarm, small communities located away from the suburbanizing influence of large cities. It was required that each site be located along the stream and within two stream miles of a Pennsylvania water quality network stream station (Pennsylvania Department of Environmental Resources).

Data on properties containing one single-family, owner-occupied dwelling, ownership of which was transferred between 1969 and 1976, were collected for these sites from public records and from telephone interviews with present property owners. Only properties occupied by the owner year-round and located within 700 feet of the stream were included in the study.

The sampling procedure was designed to isolate the influence of water quality on property value by minimizing the variability between properties of characteristics other than water quality. Similarly, a comparison across streams rather than a time-series was used to minimize the impact of changes in value that occur over time. An additional advantage of the across-stream comparison is that it gives a greater variation in water quality characteristics. Time-series data on streams that have experienced significant changes in water quality are very limited.

Specification of the Variables

The dependent variable, property value, was measured using actual sale price and excluded invalid transactions, such as sales to relatives and nominal sale prices. Sale prices were deflated to the base year 1972 using the quarterly implicit price deflators of residential nonfarm structures (U.S. Department of Commerce).

The independent variables are of two kinds, those that vary for each property and those that vary between sites but which have identical values for all properties within a site. All of the independent variables used in this study are shown in table 1 along with an indication of whether the variation is by site or individual property, the unit of measurement, and the a priori expectation of direction of effect.

The selection of the components of water quality to be included in the model was based upon their possible effects on nonconsumptive uses of the stream, primarily recreation or aesthetic appreciation. Several specific components of water quality were tried in this study—pH, dissolved oxygen, biochemical oxygen demand, acid from minerals, acid from carbon dioxide, and nitrate and phosphate concentrations. Only the three measures of acidity had consistently significant effects on property values. Acidity from minerals, acidity from carbon dioxide, and pH each had similar effects on property value when entered as the single measure of water quality. Because pH is the more widely used measure of acidity in water, it was used throughout the rest of the analysis. For some purposes, pH was transformed into a dummy variable equal to zero if pH was 5.5 or lower, otherwise equal to one. The pH of 5.5 was chosen for this purpose because water with a pH of less than 5.5 has severe limitations for recreational use.

A general measure of water quality was based on the perceptions of the property owners as determined in the survey. If the owner indicated a belief that the stream had a water quality problem and that this prevented his using the stream for a specific recreational or aesthetic activity, the value of zero was assigned to the variable. In this way, perceptions of water quality, whether factual or not, could be entered into the analysis.

The hazard of flooding was determined from interviews with present homeowners. Responses to the question about frequency of flooding were converted to probabilities ranging from zero if the property never flooded to 0.99 if the property was flooded annually.

Lots in rural communities may vary greatly in size, being as small as one-fifth of an acre to as large as several acres. In this study, lot size was calculated to the hundreth of an acre.

The opportunity to find employment nearby is an important consideration in choosing a residence and is hypothesized to be positively related to sale price. An index of potential employment (*PER*) was constructed using a gravity model to weight actual numbers of employed individuals by distance using the following equation.[1]

$$PER_i = \sum_{j=1}^{n} D_{ij}^2 + 1$$

where PER_i is potential employment by residence

[1] The authors acknowledge the assistance of Frank M. Goode in developing the final form of the equation and in providing access to data for calculating *PER* values.

Table 1. Single Equation Estimates of the Effect of Selected Variables on the Value of Residential Properties

Variable and Level of Observation (P = property, S = site)	Units	Expected Sign	Mean Values	Coefficient Values	
				Model 1	Model 2
pH (S)	pH units	+	5.694	.344* (.130)	
Interaction of pH_D and percentage change in population, 1960–70	%	+		.115* (.023)	
Perceived water quality (P)	0,1	+			.246* (.055)
Interaction of perceived water quality and percentage change in population, 1960–70	%	+			.129* (.022)
Flood hazard (P)	Probability	–	.063	−.568* (.176)	−.491* (.171)
Lot size (P)	acre	+	.917	.349* (.088)	.317* (.086)
Number of rooms (P)	number	+	9.085	.604* (.109)	.586* (.106)
Potential employment (S)	number of jobs	+	1090.052	.160* (.027)	.133* (.025)
Per pupil expenditure (S)	$	+	1007.100	1.861* (.435)	2.180* (.404)
Percentage change in population, 1960–70 (S)	%	+	.548	−.001 (.015)	−.002 (.015)
Age of house (10–24) (P)	0,1	–	.156	−.274 (.174)	−.273 (.169)
Age of house (25–49) (P)	0,1	–	.264	−.516* (.172)	−.526* (.165)
Age of house (50 and over) (P)	0,1	+ or –	.557	−.847* (.170)	−.822* (.164)
Income (>$10,000 = 1) ($P$)	0,1	+	.590	−.197* (.053)	−.169* (.052)
Constant				−6.449	−7.841
$\bar{R}^2$				.67	.69
N				212	212

Note: Standard errors in parentheses. Asterisk denotes coefficient was significant at the 1% level.

at site i; E_j is employment at the jth minor civil division (MCD) within a 20-mile radius of site i, including the MCD containing site i; and D_{ij} is distance (in miles) from the center of site i to the center of MCD_j.

Another important factor in choosing a residence is the level of services provided by local government and schools. School expenditures per pupil (annual operating budget divided by average daily enrollent) was selected as the measure of school services. Expenditure per pupil was chosen over school tax rate because state aid payments to school districts vary greatly. It is believed expenditures more accurately reflect school quality in this case than do local tax revenues. The real estate tax rate for schools and local government combined also was tried as an independent variable but did not improve the model.

The dummy variable for age of the house over fifty years is of uncertain effect on property value. In some localities in Pennsylvania, very old houses have added value as antique or historic properties. Thus, the expected effect is indeterminate.

Income in this study is reported individual family income. To increase response, the income question in the survey was worded to determine which of five income categories contained the family annual income. Thus, income was treated as a dummy variable. Several specifications were tried and a qualitative variable form with $10,000 as the dividing point was chosen. Contrary to previous studies, this study did not use median income as a proxy for housing quality but, rather, measured housing quality directly.

Several variables were considered in addition to the variables used in the final specifications of the model. Characteristics of the house and neighborhood included the age of the house as a continuous variable and the size of the stream measured by average annual flow. Accessibility characteristics

considered included the distance to a major highway, the distance from the property to the waterway, and the ease of access to the waterway indicated by a dummy variable which took the value of one if there was a building, hill, or other obstruction between the stream and the property being studied. None of these variables increased the explanatory ability of the models when added to those shown in table 1 or substituted for similar variables.

Empirical Estimates

Estimation of the model was conducted in two ways. First, all 212 property observations were combined into one pooled-data set to estimate the parameters of various forms of the equation. A second estimate of the effect of water quality on property value made use of the fact that the sample was taken in part from streams of good water quality and in part from polluted streams. The second, or paired sample, approach estimated the parameters of the equation twice, once with data from clean stream sites and once with data from polluted stream sites.

The logarithms of the dependent variable (property sale price) and the continuous independent variables were used in estimating the parameters of the equation. Other functional forms were considered. The linear, semilogarithm and inverse semilogrithmic forms were rejected because of greater hetroscedasticity and because coefficients of the selected form are more easily given economic meaning. The analysis also specifically considered the potential problems caused by multicollinearity among independent variables. Initial screening of the variables using the Klein test (Klein, p. 101) did not indicate any potential problem. Preliminary runs of the paired-sample approach seemed to indicate, however, that three variables had an interaction with water quality. These were the number of rooms, the percentage change in population, and the dummy variable representing houses between ten and twenty-four years old. Interaction terms between water quality and the three variables listed were constructed and tested. Only the interaction term between water quality and the percentage change in population was found to be significant and added to the explanatory power of the equation (Al-Ani, chap 5).

Pooled sample results. The results of two different models are presented in table 1. Model 1 uses an actual measure of water quality—pH—and its interaction with the percentage change in population. Model 2, on the other hand, uses perceived water quality and its interaction with population change. All other variables are the same in both models.

The coefficients for most of the independent variables are significantly different from zero. Only two, change in population and the dummy variable denoting houses ten to twenty-four years old, were not statistically significantly different from zero at the 1% level. The lack of significance of the change in population variable probably can be attributed to the presence of the interaction variable with water quality. It is likely that population change effects are picked up by that variable. The age of the house apparently is not significant for houses less than twenty-five years old. Houses more than twenty-five years old are, however, sold at significantly lower prices.

The second observation of importance for this study is that all of the variables reflecting conditions in the natural environment (water quality and flood hazard) are significant. Water quality, whether measured by pH or by the owners' perceptions, has a significant effect on the price of adjacent property. Water quality has an additional impact through its interaction with the percentage change in population. That variable indicates that population growth is significantly related to property value, but only for good quality streams. Flood hazard, too, is significantly related to land price with the expected negative relationship.

The coefficient for the dummy variable income has a negative sign in model one and is statistically significantly different from zero. This is the only instance in either model where a coefficient that is statistically significantly different from zero does not have the expected sign, and the authors are unable to offer any explanation for this phenomenon.

From the analysis of single equation approaches to determining the effects of water quality on housing values, it can be concluded that buyers are aware of the environmental setting of a home and, specifically, that differences in the quality of water in nearby waterways affect the price paid for a residential property. The relationship is shown to be positive, as hypothesized.

The capitalized benefits from higher quality water to a property of average value can be calculated from the results shown in table 1. A one point increase in pH represents a 17.5% increase from the mean value of pH. Using the regression coefficient for pH from table 1, one would expect a 5.95% increase in the mean sales value of residential properties. This is equal to $653.96.

Paired sample results. In addition to measuring the effect of water quality on residential property value directly, as was done with the pooled-sample approach, it is possible to examine the effect water quality has on the magnitude and relative importance of other factors affecting price. For instance, one can hypothesize that the physical characteristics of the house (size, number of rooms, age) take on additional significance to a buyer if the package does not include a high quality stream. Because the data for this study were gathered from sites that had been stratified so as to represent clean streams and polluted streams (one or more components outside the normal range), the hypothesis about interaction between water quality variables and other variables

can be tested by separately estimating the model using data from clean streams and polluted streams.[2]

The results of the paired-sample estimation of the coefficients are presented in table 2. In general, the results support the contention that when water quality is poor other characteristics of the housing package assume greater importance. The environmental variables provide a good example. In clean streams, variation in pH level is statistically very significant and positively related to property value. On the other hand, variation in pH in polluted streams has no significant effect on property value. The flood hazard has the opposite effect. On clean streams, where the average of reported flooding probability was nearly 10%, the prospect of flooding had no statistically significant effect on price. On polluted streams, however, the flooding hazard had a significant negative impact on price, even though the average of reported flooding probabilities was one-third that of properties along clean streams. Apparently, if owners do not have the benefits of a clean stream, they are influenced by negative aspects of the stream, such as flooding.

Other characteristics appear with larger coefficients and greater significance in the estimates for polluted streams than for clean streams. The importance of expenditures on schooling is not only significant in the polluted stream estimate and non-significant for clean streams, it also is dramatically larger than other coefficients in the equation. The large coefficient indicates a great importance in the minds of buyers.

Characteristics of the house itself also take on added importance when the stream is polluted. The coefficient for number of rooms is nearly twice as large in the polluted stream equation as in the clean stream equation. Likewise, the negative impact of age of the house when more than twenty-five years old is significantly greater in polluted areas. This finding takes on greater practical importance when one realizes that 85% of the houses in the polluted stream sample and 60% in the clean stream sample are over twenty-five years old.

[2] Preliminary analysis showed such interaction to be present. These interactions were tested and one, the interaction of water quality and percentage change in population, was selected to be included in the empirical model. That variable is entered in the paired sample approach in place of percentage change in population.

Table 2. Effect of Selected Variables on the Value of Residential Properties along Clean Streams and Polluted Streams

			Mean Values		Coefficient Values	
	Units	Expected Sign	Clean Streams	Polluted Streams	Clean Streams	Polluted Streams

Conclusions

The results of various forms of estimating the model show that water quality significantly affects the value of adjacent residential properties. This is true when either an index of measured water quality characteristics is used or the owners' perceptions of water quality are used. The separate analysis of clean streams and polluted streams revealed that variation in pH has a large and significant effect on property values adjacent to clean streams but no effect on property values adjacent to polluted streams. One explanation of this finding is that increases in pH within the normal range (6.5–8.5) has increased value to property owners because it permits additional recreational activities, such as trout fishing. Increases in pH below the normal range (i.e., 3.7–5.5 in this study), however, permit no additional recreational activities and therefore, have no value.

Other variables found to be statistically significant as determinants of residential property value include the age of the house, lot size, number of rooms, potential employment, income, percentage change in population, per pupil expenditure on schools, and flood hazard.

Of equal importance with the finding of the relationship between stream acidity and property values is the demonstration that analysis of real estate markets can measure at least some of the value of environmental quality. This success can be attributed to two features of this study. First, the study examined a type of environmental quality that has noticeable effect on the buyers of the type of real estate studied. The relationship between water quality and rural nonfarm residences may be much clearer than some other environmental quality-property value relationships. Second, this study used primary data on individual properties and property owners to estimate directly the effect of all variables theoretically linked to property values. This contrasts sharply with some of the previous studies which employed proxy variables and applied them to aggregate units of property, such as a census tract. Direct estimation using the actual units of decision avoids losing the environmental effect through poor specification and certainly makes interpretation of the results more straightforward.

Procedures in Estimating Benefits of Water Quality Change

Nicolaas W. Bouwes, Sr. and Robert Schneider

Wisconsin water resource managers have determined that the water quality in Pike Lake is deteriorating rapidly. The source of this problem resides with the fact that storm sewers empty directly into the lake, delivering large nutrient loads. The impending decline can be prevented by the construction of a storm sewer diversion project. This undertaking can be accomplished for a fixed cost of \$175,000—operation and maintenance costs are considered negligible. The question being asked by the resource manager is whether the benefits to be derived from preserving the present high level of water quality will justify the project cost.

Although the foregoing is hypothetical, the problem is typical of those confronting today's decision makers. What insight can economics bring to bear on issues such as these? The purpose of this paper is to address such an issue by presenting a method for estimating, *ex ante*, the benefits of water quality change by (*a*) presenting the theoretical basis for the empirical analysis, (*b*) establishing the relationship between an objective measurement of water quality utilized by water resource experts and the subjective ratings of lake users, (*c*) presenting a model including recreators' ratings of water quality, and (*d*) synthesizing these components by advancing a method which is applied to the possible decision-making situation described above.

The Theoretical Model

Consistent with the notation used by Mäler, an individual's utility is represented as a function of consumption activities, C, and environmental services, Y:

$$(1) \qquad U = U(C,Y).$$

By assuming weak complementarity, i.e., those situations where the consumption of a private good is a necessary prerequisite of the enjoyment of a given environmental quality, it is possible to derive the benefits (costs) of a quality change in a public good from information on the demand for the private good. Embodied in this notion of weak complementarity is the assumption that there are no option values, or that if the demand for some private good is zero, then so is the marginal willingness to pay for some environmental quality. An example is the case of water-related recreation, the use of which is influenced by the level of water quality. Those who do not use the lake are then assumed to be indifferent to water quality changes.

It can now be shown that this condition will allow estimation of the demand price for the environmental service, e.g., recreation visits (V). When the quality of water is WQ_O, the income-compensated demand curve for recreation visits is D_0 as in figure 1. At the price P_O, the consumer demands V_O trips and has consumer surplus ABC. If the quality of water improves to WQ_1 it is assumed to increase the marginal utility per trip, thus shifting the demand to D_1. The new consumer surplus is the triangle DEC.[1] The question to be answered is how much is the consumer willing to pay for this change?

Calculation of the benefits associated with a change in water quality as represented by willingness to pay can proceed in three steps. (*a*) A change in price from P_0 to P_1: given the demand curve D_0, the individual must be compensated by the corresponding consumer surplus ABC so as not to be made worse off by the price change. (*b*) A change in WQ: given the assumption of weak complementarity, the consumer's utility is unaffected and thus there is no need for compensation. (*c*) A change in price back to P_O: the consumer is willing to pay the new consumer surplus as represented by the area DEC. The net result is the difference between the consumer surplus before and after the water quality change. In other words, the consumer would be willing to pay $BADE$ for a change in water quality. The first step in making such a determination is the estimation of the demand curve for recreation, as measured by trips (V), including a shift variable which is a function of water quality.

Nicolaas W. Bouwes, Sr., is an agricultural economist with the Natural Resources Economics Division, ESCS, U.S. Department of Agriculture, and an assistant professor of agricultural economics at the University of Wisconsin. Robert R. Schneider is an assistant professor of economics at Williams College.

The authors wish to thank Thomas Crocker, Richard Dunford, Russell Gum, William Martin, Louise Love, Daniel Bromley, and referees from this *Journal* for helpful comments on drafts of this paper. Any errors are the responsibility of the authors.

[1] Although the assumptions required to use consumer surplus often appear restrictive, Willig has demonstrated that this need not necessarily be the case. He states that in those instances where the consumer's income elasticity is in the range of ± 1.0, and "if the surplus area under the demand curve between the old and new prices is 5 percent of income (or less), then the compensating variation is within 2 percent of the measured consumer's surplus" (p. 590). Both of these conditions are realistic for the case at hand.

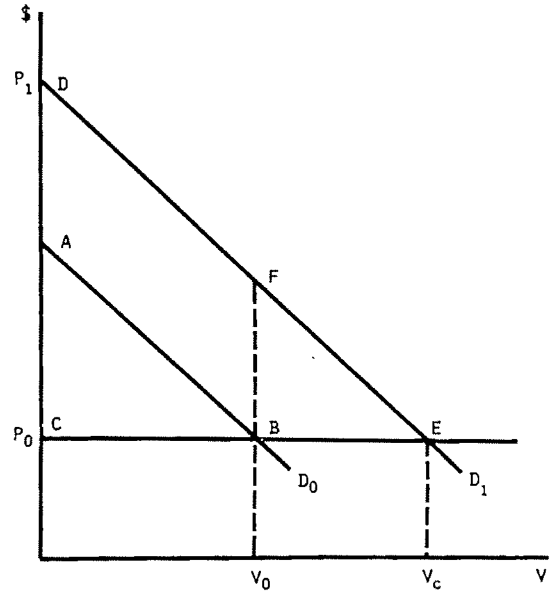

Figure 1. Benefits under complementarity conditions

Hotelling pioneered the travel-cost method for evaluating a recreational resource, and further refinements were provided by Trice and Wood, and Clawson. This approach is well documented, so no elaboration is required. The willingness-to-pay technique, a conceptually similar method credited to Davis, directly estimates consumer surplus through an interview procedure. Both of these methods have been applied to evaluating the total recreational resource, but not in assessing the value of a resource attribute such as water quality.

Some of the previous efforts to estimate the effect of a change in water quality on value of recreation resources have concentrated on the estimation of those benefits that would be attributable to the change in one or more of the physical parameters that contribute to the quality of water, e.g., recreation benefits increase as the dissolved oxygen concentration level rises (Kneese and Bower, Davis). Stevens hypothesized that the quality of the recreation experience (fishing) is a function of angling success per unit of effort, which reflects water quality. Reiling, Gibbs, and Stoevener employed use-intensity factors for swimming, fishing, and water skiing as a proxy for water quality. In the latter case, the indices were subjective estimates, by Forest Service and Environmental Protection Agency employees, of the amount the lakes were used for various activities. The major shortcoming in these research efforts is that the techniques do not contain a systematic relationship between the subjective index used as a proxy for water quality and physically measurable water quality parameters. Perhaps more important, these indices do not reflect recreators' perceptions of water quality.

Objective and Subjective Water Quality Relationship

Ultimately, the existence or nonexistence of benefits emanating from a water quality change are determined by whether an improvement is perceived by the affected water user. Thus, to estimate adequately the benefits associated with water quality changes, it is necessary to predict how lake users perceive water quality. However, water resource experts do not deal with the subjective form of rating as would the typical recreator, but in more objective, measurable terms such as turbidity, dissolved oxygen, and BOD in parts per million, etc. It is therefore necessary to determine if there exists a relationship between the more objective water quality measurements as utilized by the scientists and the subjective rating of water quality as perceived by the lake users.

To ascertain the existence of the relationship, it was necessary to seek out a water quality index that would be readily amenable to testing. The choice was Uttormark's Lake Condition Index (LCI) which was recently developed to classify all Wisconsin lakes larger than 100 acres, providing a system to facilitate resource decision making. One of the main considerations in developing the LCI was to produce an inexpensive lake classification system. Thus, the existing availability of data greatly influenced the choice of parameters used to classify lakes. The lake water quality parameters used to evaluate the lakes are dissolved oxygen in the hypolimnion, secchi disk transparency, fish winterkill, and the extent of macrophyte or algae growths. Penalty points are assigned to these parameters, depending upon the degree to which they exhibit undesirable symptoms of water quality, and then added to produce the relevant LCI. The possible range is zero to twenty-three points, with these amounts representing the finest and poorest levels of water quality, respectively. The resulting classification system was tested by comparisons with other more data intensive studies, the relative ranking of lakes to that of area resource managers, and consistency in ranking when lake information generated from other studies was used with the LCI method—in each instance the LCI compared favorably. For purposes of this study, the LCI bears three advantages over other indices: (*a*) it provides a simple scaler for lake classification, much like what could be expected of the average lake user; (*b*) it has been used to rate all Wisconsin lakes in excess of 100 acres; and (*c*) it is relatively simple.

Data used to test the relationship between subjective and objective water quality rating were obtained by on-site interviews at eight southeastern Wisconsin lakes. In addition to the standard cost, time, and demographic questions, respondents were asked perceptual questions regarding water quality of that particular survey lake. Specifically, recreators were asked to rate the lake water quality on a zero to twenty-three scale, such as that employed by the LCI. The effectiveness of the LCI in

predicting the public's perception of water quality was tested by regressing the average rating ($\bar{R}$) of all recreators for each lake on the corresponding LCI for that lake. The results of this analysis were encouraging, yielding the working equation

$$\ln \bar{R} = 1.948 + \underset{(3.37)}{.0364}\ \text{LCI}, \tag{2}$$

where the values in parentheses are computed t-values, the sample size was 7 and the R^2 .694. Equation (2) will be utilized within the resource evaluation model below to predict the changes in recreators' perceptions of water quality.

The Statistical Model

The general form of the model used to estimate water quality benefits is of the Clawson-Hotelling genre:

$$V_{ij} = \alpha + \sum_{k=1}^{n} \beta_{ik} X_{ijk} + e_{ij}, \tag{3}$$

where V_{ij} is the number of visits by decision-making unit i to lake j, X_{ijk} is the value for the independent variable k for the decision-making unit i at lake j, and e_{ij} is the error term. The primary objective is to produce a statistical demand curve with reliable estimates of the structural parameters—particularly those of the cost variable from which the resource value is derived, and that of the water quality variable which is used to determine the economic significance of a water quality change.

The final estimated demand curve for visits from the regression analysis is

$$\begin{aligned} V_O = 43.22 &- \underset{(.950)}{.317}\, C + \underset{(2.10)}{.008}\, C^2 \\ &- \underset{(2.93)}{5.264}\, \ln \bar{R} - \underset{(3.63)}{.162}\, T \\ &+ \underset{(2.81)}{.0003}\, T^2 - \underset{(2.35)}{.321}\, I, \end{aligned} \tag{4}$$

where V_O is number of visits for the year, C is total variable cost per trip, $\bar{R}$ is recreator's rating of water quality, T is round-trip time and I is recreator's annual income. For this regression, the sample size was 195 and the R^2 .203. The low t-value on cost may reflect the possibility that time is perhaps a more binding constraint than costs when considering relatively short day trips. The income coefficient carries a negative sign and may suggest that recreators tend to substitute other activities for day trips as income increases. The rating variable proved to be consistent in this and other model specifications, demonstrating a level of significance of approximately 1% or better.

It was realized that other site amenities might contribute to users' perceived ratings; thus, the survey lakes were chosen so that they were as similar as possible except for water quality. That is, the lakes were of similar size, ranging between 400 and 600 acres; location choice was made so that physiographic characteristics would be comparable; and lake sites possessed many of the same amenities deemed desirable by lake day-users, such as lifeguards, boat launching facilities, and beaches.

The data used to estimate the above demand curve are in the form of individual observations rather than the commonly employed zone averages. The justification for this approach lies in the fact that without the inclusion of time in the estimated demand equation, the cost coefficient generally will have too great a magnitude and, hence, an under-evaluation of the resource value. However, when zone averages are employed, there exists a high degree of multicollinearity between cost and time; thus, time has been excluded in most evaluation procedures. Estimation procedures based on individual or group observations avoid this problem. However, the resulting R^2 is reduced considerably, even though the t-values on the estimated parameters will be high. For purposes of resource evaluation, concern is more with the level of significance of the individual variable than with the magnitude of the coefficient of determination (Brown and Nawas, p. 249; Gum and Martin, p. 560). In this study it is the cost variable that is used in evaluating the resource and the shifter variable, rating, that is of interest.

Economic Benefits under Current and Alternative Water Quality Conditions

To estimate the resource value under current water quality conditions, a two-step evaluation process, as used by Gum and Martin, was employed. This approach requires applying a derived statistical demand curve to each individual observation, using the recreator's observed cost and visit data to reflect behavior at zero additional site cost. This is then used to estimate an aggregated demand curve for the total recreation experience from which the resource value is estimated.

For example, by introducing a change in costs term, c, into equation (4) the estimate of visits becomes:

$$\begin{aligned} V_c = 43.22 &- .317\,(C + c) + .008\,(C + c)^2 \\ &- 5.264 \ln R - .162\, T + .0003\, T^2 - .321\, I. \end{aligned} \tag{5}$$

By subtracting equation (5) from equation (4), the individual decision-making unit's demand curve can now be represented by equation (6),

$$V_c = V_O - .317\, c + .016\, Cc + .008\, c^2. \tag{6}$$

The evaluation of the resource is accomplished by using equation (6) to estimate an aggregated demand curve. This is done by applying it to the cost and visitation data of each of the representative decision-making units. Costs (c) are increased until the number of trips equals zero or starts to increase.

As it is illogical for the number of trips to increase as costs increase, thus, trips are set equal to zero in the latter instance (Gum and Martin). This result is then expanded by the representation rate of that observation. The representation rate or weighting factor is determined by the response rate: the total number of recreators divided by the product of the average number of trips and party size of the sample and the number of observations in the sample. These expanded individual demand curves then are summed horizontally to construct the aggregate demand curve from which the resource value is estimated, e.g., the area under this curve reflects the consumer surplus associated with the resource.[2]

To estimate the annual benefits associated with a change in water quality, i.e., *BADE* in figure 1, it is necessary to determine how a change in water quality will modify recreator's behavior. The change in water quality is reflected in the model so that the initial number of trips is more or less than under previous water quality conditions, i.e., $V^*_0 \gtrless V_0$, where the difference is 5.264 ($\Delta ln\ \bar{R}$) having been estimated by equation (2). Substituting V^*_0 for V_0 in equation (6) gives the desired result.

The resulting change in resource value under various levels of water quality can be determined by calculating the difference between the initial resource value and that occurring after the water quality change.

A Water Resource Management Scenario: The Problem and Solution

To perform an *ex ante* analysis of the hypothetical problem we presented our resource manager above it is necessary to (*a*) establish the resource value with current water quality conditions; (*b*) determine the impact on users' perceptions of the potential decline in water quality; and (*c*) estimate the decline in resource value that would be avoided by the project.

To demonstrate the effects on resource evaluation of a change in water quality, it is necessary to determine the number of recreators that utilize the resource with current water quality conditions. The number of individual recreators to visit Pike Lake for the year prior to the survey, 1975, was 168,629. This will be assumed to be an approximation of the number for the current year. This count is considered accurate, as access to the lake is limited to supervised entrances where head counts are taken. It is determined from the survey data that the average number of trips per party during the previous season was 13.9 trips and average party size was 6.15 persons, yielding 1,972 different parties, or approximately 27,400 total group visits at the lake over the course of the year.

With this information and the pertinent individual group information required by equation (6), it is possible to estimate the resource value under current water quality conditions by employing the procedure described above. The results of the computations are presented in table 1, which reflects resource value as $429,038.

The next step in this method requires that we estimate how the expected change in water quality, i.e., ΔLCI = 7, will affect the recreator's perceived rating. This movement will be predicted by the use of equation (2). Repeating the resource evaluation procedure as before, but employing the modified form of (6), i.e., with V^*_0 substituted for V_0, it is possible to estimate what the potential loss in benefits would be with deteriorated water quality conditions. These results are also presented in table 1 and the resource value is now $390,074. Thus, the estimated annual benefits, i.e., area *BADE* in figure 1, would be $429,038 − $390,074, or $38,964. This amount, as in most of these recreational analyses, may represent somewhat of an overestimation as substitutes and alternative activities are not accounted for. One possible way to mitigate this would be to determine the lower limit of benefits, thereby constructing a range of possible benefits. Reconsider the case in figure 1, but rather than allowing the recreator to expand the number of trips taken to V_1 we restrain him to V_0, his original number of trips, and calculate the corresponding consumer surplus, *BADF*, thereby not concerning ourselves with substituting one activity with another. Now we have established the range between *BADE* and *BADF*. If the range is narrow, the substitution effect can be considered minor.

The present value of the benefit stream, assuming a modest twenty-year period and 10% discount

Table 1. Resource Value with Alternative Water Quality Conditions

	Present Conditions (LCI = 3)		Expected Conditions (LCI = 10)	
Added Cost per Trip ($)	Total Group Trips	Total Revenue ($)	Total Group Trips	Total Revenue ($)
0	26,996	0	24,383	0
3	25,632	76,896	23,195	69,584
6	24,577	147,461	22,282	133,692
9	23,820	214,379	21,617	194,553
12	21,521	258,247	19,535	234,420
15	21,264	318,957	19,305	289,582
18	13,966	251,392	13,111	236,002
21	0	0	0	0
Consumer Surplus Value		$429,038		$390,074

[2] It is necessary to assume here that the demand functions are aggregates of homogeneous groups of recreators, i.e., similar tastes and preferences, react the same to price changes, etc. (Mäler p. 184). This assumption is mitigated by the use of individual observations (Gum and Martin p. 564).

rate, is $331,740. Given the expected costs and benefits associated with this project, it would appear to be a wise decision for the water resource manager to recommend the project.

The Demand for Agricultural Research: A Colombian Illustration

Grant M. Scobie

The generation of new technology has come to be viewed as an economic activity to which scarce resources can be devoted, and for which measurable output can be defined (Schultz 1970). Society, either individually or collectively, makes conscious investment decisions to allocate resources to research activities with the expectation that the present value of some future income streams resulting from the technological advances will exceed the cost of their generation. This leads naturally to the concept of efficiency of resource use and the evaluation of whether the research expenditures constituted a socially profitable use of resources. Griliches, Peterson, Ayer and Schuh, and Duncan provide well-documented examples of the analysis of the returns to investment in agricultural research. Evenson (1975, 1976, 1977) recently has extended these studies to encompass the returns to the international diffusion of innovations.

In addition to the efficiency criterion, economists increasingly have focused attention on the distributional impact of technological change. Typically a comparative static Marshallian framework is used to estimate the gross social benefits accruing to producers and consumers (e.g., Akino and Hayami). This is accomplished by comparing the producer and consumer surplus with and without the technological change, which is captured by a displacement of the product supply curve. The procedures for measurement of the relevant areas, questioned by Scobie, have been clarified recently (Jarrett and Lindner, Lindner and Jarrett, Sarhangi et al.).

Other researchers have considered the impact of innovation on functional income shares (Ayer and Schuh, Wallace and Hoover). More recently, Scobie and Posada (1977, 1978) examined the impact of research-induced benefits and costs on the distribution of household income at the national level. The increased attention to distributional impacts reflects an important step in the development of a more complete analysis of technological change, one in which the economic and political forces leading to the generation of new technology are themselves related to and explained by matters of efficiency and equity. In short, a conceptual framework is sought in which technological change becomes a truly "endogenous" element.

Hayami and Ruttan have offered relative factor prices as an engine governing the force and direction of technological change, and Ruttan (1973, p. 46) extends the "induced innovation perspective to include the process of institutional innovation" (see also Ruttan 1978). The demand for publicly financed research is explained by Guttman in terms of political interest groups, i.e., the beneficiaries of the research. De Janvry (1977) has developed an explicit model of generation of new technology in which he identifies the determinants of the supply of and demand for technological change, again sharpening the focus on the sociopolitical interdependencies. While being a relatively complete statement of the dialectical process which generates technological and institutional change, enormous empirical challenges remain. De Janvry's attempt to construct a social payoff matrix for Chile or the work of Evenson (1977) in constructing measures of research output serve to caution the ambitious. However, economists must venture beyond the mechanical calculation of internal rates of return to historical research programs and continue to enrich their models with social and political dimensions.

This paper examines the process of technological change in the Colombian rice sector. An attempt is made to articulate some of the political and economic forces that governed the demand for new technology and which influenced (and were influenced by) the distribution of costs and benefits. The Colombian experience is instructive, as it permits an analysis of an apparent paradox: namely, the simultaneous investment in research and discrimination against the agricultural sector.

Background

Since 1957, an extensive and successful program of rice research has been conducted in Colombia. The high-yielding varieties bred and adapted for irrigated culture were instrumental in the fivefold rise in output between 1957 and 1974. The real domestic price of rice fell as a consequence, and consumers

Paper No. 5909 of the Journal series of the North Carolina Agricultural Research Service, Raleigh.

The support and interest of John L. Nickel, Director-General of CIAT, and Peter R. Jennings of the Rockefeller Foundation are gratefully acknowledged. Improvements on earlier drafts followed from the insightful comments of G. Edward Schuh, T. W. Schultz, Paul R. Johnson, Alberto Valdés, Per Pinstrup-Andersen, and Reed Hertford. The responsibility for residual scientific solecisms must abide with the author.

(rather than producers) were the principal beneficiaries of the research. The rise in output was sufficiently marked that the investment in the research generated an internal rate of return probably exceeding 80% (Scobie and Posada 1978).

The demand for research (and implicitly technological change) was expressed by three groups, each of which contributed to the funding of the research. Specifically, these "demanders" were (*a*) producers of rice (who paid a research levy on each unit of production, (*b*) consumers (whose tax revenues were channeled through the national fisc to the research program), and (*c*) international donors (initially the Rockefeller Foundation and, later, indirect support of the Centro Internacional de Agricultura Tropical). To explain the existence and the relative magnitudes of the contributions by these groups of demanders of technological change is the purpose of the next section.

The Demand for Research and Technological Change

A basic premise is that the distributional outcome of the new rice technology followed as a result of economic policies adopted at the national level, not directly related to the rice sector. Specifically, Colombia's industrial protection policy, through the use of tariffs against imported manufactured goods, has a three-pronged bias against the agricultural sector, including, of course, the rice production sector. In the first place, the price of manufactured inputs used by agriculture are raised. Second, returns to investment in manufacturing are augmented by the tariff barriers, encouraging more domestic resources to flow into the industrial sector. Availability of resources to agriculture is thereby reduced or, alternatively, their prices inflated, making the generally unprotected agricultural sector less competitive. Finally, and most important in the present context, the price of foreign exchange could be maintained artificially low (Scobie and Johnson), making the export of products less attractive. This bias against the agricultural sector has been documented widely (Schuh 1968, and Valdés). Little, Scitovsky, and Scott note (pp. 177–78), "Protection of manufacturing produces a bias against agriculture, in that it reduces resources available for agricultural investment, as well as reducing the incentive to produce and sell, especially as far as exports are concerned. . . . Our view is that the bias has been excessive; that in several of the countries the effect on agricultural production has been damaging, and that agricultural exports earn less than they should have done in most countries."

The Colombian case conforms to this general pattern. Certainly, almost no rice was exported during the period of rapid output growth (1968–74) that accompanied the introduction of modern varieties. This lack of exports was due, at least in part, to the relatively unattractive exchange rates facing potential rice exporters as a result of the industrial protection policy and the concomitant overvaluation of the peso. Nelson, Schultz, and Slighton review the political determinants of Colombian overvaluation.

The set of general economic policies, including tariff protection and the related price of foreign exchange, together with the particular mix of commodity policies which prevail at any point in time, are a product of continually evolving economic and political forces. These forces often are opposed, reflecting the interests of different groups. Producer organizations typically are concerned with presenting cases for remunerative farm prices and promoting exports. On the other hand, manufacturing groups press for tariff protection and overvalued exchange rates. Interestingly, such policies additionally have fostered cheap domestic food supplies in the presence of rapid agricultural innovation, thereby lowering the price of wage goods and indirectly subsidizing the price of labor to the manufacturing sector. As Barraclough notes, rapid urbanization, together with growth in the industrial, banking, and financial sectors, generally has increased the political weight of manufacturing relative to agricultural interests; Torres provides some specific estimates for Colombia. While the rice growers' organization (FEDEARROZ) has vigorously represented the interests of rice growers since its inception (Leurquin, pp. 241–44) and frequently won concessions favoring rice producers (e.g., a token export subsidy introduced in 1976), its influence has tended to be supplanted by national economic strategies promoted by an increasingly powerful entrepreneurial class whose political power base lies less and less with agricultural interests (Dix). The net result of these forces has been that the benefits of the new rice varieties were captured by consumers as a result of the cheap food policies which are consistent with and complementary to protection of the industrial sector.

As a result of the unfavorable price of foreign exchange, the expanded production was sold almost exclusively on the domestic market. As Harberger (1970, pp. 107–08) notes, "the basic principle here, of course, is that each new restriction on imports lowers the equilibrium exchange rate relative to the internal price level, thus reducing the market incentives facing the export trades." With a moderately inelastic domestic demand curve, internal prices fell, resulting in the capture of the net benefits by rice consumers. In discussing the overvaluation of the U.S. dollar, Schuh (1976, p. 8) argues that one consequence is a failure "to capitalize on its technical progress as a source of exchange earnings and instead would channel the benefits of technical change to the domestic consumer in the form of lower agricultural prices."

On the basis of the foregoing argument, one would expect that Colombian rice exports would have been much greater had a different exchange rate policy been pursued. However, to quantify the impact on exports, some estimate is needed of the

"true" value of foreign exchange. The social opportunity cost of foreign exchange (Harberger 1972, p. 125) was chosen as such a measure. It is given by $E_s = [\epsilon E - \eta\ (M/X)\ E(1 + t)]/[\epsilon - \eta\ (M/X)]$, where E is the nominal price of foreign exchange facing potential exporters, t the uniform ad valorem duty on imports, (M/X) the ratio of imports to exports, and ϵ and η are the elasticities of the private sectors' supply of exports and demand for imports. The values of ϵ and η were taken as 2.5 and −2.3, respectively (Johnson, p. 169). The "average" tariff level for 1975 was reported as 31% (Departmento Nacional de Planeación), but is generally believed to have been reduced substantially since 1970. The dynamics of this change lie beyond the present inquiry; only the existence of an import tariff is germane.

Using the estimates of E_s and the average FOB price received by six Latin America rice exporters, an implied domestic peso price was calculated. This price (adjusted for milling and transport) was used to estimate domestic supply and demand, the difference being the exports that would have prevailed at the more favorable exchange rate, assuming that Colombian exports would not depress external prices. The results are summarized in table 1.

The important conclusion is that at a more attractive exchange rate, Colombia would have been able to compete favorably in external markets, and exports would have been much greater than those actually recorded. In fact, by 1975 the domestic price of rice had fallen to a level which made exporting attractive (even at the nominal price of the peso), and Colombia will now possibly become a more consistent rice exporter. This will mean, however, that future direct benefits of new rice technology will be captured by producers and foreign consumers, rather than by Colombian consumers as has been the case.

If the demand for agricultural research by different groups is related to the expected benefits they receive, then the anticipation of an export trade should be reflected in an increasing share of the research costs being borne by the producers. The Colombian research program was undertaken specifically to lower domestic rice prices. Consistent with the potential payoffs, the research was wholly financed by consumers through the tax-supported national rice research program. Improved technical efficiency of rice production resulted, and producers began to visualize the prospects of an export trade. Through FEDEARROZ they proposed the research levy and became responsible for its administration. By 1975, when significant quantities were exported, rice producers were contributing almost twice as much as consumers to the funding of rice research. Consumer contributions had fallen absolutely and comprised only about 20% of the research funding. From 1957 to 1964, annual consumer contributions averaged 78% of the national funding for rice research; from 1965 to 1974, the shares of consumers and growers were 40% and 60%, respectively. The changing importance of producer and consumer financing of rice research is seen as being consistent with the potential distribution of benefits of technological change.

This conclusion in no way precludes the possibility that producers might be motivated to invest in research even in the absence of export trade. The U.S. experience suggests that producer-supported research is not inconsistent with an inelastic final demand. Given the atomistic and hetereogenic nature of agriculture, astute profit-seeking producers can capture rents to early innovation. "Prices drop, . . . this eliminates the quasi-rents of the early adopters, and they must again look for new technological opportunities. They do this by pressing the agribusiness firms and agricultural experiment stations to innovate further" (de Janvry 1978, p. 313). Producer contributions to rice research motivated by the quest for innovator rents may well explain the initial funding and conceivably even account for the increasing relative importance of producer contributions. However, that increase is also consistent with the expectation that Colombia would be an exporter.

Throughout the period since 1957, international donors have contributed to the funding. In the

main, these funds come from developed countries, which tend to be temperate zone importers of tropical products (the United States, in the case of rice, being an exception). The potential benefits to their consumers through cheaper imports of tropical products may not be an irrelevant consideration in voting public funds for agricultural research in the tropics. As Josling (p. 169) notes, "crops such as cassava (whose research is heavily supported by Canada) are finding outlets as animal feed in the developed country markets." In addition, investment in enhanced agricultural productivity broadens the market for the developed world's manufactured exports and helps create a more favorable economic and political environment for the operation of its multinational enterprises.

Viewed in this light, the Consultative Group on International Agricultural Research (CGIAR), which channels funds to the network of tropical research centers, represents an institutional mechanism of the developed countries for investing in tropical research. The returns to that investment come, in part, from cheaper imports, increased export demand, and an enhanced environment for multinational business. One should not infer that humanitarian motives are irrelevant: merely that the developed nations' investment in less-developed countries' (LDC) agricultures does have an economic rationale. Crawford (p. 281), commenting on the formation of the CGIAR, notes that "impetus for this action was the desire to encourage a greater research effort aimed at assisting developing nations to increase the quantity and improve the quality of their agricultural output and thus to raise standards of living." However, he continues, "all parties realized that increased agricultural productivity was essential to economic and social development in the great majority of these countries."

This mechanism for international investment in tropical research is becoming increasingly important relative both to the private- (e.g., United Fruit Co.) and public- (e.g., the U.K. Tropical Products Institute) sponsored research, which characterized the colonial and interwar periods, and to the bilateral aid programs of the fifties and sixties. The evolving institutional mechanisms for investment in developing agricultures can be viewed, at least in part, as serving the same ends as these precursors while presumably being more internationally palatable.

Concluding Remarks

A mixture of public, private, and foreign funds were combined to support a varietal research program for the Colombian rice industry. The net benefits of the ensuing technological change appear to have been captured disproportionately by low income consuming households (Scobie and Posada 1978, table 4). In the presence of a protective tariff structure, an industrially dominated body politic has the incentive to invest tax revenues in research, as additional output would lower the domestic price of a principal wage good. Rice is the major source of calories and the second most important source of protein in the Colombian diet, and between 1970 and 1974 its retail price fell by 46%, 65%, and 90% relative to beans, cassava, and potatoes.

Grower contributions to the research program have become relatively more important over time. As the new technology continued to lower domestic production costs, the possibility of exporting became a reality, and, in fact, exports rose to 175,000 tons in 1975. When facing a more elastic export demand curve, producers are likely to capture a greater share of the benefits of technological change.

In summary, the share of the costs of the research program borne by consumers and producers is consistent with the expected distribution of net benefits. Initially, the investment was met wholly by tax revenues. The explanation offered for this phenomenon is consistent with the cheap-food policies pursued by many developing countries. Discriminatory exchange rate policies and the accompanying stagnation of the agricultural sector generally constrain the demand for research (Schultz 1977). However, by investing in research and diffusion of output expanding technology, a dynamic agricultural sector can emerge even in the presence of an exchange rate distorted by a protectionist industrial policy. The increased production is diverted to the domestic market, lowering internal food prices. Use of tax revenues to finance agricultural research for basic food commodities is therefore seen as having a consistent economic rationale, even in the presence of a distorted exchange rate.

From the viewpoint of economic efficiency, one may want to dismantle the protective structure and operate in a "first-best" world. The present discussion takes the distortion as given and suggests that, on both efficiency and equity grounds, public investment in agricultural research may be justified. An alternative view is that the export sector justifies some compensation (which could be in the form of publicly subsidized research) for the tariffs awarded to the import-competing sector. Harris discusses this issue. This is quite apart from the argument that the product of agricultural research might be a collective good (Samuelson) that would be underproduced were its provision solely in the domain of private markets.

By considering some aspects of the political economy of investment in research, we resolve the apparent paradox of simultaneous discrimination against agriculture (through an overvalued exchange rate) and public funding of investment in research into basic food crops. Investment in the generation of new technology must continue to be an important strategy for enhancing agricultural output in the developing world. By viewing that investment in the context of competing economic

and, hence, political interests, richer insights are gained into the scope and limitations of publicly funded research as an instrument for enhancing economic growth.

Kentucky's ANSER: The Agricultural Network Serving Extension and Research

David L. Debertin, Lynn W. Robbins, and Larry D. Jones

Kentucky's Agricultural Network Serving Extension and Research is a computerized information network that will deliver decision aids and can be used for data retrieval. Unlike some computer systems, ANSER is geared to serve the needs of many interests. The system is designed to meet the needs of a diversified clientele including farmers, county agents, rural development specialists, agribusinessmen, local political figures, and other decision makers. These clientele share a common need for up-to-date assistance in making knowledgeable decisions. The scope of ANSER is broad-based and comprehensive. By studying systems developed in other states, extensive planning by personnel in the college of agriculture has been done to ensure that the system has appeal to the diverse clientele of agricultural economics (Diesslin; Harsh; Kendrick, Thompson, Murray; Payne).

This paper (*a*) describes the design philosophy upon which the system's development was based, (*b*) outlines the software development effort, (*c*) describes the hardware selections, and (*d*) explains how clients will use the system.

Design Philosophy

Extension-oriented, computer-assisted, decision-making models have been developed following two distinct approaches. Advocates of the first approach argue that initial clientele acceptance will not occur unless programs are simple to use and require only a small amount of user-supplied data. Examples include many of the programs available on the CMN network (Chapman, Infanger, Robbins, Debertin), Telplan, and AGNET, such as those that calculate loan cost, break-even prices for livestock, and buy versus lease costs for farm machinery.

Advocates of the second approach argue that decision making is becoming increasingly complicated, and complicated decisions require assistance from complex, computerized decision models. For example, a computerized decision aid capable of modeling an individual farm in detail may require user input of 300–500 data items. This design may place substantially more demand on both the system's hardware and software components.

The Kentucky approach was to develop a system suited for both limited user data input systems and large-scale decision models. As a result ANSER will handle both interactive and batch processing on a decision maker-oriented rather than a researcher-oriented basis. This approach is necessary for, as Candler argues, extension software requirements are much more demanding than those of research. It is likely that such heavy requirements explain the slow adoption of computer-assisted decision making in extension.

Kentucky's ANSER network is designed to make full use of existing software that has been developed in other states as well as Kentucky. For example, many of the smaller scale programs on the CMN network will be adapted on ANSER. Programs would include calculating true interest rates, buying machinery versus lease, break-even prices, and investment capitalization programs such as calculating present value. Other large-scale programs are being adapted from Michigan, Ohio, Indiana, and South Carolina.

Work is taking place in Kentucky in designing input and output for existing research models to make them useful to extension clientele. The use of existing software in the ANSER Network has necessitated a choice of hardware that allows a high degree of flexibility. Four examples illustrate the integration of hardware choices and software development occurring at Kentucky.

Examples of Software Components: The Beef Simulator

The agricultural economics department, in conjunction with the departments of agricultural engineering, agronomy, and animal sciences have developed a large-scale simulation model of the beef-feed enterprises of a livestock farm in the Southeast (Smith et al.). The model simulates the growth of both plants and beef animals, energy requirements, cash flow, and net worth in a dynamic setting. Detailed descriptions of a farmer's land, labor, machinery, feed, money, resources, sources of credit, and other information are needed for model operation. Alternative management strategies for beef cattle production also are specified by the farmer. Output consists of forty pages of computer printout and

---

David L. Debertin is a professor, Lynn W. Robbins is an associate professor, and Larry D. Jones is extension professor of agricultural economics, University of Kentucky.

provides the farmer with detailed information with regard to the effects of alternative management strategies on the profitability of the beef enterprise.

KASH PROFITS

The KASH PROFITS program uses a linear programming model consisting of 116 rows and 185 columns (Debertin, Moore, Bradford, Jones; and Debertin, Moore, Jones). The output is designed to aid commercial corn-soybean farmers in planning crop patterns, making machinery acquisitions, and in the timing of planting and harvest operations. Farmer input is achieved by completion of an input form. Detailed information with regard to the availability of land, labor, and machinery, expected crop yields, and prices and other information is required.

The DISK System

The Development Information System for Kentucky (DISK) is a joint project sponsored by the department of agricultural economics and the department of rural sociology (Maurer and Pigg). The initial component of DISK is the development of a computerized retrieval system for socioeconomic data. Data for each Kentucky county on population, incomes, employment, and other social indicators are included in a format suitable for use by local decision makers.

While initial emphasis has been placed on building a data retrieval system, an analysis component also is being developed. Seven graduate students currently are working on research projects that will generate models eventually to become part of the analysis component. These models are designed to simulate and predict county level agricultural production commodity by commodity, taxation and revenue, employment, population, and transportation. Each is being designed for use in a problem-solving setting. Users will be public or private decision makers who have access to a computer terminal. Most will make use of data stored within the data retrieval component of DISK. Potential clients of the DISK system include county agents, public officials such as mayors and county judges, development administrators and planners, and other local citizens.

Buying (Selling) Beef for Home Freezers

A FORTRAN program is being developed which will assist consumers in deciding whether or not to buy bulk beef for home freezers. Input includes type of purchase, grade, yield grade, cost, and freezer space available. Output includes edible pounds of meat by cut, price per edible pound by retail cut, freezer space utilized, and freezer cost. One component of the model assists producers in evaluating how their asking price for a live animal translates into a price per edible pound of selected cuts of meat. This program is designed to run interactively on a computer terminal located at the local level.

Hardware Requirements

Each project places special requirements on the hardware configuration for ANSER. The beef simulation model uses a large amount of core, making access to a major CPU essential. The quality of input and output required by the model makes a conventional remote terminal impractical for user access. Because of the size of the output, high speed line printing is necessary.

The KASH PROFITS program also uses a substantial amount of core. In addition, access to a linear programming solver such as MPS 360 at the host computer is required. The KASH PROFITS program differs from the beef simulation model in that a smaller quantity of input is required. The output of the KASH PROFITS program consists of 654 lines. Hence, the KASH PROFITS program could be accessed at a remote terminal operating at 180 characters per second. However, if used in a workshop with forty to fifty participating farmers, a high speed line printer is required.

The information retrieval component of DISK is designed for access through a conventional remote terminal operating at low speeds (thirty characters per second). Most information retrievals result in tables consisting of 100 lines or less. A highly portable terminal is ideal for access to DISK. A portable terminal also makes easy access possible for the variety of potential clients of the DISK system.

The Beef Buying program for producers and consumers will run from a thirty characters per second terminal and requires hardware capable of handling interactive programs. The output will consist of less than 100 lines.

Systems Design

The selection of hardware components of ANSER is consistent with the requirements of software development efforts. The system consists of three major components: a host computer consisting of the current IBM 370-165 CPU at the University of Kentucky, minicomputers located at Lexington and at two regional centers, and remote terminals at county agents' offices. Associated with each minicomputer will be card-reading and line-printing capability at 600 lines per minute. Leased lines will connect the host IBM 370-165 with the minicomputers and the remote terminals. This gives the local county agent the full power of the IBM 370-165 twenty-four hours a day. Figure 1 illustrates the concept for the host computer located at Lexington, Kentucky, and one of the regional centers approximately 225 miles away from Lexington.

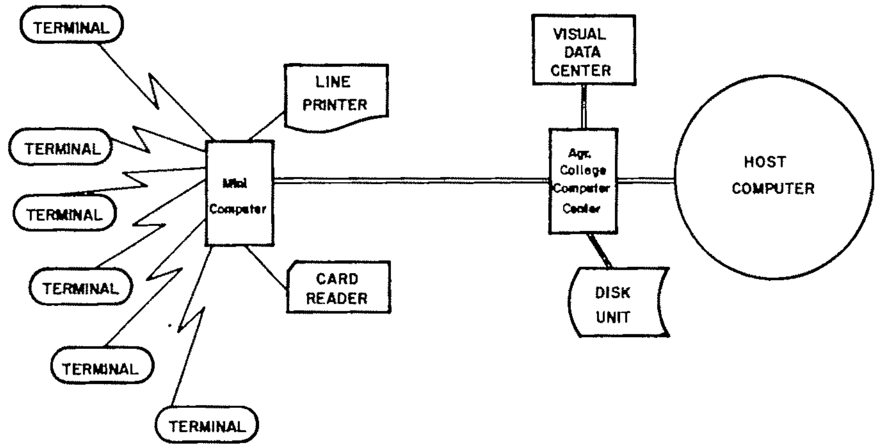

Figure 1. The host computer and the terminal system

The host computer will serve as the batch-processing unit for large models being used in the ANSER system. Linked to the host computer at Lexington will be a minicomputer in the agricultural college. This minicomputer will enable the host computer to be used interactively, and will preprocess input prior to processing by the host CPU, as well as do the complete processing of smaller programs. Card-reading and line-printing capabilities were selected to meet the needs of researchers in the agricultural college as well as extension personnel who wish to work with computerized decision models (such as KASH PROFITS or the beef cattle simulator) on campus. Sufficient disk storage space for the DISK project and other information systems that feature data retrieval will be located at Lexington and linked to the minicomputer.

Regional centers will be linked to the Lexington campus via a leased line. Minicomputers will serve as multiplexors so that multiple signals can simultaneously pass through the leased line. Card-reading and line-printing capabilities equal to those available on the Lexington campus will be available at each regional center. This will enable agricultural economists to hold workshops using batch-oriented, computerized, decision models with forty to fifty farmers in the western part of the state. Remote computer terminals to be located in county agents' offices will be wired into the minicomputer closest to their office.

County agents will be free to choose the type of computer terminal best suited to the software being accessed in the system. County agents located in the large, commercial, grain-producing areas probably will choose a nonportable terminal capable of printing 132 characters per line and operating at 180 characters per second. These are the requirements if KASH PROFITS software is to be accessed at the county agents' offices. Other counties may select a portable terminal capable of printing only 80 characters per line and operating at 30 characters per second. These parameters are compatible with the DISK software. Some counties may elect to purchase both a stationary and a portable terminal.

Computer programmers are employed for developing much of the input and output as seen by extension clientele. This work does not proceed without a complementary coordinated effort by state extension specialists within agricultural economics and other departments of the agricultural college. The state extension specialist will judge the suitability of a specific input and output design for his particular clientele. Moreover, the specialist who uses the software as part of an extension program bears responsibility for the accuracy of the software.

Table 1 provides an overview of the estimated costs of the completed computer network. Counties will each pay the one time cost of the computer terminal and be responsible for the cost of leased lines as well as maintenance. The college of agriculture will be responsible for the lease and maintenance of minicomputers and other equipment at the regional centers. The cost of computer time on the University of Kentucky computers will be shared by the county and the state.

Training of Clientele Groups

A major effort in the ANSER program is being devoted to the design of training facilities for county agents, community leaders, and other interested clientele groups. This effort has culminated in the building of the visual data center.

The visual data center is planned to serve three needs: (*a*) It will serve as a workshop center for efficient training of forty to fifty persons on the use of computer software available through ANSER. (*b*) It will be the center for working with farmers and others who are using models such as the beef cattle simulator and KASH PROFITS. And (*c*), it will serve as a place to bring clientele during the early testing of new software. A visual data center

Table 1. Estimated Hardware Costs for University of Kentucky ANSER Network

One Time Charges	Dollars per County	Total Dollars for 120 Counties, 3 Regional Centers
County computer[a] terminal-(cathode ray tube)	3,500	420,000
County printer (180) characters per second)[a]	3,000	360,000
total	6,500	780,000
Monthly Charges		
Leased lines for county terminals[a]	50/mo.	6,000/mo.
Maintenance of county terminals[a]	100/mo.	12,000/mo.
Lease of minicomputers,[b] line printers, and card readers at regional centers	1,700/mo.	5,100/mo.
Maintenance of regional center[b]	350/mo.	1,050/mo.
total	2,200/mo.	24,150/mo.

[a] To be paid by the County.
[b] To be paid by the University of Kentucky, College of Agriculture.

is currently being built at the agricultural college on the Lexington campus. Plans call for a visual data center to be located at the other regional centers.

Figure 2 illustrates the visual data center. The major equipment in the visual data center is a large screen television set suitable for viewing by forty to fifty persons. This television is wired to a computer terminal that outputs to a video signal. The terminal is linked to the minicomputer through to the host computer. Lines also connect portable terminals located on countertop space near each seat. The arrangement enables the instructor to display on the large screen television procedures to be used in accessing the computer. County agents, students, farmers, or others in the room will be able immediately to follow the same procedure using the terminal located directly in front of them. Incorrect responses by those in the room will become apparent immediately, because the output generated on the terminal can be compared easily with that on the large-screen television. This will provide for efficient instruction of large groups on proper terminal-operating procedures.

The room also is designed as an instructional area enabling the use of conventional video tape technology. Video tapes may include instructional aids designed to teach FORTRAN-programming fundamentals and keypunch operation, as well as video tapes in subject matter areas not directly related to computers.

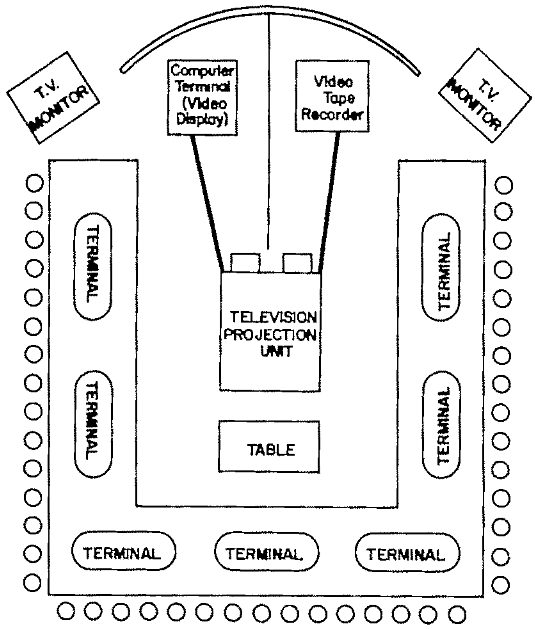

Figure 2. The visual data center

Implications

Does the ANSER system and the experience in designing it provide a basis for generalization? What design parameters, use intensions, projected utilization frequencies, manpower and resource requirements, and hardware costs are transferable? All would be transferable to a state that has the same environment that existed in Kentucky. While this is unlikely, the ANSER project has much to offer with respect to its design and utilization experiences.

That there is less to be gained in general from specific resource requirements and costs or costs estimated can be illustrated from what was planned initially with respect to the county delivery design. The original design consisted of nine minicomputers interfacing with the IBM 370. This was evaluated as the best method because of university policy with respect to centralized computing.

As the projected magnitude of computing grew, that policy was changed to allow the agricultural college to have its own computing capacity (still interfaced with the 370, however). This policy change allowed for a further cost saving. The new agriculture college computer allowed the network to be designed as explained. Three minicomputers were retained to allow concurrent usage by all of the Commonwealth's counties. This design also allowed the monthly leased line charge to be kept within reason.

The development of a computerized information network represents a multifaceted approach involving (*a*) identification of problems where computer-assisted decision aids would be useful, (*b*) design of

computer software useful in solving the problem as defined, and (*c*) the selection of hardware consistent with requirements imposed by the software. Recent advancements in computer technology are now making it possible to use with clientele extension software which a few years ago would be considered too complex or too costly. These advancements include: (*a*) the availability of terminal printers that operate at speeds much greater than thirty characters per second, making it possible to design interactive software for terminal use which generates much larger quantities of information for clientele than before; (*b*) the rapid decrease in the cost of on-line disk storage space, making possible the storage of large data banks with information available for instantaneous retrieval by clientele; and (*c*) cost reductions in processing capabilities—these cost reductions have made possible the decentralization of systems using minicomputers at remote locations with computers linked via leased telephone lines.

While progress has been made in the last decade, the development of comprehensive computer software for extension application continues to be a slow process. This process involves an integrated effort between both extension and research faculty. A computer network is not an end in itself but only a vehicle for the delivery of information to extension clientele. A well-designed computerized system will sell itself only if programs supply information of fundamental importance to clientele groups.

Corn Acreage Response-Function Estimation with Pooled Time-Series and Cross-Sectional Data

James K. Whittaker and Robert L. Bancroft

A great deal of research has been done on the estimation of the parameters of acreage response models for various crops. Econometric acreage response studies have traditionally used more than twenty time-series observations to estimate the parameters of the model. A time period this long can include rapid advances in technology and changes in the acreage response coefficients.

The nature of technology makes it difficult to quantify. Crop technology is comprised of a large number of variables including advances in herbicides and pesticides, new types of machinery, improved varieties, and better farm management practices. Past acreage response studies have largely relied on linear time trends to account for changes in technology. If technology does not advance linearly, then models accounting for technology with a linear trend are misspecified and likely will contain biased coefficients.

This paper demonstrates how pooled time-series and cross-sectional data can be used to estimate the parameters of a Midwest corn acreage response function. The use of pooled data reduces the number of time-series observations that are necessary for parameter estimation. This reduction in the number of time-series observations lessens the effect of technology, and likely will eliminate the need to attempt to quantify it, as well as greatly reduce the possibility that the acreage response coefficients will change during the period under study.

Model Specification

The empirical Midwest corn acreage response model consists of time-series observations from Indiana, Illinois, Ohio, and Iowa. The model is specified in equation (1).

$$(1)\quad CA_t = f(PC_{t-1}, PS_{t-1}, GDP_t, GB_t, BIL, BOH, BIA),$$

where CA_t is state acres of corn planted in thousands of acres in year t; PC_{t-1}, state average market price of corn lagged one year in dollars per bushel; PS_{t-1}, state average market price of soybeans lagged one year in dollars per bushel; GDP_t, announced U.S. government corn diversion price times the fraction of the base corn acreage eligible for diversion in dollars per bushel (Houck et al., p. 7–15); GB_t, binary variable = 1 in years in which direct support payments were included in GDP_t (1966–73), = 0 otherwise (1963–65, 1974) (Houck and Ryan, p. 186); BIL, binary intercept shifter for Illinois; BOH, binary intercept shifter for Ohio; and BIA, binary intercept shifter for Iowa. The data consist of time-series observations on the cross-sectional units (i.e., the four states) for the years 1963 through 1974, resulting in forty-eight pooled observations.

Empirical Results

The coefficients of equation (1) were estimated with ordinary least squares (OLS). Equation (1) reflects the assumption that the acreage response to crop price change is homogeneous across the four states. Because there are large differences in corn acreage among the four states, equation (1) was estimated in a double logarithmic functional form so that the estimated acreage price elasticities would be constant across states.

Although the four-state region is relatively homogeneous, the assumption of constant corn price, soybean cross-price and corn diversion cross-price elasticities across states was tested to check the possibility of biased coefficients due to a misspecified model. Coefficient shift variables were formed for use with the lagged prices of corn, soybeans, and corn diversion. The parameters of the model in equation (1) were estimated with these coefficient (elasticity) shift variables included. The null hypothesis that all nine elasticity shift coefficients are jointly equal to zero was rejected at the .05 significance level. However, in this model, all estimated coefficient shifters were individually nonsignificant except that for Iowa corn diversion price ($IAGDP$). Equation (1) was reestimated with $IAGDP$ included. Then the null hypothesis that the other eight elasticity shift coefficients were zero

was not rejected at the .05 significance level.[1] Equation (1), including *IAGDP*, was chosen as the best model. Its estimated coefficients are presented as equation (1.1) in table 1.

Previous studies by Houck et al., Wallace and Hussain, and Penn contain linear time-trend coefficients in corn acreage response equations that are two to four times the size of their standard errors. To test the need for such a measure of technology in this study, equation (1.1) was reestimated twice: once with a linear time trend included and once with the logarithm of a time trend included. Neither estimated coefficient was significantly different from zero, supporting the hypothesis that the need to include a linear time trend as a measure of technology is eliminated by shortening the time frame used for parameter estimation.

It was assumed that the error terms of the model were serially correlated, and heteroscedastic, but cross-sectionally independent.[2] Consistent estimates of the first-order serial correlation were obtained for each of the four states using the procedure described in Kmenta (pp. 509–10). The observations from Illinois exhibited significant serial correlation and were adjusted accordingly. The generated least squares estimates for model were then obtained (Kmenta, pp. 510–11).[3]

The signs on all the parameter estimates in each of the three equations are consistent with a priori expectations. The estimated coefficients in equation (1.3) are all at least twice the size of their standard errors except for soybean price. The estimated corn acreage elasticity in this study, .22 in model 1.3, is somewhat larger than estimates by Penn, Houck et al., and Ryan and Abel, which are all in the range of .12 to .17. There are several plausible explanations for this difference in elasticities. All previous studies used time-series observations beginning in the late 1940s or early 1950s, but this study used observations beginning in 1963. There is no a priori reason to assume the elasticities of acreage are constant over time.[4] Also, previous studies have estimated acreage elasticities with respect to weighted corn-price support rates, and although Houck and Ryan demonstrate that actual price lagged one year and weighted corn support price are highly correlated, some difference between acreage elasticities estimated with these two variables is to be expected. Finally, previous corn acreage response models have been linear in prices and acreages, and, therefore, elasticities were measured at the means; but the double logarithmic functional form of this study implies a constant acreage elasticity.

To test how well the transformed model fits the data, the actual and predicted acreages [from equation (1.3)] were compared. The prediction error for the region was never greater than 5%, was under 3% in all but one year, and averaged only 1.9%. In addition, the model correctly identified all four acreage turning points in 1967, 1969, 1971, and 1972.

While the final model [equation (1.3)] performs well, no claim of superiority over existing corn acreage response models using time trends is claimed. Pooling may not exhibit great advances in corn acreage response estimation, but pooled time-series and cross-sectional data are a feasible base for alternative estimates of acreage response functions, and would be particularly advantageous in response functions where technology does not advance linearly. Acreage response estimation is but one use of pooled time-series and cross-

[1] The authors realize that this significance test is based on a preliminary test, but feel the results could be enlightening.

[2] These assumptions imply that the variance of the error term differ across states (heteroscedasticity), but for a given year, the error terms of any two states are independent (cross-sectional independence).

[3] An alternative specification of the behavior of the error terms when pooled data is used is the error components model [see for example Kmenta (pp. 514–516) and Wallace and Hussain]. The error components model was not employed in this research because the necessary computer software was not available to the authors.

[4] The estimated elasticities from previous studies change by no more than .01 when calculated at mean support price and acreage for the time periods 1950–70, 1950–74, or 1963–74. In addition, the mean lagged market price-mean acreage ratio is also nearly constant for these three alternative time periods, indicating that the size of the elasticity in this study is not merely a reflection of recent high prices.

Table 1. Regressions Using the Log of Corn Acres as the Dependent Variable

Equation[a]	Constant	*ln*[b] PC_{t-1}	*ln* PS_{t-1}	*ln* *GDP*	*GB*	*BIL*	*BOH*	*BIA*	*ln* *IAGDP*	R^2
(1.1) Coefficient	8.546	0.260	−0.068	−0.096	0.065	0.667	−0.437	0.863	−0.558	.994
Standard Error	0.073	0.066	0.051	0.269	0.018	0.017	0.017	0.040	0.227	
(1.2) Coefficient	7.503	0.230	−0.013	−0.131	0.063	1.651	−0.440	0.831	−0.393

A Note on the Use of Exponential Functions for Estimating Farm Size Distributions

Bruce L. Dixon and Steven T. Sonka

Recently, considerable public and professional concern has been expressed regarding the future structure of U.S. agriculture (Doering, Barkley). These expressions of concern have considered changing features of U.S. agriculture such as concentration of production on larger units, adoption of large-scale capital intensive production technologies and rapid escalation of land prices (Raup, Klepper et al., Moles). Of course, concern about the structure of agriculture is not entirely a recent phenomenon. Price and income support legislation consistently has cited the structure of agriculture and particularly the family farm as variables of considerable importance (Spitze). Implicit in these concerns is the suspicion that changes in the structure of agriculture may have at least some attributes which are socially undesirable (Heady, Goldschmidt).

As these concerns about the future structure of agriculture are discussed, the need for processes capable of projecting that future structure intensifies. In particular, information, which addresses the question, "What will be the farm structure of the future if present forces continue?" is particularly valuable. In order to provide this information, however, the researcher needs to be able to evaluate and estimate the distribution of farm numbers across whatever measure of farm size is being utilized. This research note analyzes the regression approach to fitting an exponential function to an observed distribution as suggested by Boxley and Ching. Initially the note discusses the implied, hypothesized structural model and the use of regression for parameter estimation. Subsequently, alternative approaches are suggested and empirical comparisons presented.

The Regression Approach

Dovring (1962, 1969, 1973), Boxley, and Ching have all used exponential functions to represent farm size distributions. The studies by Boxley and Ching use a simple form of an exponential function that is easy to estimate using ordinary least squares (OLS) and frequently appears to fit the data well. Initially in this note we investigate the underlying assumptions of the Boxley and Ching model to determine the appropriate use of such a model.

Boxley and Ching employ a decumulative distribution function written as

$$(1) \qquad Y_i = Ae^{-Bx_i},$$

where Y_i is percentage of farms larger than x_i, x_i is lower limit of farm size for a given size class divided by the average farm size, e is base of the natural logarithms, and A,B are parameters.

By taking natural logarithms of (1), OLS estimates of lnA and B are obtained easily. As Ching notes, it is desirable that A and B be estimated so that $Y_i = 100$ when x_i equals its minimum value. Therefore, Ching suggests utilizing restricted least squares such that

$$(2) \qquad A = (100/e^{-Bx_1}).$$

where x_1 is the minimum farm size.

While it is not clear how Ching obtains estimates of A and B, the desired result of (2) can be obtained easily using a slight modification of OLS methods. To demonstrate this method define A as in (2) so that (1) is written as

$$(3) \qquad \begin{aligned} Y_i &= (100/e^{-Bx_1})e^{-Bx_i} \\ &= 100e^{B(x_1-x_i)}. \end{aligned}$$

Logarithms are then taken of (3) and an additive error term, u, is hypothesized for the model to obtain an OLS estimate of B from.[1]

$$(4) \qquad ln(Y_i/100) = B(x_1 - x_i) + u \; ; \; u \sim N(0, \sigma^2).$$

A problem with using (4) is that the variance of the error term is frequently heteroscedastic. The reason is that for the smaller x_i, the Y_i tend to be large. The logarithms of the Y_i associated with the smaller x_i most likely will exhibit little variation among each other relative to the logarithms of the

Bruce L. Dixon and Steven T. Sonka are assistant professors in the Department of Agricultural Economics and Rural Sociology at the University of Illinois, Urbana-Champaign.

The authors would like to thank Earl R. Swanson and John T. Scott, Jr., for a critical review of a preliminary draft. They also wish to thank Folke Dovring for stimulating their interest in the topic and for providing insights into the material.

[1] A pleasing result of this method is that A does not have to be estimated, neatly circumventing the problems of obtaining an unbiased estimate of A from the OLS estimate of lnA (see Goldberger). Furthermore, the first observation of the data requires u_1 to be zero because both the dependent and independent variables are zero. Therefore, letting there be n class sizes, the error term can only vary over $n - 1$ dimensions. Since one parameter, B, is estimated to explain the variation over the $n - 1$ dimensional space, the estimate of the variance of u has $n - 2$ degrees of freedom.

Y_i associated with the larger x_i. Thus the potential for heteroscedasticity is substantial. In such cases, of course, the OLS estimate of B, $\hat{B}$, is inefficient. Consequently, statistical inference on B becomes more complicated. For example, Ching uses a Chow test to determine if the parameters of (1) change over successive time periods. However, one of the underlying assumptions in Chow's procedure is that the error terms for all of the observations are homoscedastic.

A further complication is that the normality assumption on the error term in (4) has some curious implications. As Goldberger discusses, the normality of u implies that Y_i has a log-normal distribution. This means that the Y_i have a log-normal distribution conditional on B and x_i. Thus predictions of Y_i given x_i using (3) will be estimates of the median of Y_i and not the mean of Y_i.

Critique of Regression Approach and an Alternative Interpretation

In the above paragraphs we have suggested several reasons why OLS most likely will be a poor estimator of B; and that to ascribe some statistical properties to $\hat{B}$, a distributional assumption has to be made about the error term in (4) that has unintended implications for the predicted values of Y_i. While these problems can be patched up with a generalized least squares estimator combined with an estimator used by Goldberger, the regression approach to estimating B leads to further complications. To wit, observe that the negative of the derivative of (3) with respect to x_i is

$$\frac{-dY_i}{dx_i} = 100Be^{-B(x_i-x_1)},$$

which, when divided by 100, is simply

$$(5) \qquad = Be^{-B(x_i-x_1)}.$$

Expression (5) is the exponential density function where x_1 is a location parameter. Thus use of the functional form of (3) for a decumulative distribution function implies that the distribution of farm sizes is given by the exponential density function. In the exponential density B is the reciprocal of the mean. Because the x_i are farm sizes divided by the mean farm size, the mean of x_i is one so that B should be very close to 1.[2] To use (3) with a B different from 1 says that the population has an exponential distribution but its mean is different from what the data say it is, clearly a contradiction! A regression estimate of B different from 1 has the strong implication that (1) is a misspecification of the true distribution of farm sizes.

[2] Because the random variable is x_i less x_1, $B = 1/(1 - x_1)$. However, x_1 is likely to be very small compared to the other x_i so that for most practical purposes B can be considered equal to one.

Suppose that the researcher is willing to tolerate a misspecified model in exchange for a model that explains the variation in farm size well. Then the regression approach may be superior to specifying the population to be exponentially distributed. This latter approach requires B to be essentially one while regression approaches make no restrictions on the estimated value of B. Therefore, the regression model might possibly be superior to the exponential density in explaining variation in Y_i.

A comparison of methods demands a criterion. In their book on fitting frequency curves, Elderton and Johnson suggest that discriminating between curves on the basis of a minimum chi-square goodness-of-fit test is a plausible method. The chi-square statistic is defined as:

$$(6) \qquad \chi^2 = \sum_{i=1}^{n} [(\hat{m}_i + m_i)^2/\hat{m}_i],$$

where n is the number of classes, $\hat{m}_i$ is the number of observations predicted to be in the ith farm size class by a given model and m_i is the actual number of elements in the population that are in the ith size class. Thus chi-square is the sum of squares of observed frequency less actual frequency where each square is weighted by its expected class frequency. Additional alternative criteria could be suggested, of course, depending on the shape of the loss function for inaccurate predictions.

An Empirical Example

Some of the above ideas and problems can be explored further by examination of an empirical example. Census of Agriculture data for 1974 for farms in Illinois are used here (U.S. Bureau of the Census). The state is divided into four regions: northern, west-central, east-central and southern, which shall be referred to as areas one through four, respectively. The areas are differentiated by the predominant type of agricultural activity. Our empirical analysis is confined to comparing OLS, a maximum likelihood estimator (MLE) with u assumed heteroscedastic, and the exponential distribution. The class sizes are those given in the Census.

OLS estimates of B in (4) are shown in table 1. The null hypothesis of homoscedasticity is tested using the method of Goldfeld and Quandt. All of the F statistics are significant at the 1% level so that the hypothesis of homoskedasticity is rejected.[3] Consequently, (4) is reestimated using a maximum likelihood estimator where the variance of u_i, σ_i^2, is assumed to be $\sigma_i^2 = \sigma^2 x_i^\delta$, where δ is some positive

[3] There are twelve size classes. As discussed in footnote 1, the first observation holds no information for estimating the variance of u (and also no information of the estimate of B). Hence, the eleven observations Y_2, x_2 through Y_{12}, x_{12} are divided into two groups of five for the Goldfeld and Quandt test with Y_7, x_7 omitted.

Table 1. Regression Results for Fitting Exponential Functions

Statistics	Area 1	2	3	4
OLS estimate of B[a]	.795 (.038)	.907 (.021)	.976 (.022)	.753 (.034)
F statistic for heteroskedasticity for the OLS models[b]	1625	639.8	761.7	1529
MLE estimate of B[a]	.922 (.048)	.948 (.026)	.934 (.034)	.956 (.037)

[a] Standard errors of the estimates are in parentheses below each estimate.
[b] Significant at the 1% level.

Table 2. Chi-Square Values for the OLS, MLE, and Exponential Models of Farm Size Distribution

Model	Area 1	2	3	4
OLS	1983	1014	1480	2872
MLE	1446	863.2	1566	1121
Exponential	1496	805.8	1479	1380
Exponential with B estimated to minimize χ^2[a]	1426 (.951)	804.2 (.995)	1475 (.989)	1097 (.936)

[a] The value of B in (3) that minimizes chi-square is given in parentheses below the respective chi-square values.

number and normality is attributed to the additive error term. These estimates are given in table 1.

The chi-square statistics for MLE and OLS are given in table 2. The MLE models are clearly superior in explanatory power in three of the areas and in Area 3, where the OLS estimate is better, the margin of superiority is comparatively small. Notice that all of the MLE estimates appear to be close to one and, in terms of minimum chi-square, the OLS estimates that perform better relative to their respective MLE estimates are those closest to one. Thus OLS estimates of B substantially different from one appear to be associated with a poor explanatory model.

The third line of table 2 gives the resulting chi-square statistics for fitting the exponential density directly to the data. This is a simple matter since the population means are known. The exponential distribution fits better than OLS in all of the areas, and it is superior to MLE in two out of four areas. The superiority of the exponential over OLS is somewhat surprising since $\hat{B}$ can take on any value in the OLS model. However, the OLS estimates of B minimize the sum of squares of the logarithm of Y_i less its predicted value. Such a criterion is not closely related to explaining the variation in Y_i.[4]

To show the minimum chi-square obtainable for the exponential model (3), B was varied until a minimum was obtained. The chi-square statistics are given in the fourth line of table 2. In areas two and three the improvement over the exponential density is negligible. In area four the improvement over MLE is very slight. And in area three even OLS comes very close to the minimum chi-square. The fact that no one method is superior to the others shows simply that with varying shapes of distributions, different estimators or functional forms for different models are required.

[4] Furthermore, the coefficient of determination between $ln(Y_i/100)$ and x_i is not a good indicator of fit. For the OLS models the coefficients of determination are .961, .992, .992 and .961 and for MLE they are .921, .989, .990, and .848, respectively, for areas one through four.

The failure of any of the estimated distributions to fit the data is not surprising. Most likely no well-recognized, continuously differentiable distribution will fit the data well. In Illinois, land has been largely parceled out in 40-, 80-, 160-, etc., acre sizes due to the relatively level topography. Thus it seems quite logical that the actual distribution has many peaks, and unimodal distributions such as all of the models considered in this study will have difficulty fitting the data precisely.

Conclusions

We have brought out some of the underlying problems in using a regression approach to estimate a decumulative exponential distribution function. Because the regression approach implies an exponential density, curve fitting requires knowing only the mean of the population. This latter approach is logically consistent with the hypothesized model and is more in keeping with the traditional methods of fitting distributions to data. In terms of explanatory power the empirical examples show OLS to be generally inferior to other methods, particularly when the estimated OLS parameter is substantially different from one.

Perfect Aggregation Conditions for Quadratic Programming Models

N. Oguchi and A. Guccione

Sufficient conditions for the perfect aggregation of linear programming models were given by Day in 1963. Essentially the same set of conditions was shown to be necessary by Guccione and Oguchi in 1977.[1] Here we extend these results to quadratic programming systems, a natural first step in the study of consolidation for more general nonlinear programming models. We assume that the reader is familiar with Ijiri's excellent survey of the aggregation problem, aware of its general structure, and thus of its relevance to economists.

The problem under study is the following: Let the tth microsystem ($t = 1, \ldots, T$) be described by the couple of dual programs,

(1) $$\max \mathbf{p}'_t\mathbf{x}_t - (\tfrac{1}{2})\,\mathbf{x}'_t\mathbf{C}_t\mathbf{x}_t \quad \text{s.t. } \mathbf{A}_t\mathbf{x}_t \leq \mathbf{b}_t \text{ and } \mathbf{x}_t \geq \mathbf{0},$$

(2) $$\min \mathbf{b}'_t\mathbf{u}_t + (\tfrac{1}{2})\,\mathbf{x}'_t\mathbf{C}_t\mathbf{x}_t \quad \text{s.t. } \mathbf{A}'_t\mathbf{u}_t \geq \mathbf{p}_t - \mathbf{C}_t\mathbf{x}_t \text{ and } \mathbf{u}_t \geq \mathbf{0},$$

where $\mathbf{C}_t$ is a positive semidefinite matrix, and where all terms are defined as in Van de Panne's well-known textbook (pp. 261–96). Let the corresponding macrosystem ($t = 0$) be specified by the relations

(3) $$\mathbf{p}_o = \sum_{t=1}^{T} \alpha_t\mathbf{p}_t,\ \mathbf{C}_o = \sum_{t=1}^{T} \alpha_t\mathbf{C}_t,$$

$$\mathbf{A}_o = \sum_{t=1}^{T} \beta_t\mathbf{A}_t,\ \mathbf{b}_o = \sum_{t=1}^{T} \mathbf{b}_t,$$

where the (arbitrary) weights α_t and β_t must satisfy the restrictions

$$\alpha_t, \beta_t \geq 0,\ \sum_{t=1}^{T} \alpha_t = \sum_{t=1}^{T} \beta_t = 1.$$

We wish to investigate which conditions must be imposed on the matrices $\mathbf{A}_t$ to satisfy, for (conveniently restricted sets of) all values of the matrices $\mathbf{p}_t$, $\mathbf{C}_t$, and $\mathbf{b}_t$, the relations

(4) $$\mathbf{x}^*_o = \sum_{t=1}^{T} \mathbf{x}^*_t \text{ and } \mathbf{y}^*_o = \sum_{t=1}^{T} \mathbf{y}^*_t,$$

(5) $$\mathbf{u}^*_o = \sum_{t=1}^{T} \alpha_t\mathbf{u}^*_t \text{ and } \mathbf{v}^*_o = \sum_{t=1}^{T} \alpha_t\mathbf{v}^*_t,$$

where $\mathbf{y}_t$ and $\mathbf{v}_t$ are, respectively, primal and dual slack variables, and where the starred variables indicate optimal solutions to the systems (1) and (2) ($t = 0, 1, \ldots, T$). That is, the starred variables satisfy the Kuhn-Tucker conditions

(6) $$\mathbf{A}_t\mathbf{x}_t + \mathbf{y}_t = \mathbf{b}_t,$$

(7) $$\mathbf{A}'_t\mathbf{u}_t - \mathbf{v}_t = \mathbf{p}_t - \mathbf{C}_t\mathbf{x}_t,$$

(8) $$\mathbf{u}'_t\mathbf{y}_t + \mathbf{v}'_t\mathbf{x}_t = \mathbf{0}, \text{ and}$$

(9) $$\mathbf{x}_t, \mathbf{y}_t, \mathbf{u}_t, \mathbf{v}_t \geq \mathbf{0}.$$

We note immediately that unconstrained, perfect aggregation is obviously impossible, and that therefore restrictions must be imposed on the domains of the exogenous variables $\mathbf{p}_t$, $\mathbf{C}_t$, $\mathbf{b}_t$. That is, in terms of Ijiri's useful classification scheme, "constrained consistency" rather than "total consistency" is relevant here. As is well known, the choice of appropriate subsets of the exogenous variables' domains is in general not unique. In practice, a balance must be struck between the empirical relevance of the restrictions imposed and the generality of the results obtained. We assume, first, that all matrices $\mathbf{p}_t$, $\mathbf{C}_t$, $\mathbf{b}_t$ are equal over the microsystems. Although this choice is restrictive, "it may be appropriate for firms, especially in circumstances in which quasi-linearity is also appropriate" (Lancaster, pp. 213–14). Second, we constrain the exogenous variables to those values which imply the same pattern of zeros in all the optimal solutions (a more transparent, geometric interpretation of this condition will be given below). The implications of these two restrictions are summarized in the following propositions.

PROPOSITION 1. *Perfect aggregation of the primals is possible if, and only if, all matrices $\mathbf{A}_t$ ($t = 1, \ldots, T$) are equal.*

Proof. Notice that if $\mathbf{A}_t = \mathbf{A}$, $\mathbf{b}_t = \mathbf{b}$ ($t = 1, \ldots, T$), then $\mathbf{A}_o = \mathbf{A}$ and $\mathbf{b}_o = T\mathbf{b}$. Let the vectors $(\mathbf{x}_o, \mathbf{y}_o)$ be a solution to equation (6) for the macrosystem, then the vectors $(\mathbf{x}, \mathbf{y}) = T^{-1}(\mathbf{x}_o, \mathbf{y}_o)$ solve (6) for the

Helpful comments by W. J. Gillen and an anonymous reviewer of an earlier draft of this paper are gratefully acknowledged.

[1] A number of interesting papers should be mentioned here, in particular those by Miller, Lee, and Marenco. In addition, Paris and Rausser have derived a set of sufficient conditions which depend on endogenously determined (rather than arbitrarily fixed) aggregation weights.

microsystem. If the solution $(\mathbf{x}_o, \mathbf{y}_o)$ is optimal, by the second restriction on the exogenous variables, $T^{-1}(\mathbf{x}_o, \mathbf{y}_o)$ must also be optimal.

To prove necessity, consider the special (but permissible) case in which $\mathbf{C}_t = \mathbf{0}$ for $t = 1, \ldots, T$. Then the requirement of equal technologies can be obtained immediately from the necessary conditions for the linear-programming case (see Guccione and Oguchi).

Remark

We can now discuss the second constraint on the exogenous variables. Assume we know the optimal macrosolutions $(\mathbf{x}^*_o, \mathbf{y}^*_o)$ and $(\mathbf{u}^*_o, \mathbf{v}^*_o)$. What restrictions must be imposed on the matrices $\mathbf{p}_t, \mathbf{C}_t, \mathbf{b}_t$ (in addition to equality over microunits), to obtain the same pattern of zero entries in the optimal microsolutions $(\mathbf{x}^*, \mathbf{y}^*)$ and $(\mathbf{u}^*, \mathbf{v}^*)$? The vectors $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}) = T^{-1}(\mathbf{x}^*_o, \mathbf{y}^*_o)$ satisfy both equations (6) and the two first inequalities in (9) and display the property desired. Let the pattern of zeros in equation (8) be the same at both levels of consolidation. If the dual solution $(\tilde{\mathbf{u}}, \tilde{\mathbf{v}})$, defined by setting the right-hand side of equation (7) equal to $(\mathbf{p} - \mathbf{C}T^{-1}\mathbf{x}^*_o)$, and choosing the zero entries as in (8), were to satisfy the last two conditions in (9), $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}) = (\mathbf{x}^*, \mathbf{y}^*)$ and $(\tilde{\mathbf{u}}, \tilde{\mathbf{v}}) = (\mathbf{u}^*, \mathbf{v}^*)$. But then, the relevant question is whether any change in signs takes place in the solution of equation (7). There will be no change if, and only if, both $(\mathbf{p} - \mathbf{C}\mathbf{x}^*_o)$ and $(\mathbf{p} - \mathbf{C}T^{-1}\mathbf{x}^*_o)$ lie in the cone spanned by the columns of the matrix $(\mathbf{A}' - \mathbf{I})$. In practice, this condition can be detected only by means of post-optimality analysis. That is, having solved the primal macroproblem, parametric programming must be performed on the right-hand-side constants of the constraints, and the solutions compared.

PROPOSITION 2. *Perfect aggregation of the duals is, in general, impossible.*

Proof. From the first relation in (3) and the main dual constraints we obtain

$$\mathbf{A}'_o\mathbf{u}^*_o - \mathbf{v}^*_o + \mathbf{C}_o\mathbf{x}^*_o = \sum_{t=1}^{T} \alpha_t\mathbf{A}'_t\mathbf{u}^*_t - \sum_{t=1}^{T} \alpha_t\mathbf{v}^*_t + \sum_{t=1}^{T} \alpha_t\mathbf{C}_t\mathbf{x}^*_t,$$

or, since $\mathbf{A}_t = \mathbf{A}$, $\mathbf{C}_t = \mathbf{C}$, $\mathbf{x}^*_o = T\mathbf{x}^*$,

$$\mathbf{A}'\left(\mathbf{u}^*_o - \sum_{t=1}^{T} \alpha_t\mathbf{u}^*_t\right) - \left(\mathbf{v}^*_o - \sum_{t=1}^{T} \alpha_t\mathbf{v}^*_t\right) = \left(\sum_{t=1}^{T} \alpha_t\mathbf{C}\mathbf{x}^*_t - \mathbf{C}T\mathbf{x}^*\right).$$

For perfect aggregation of the dual variables [see equation (5)], it is required that the right-hand-side expression be null. That is, after some obvious manipulations and premultiplication by the vector $(\mathbf{x}^*_o)'$,

$$(1 - T)(\mathbf{x}^*_o)'\mathbf{C}\mathbf{x}^*_o = 0.$$

But this equation holds only in two special cases: when the number of units to be aggregated is one, and when the systems considered are essentially linear.

Ijiri's discussion of constrained aggregation (pp. 771–72) seems to imply the following research strategy. First, the problem should be shown intractable in unrestricted form and the exogenous variables conveniently constrained. Then, the possibility of extending their domains should be tested. With reference to the last stage, we conjecture that, for the given aggregation framework, additional research efforts would be met by rapidly declining returns. However, progress is possible if the aggregation weights are allowed to be endogenous.[2]

[2] As an interesting example, let the aggregation weights for the matrices $\mathbf{C}_t$ be all equal to T^{-2}, all other weights being defined as in the text. Then, if the exogenous variables and the technologies are equal (over microunits), we have

$$\begin{aligned}\mathbf{p} - \mathbf{C}_o\mathbf{x}^*_o &= \mathbf{p} - \mathbf{C}T^{-1}\mathbf{x}^*_o \\ &= \mathbf{p} - \mathbf{C}T^{-1}T\mathbf{x}^* \\ &= \mathbf{p} - \mathbf{C}\mathbf{x}^*.\end{aligned}$$

That is, no post-optimality analysis is required and the microsystems can be aggregated. For this approach to consolidation, in the context of mathematical programming, see the paper by Paris and Rausser.

The Factor Share Approach to Production Function "Estimation": Actual or Estimated Equilibrium Shares?

C. Richard Shumway, Hovav Talpaz, and Bruce R. Beattie

For years agricultural economists have been concerned with obtaining reliable estimates of production function parameters. Among other reasons, such estimates are needed to address policy issues involving resource misallocation, supply response, and factor demand in agriculture. The appeal of production function approaches to such problems, as contrasted with direct estimation of product supply and factor demand relationships, is with the richness of the model for addressing cross-price effects and matters of resource allocation.

However, as is well known, problems of multicollinearity and technological change have thwarted most efforts to obtain reliable estimates of aggregate production elasticities by direct estimation (Doll; Rosine and Helmberger). In an effort to circumvent the multicollinearity barrier posed by direct estimation, Tyner and Tweeten (1965) indirectly estimated aggregate production elasticities for U.S. agriculture using a factor share approach. Noting that in equilibrium, factor shares equal factor elasticities for an industry comprised of profit-maximizing firms, Tyner and Tweeten synthesized a Cobb-Douglas production function by estimating equilibrium factor shares based on historical data and the Nerlove partial adjustment model. Equilibrium factor shares were estimated individually for each of nine input categories assuming that actual adjustment between any two years was a constant proportion of the extent of own-factor disequilibrium. Estimates were developed for several decades by including dummy variables in the model. In a subsequent article Tyner and Tweeten (1966) developed estimates of resource misallocation, product supply elasticity, and factor demand elasticities based on their indirectly estimated Cobb-Douglas production functions.

In 1974 Rosine and Helmberger published an article with a similar intent. They also explored several macro policy issues based on a synthesized Cobb-Douglas production function for U.S. agriculture. They used a simpler model than Tyner and Tweeten, by assuming that production elasticities were given by actual factor shares. In effect, Rosine and Helmberger assumed instantaneous adjustment to equilibrium thereby avoiding numerous estimation difficulties. (See writings of D. Gale Johnson in 1948 and Ruttan and Stout in 1960 for examples of earlier expressions of interest in factor shares.)

To develop normative estimates of production elasticities following a factor share approach, it seems clear, a priori, that the Tyner-Tweeten approach should be preferable conceptually to that of Rosine and Helmberger. In the words of Tyner and Tweeten, "the use of [actual] factor shares as production elasticities trades the intercorrelation problem for the dubious assumption that economic equilibrium prevails" (1965, p. 1462). The purpose of this paper is to evaluate the practical effects of the assumption of continual economic equilibrium (instantaneous adjustment) on production elasticity estimation.

In the following section the Rosine-Helmberger and Tyner-Tweeten factor share approaches are briefly reviewed. We then examine empirical results from a refitting of Tyner and Tweeten's factor share adjustment model, using 1910–76 data to ascertain the extent to which predicted equilibrium factor shares deviate from actual factor shares, the Rosine-Helmberger approach. The paper concludes with some recommendations for further research on production function estimation in terms of both direct and indirect (factor share) approaches.

Two Alternative Factor Share Adjustment Approaches

While no rigorous theory of factor share adjustment has been suggested in prior literature, a connection can be made with the neoclassical theory of the firm. An industry comprised of profit-maximizing, perfectly competitive firms is in equilibrium when the partial production elasticities equal their factor shares, i.e.,

$$(1)\qquad (\partial y/\partial x_i)(x_i/y) = r_i x_i/py,$$

where y is product quantity, x_i is quantity of factor i, and r_i and p are factor and product prices, respectively. The left side of (1) is the elasticity of output

Texas Agricultural Experiment Station Technical Article No. 14734.

The authors express appreciation to Bruce Gardner, John Penson, and Robert Taylor for many helpful comments on this paper, and to Fred Tyner and Luther Tweeten for sparking their interest in the subject. The authors also thank Don Durost for providing and interpreting unpublished U.S. Department of Agriculture data used in this study.

with respect to factor use. The right side is the factor share, which in equilibrium is denoted F^*_i.

As technological and economic conditions change, the optimal quantities of y supplied and x_i demanded change and so, therefore, does F^*_i. Because prices fluctuate widely and technology changes over time, producers operate in both an uncertain and temporal world. Actual factor share (F_i) is simply a manifestation of producer decisions implied by equation (1). Because of uncertainty and the fact that it takes time to adjust fully to a new set of technical or economic circumstances, F_i is likely not the same as the unobserved F^*_i. That, in effect, was the Tyner-Tweeten hypothesis.

The Rosine-Helmberger approach represents the ultimate in simplification; equilibrium is assumed and actual factor shares are taken as estimates of the production elasticities. Adding the time subscript t to our notation, Rosine and Helmberger implicitly assume that $F^*_{i,t} \equiv F_{i,t}$. That is, instantaneous and complete adjustment of all factor shares is assumed so that the system is continually in equilibrium. The simplicity of the Rosine-Helmberger approach is appealing because no estimation is required. This procedure assumes that actual factor share is equilibrium share, i.e., no deviation is postulated.

Tyner and Tweeten, on the other hand, rejected the assumption of instantaneous adjustment or continuous equilibrium. Dropping the subscript i for the moment, they hypothesized an adjustment model for each factor share of the form

$$(2) \qquad F_t - F_{t-1} = \gamma(F^*_t - F_{t-1}),$$

where γ is the proportion of adjustment accomplished during period t, $0 < \gamma \leq 1$. This equation was expressed in stochastic form as

$$(3) \qquad F_t = \beta_0 + \beta_1 F_{t-1} + e_t,$$

where $\beta_0 = \gamma F^*_t$ and $\beta_1 = 1 - \gamma$. Implied equilibrium factor share, $\beta_0/(1 - \beta_1)$, was postulated to change from decade to decade by including zero-one dummy variables (D) on the intercept, i.e., $\beta_0 = \beta'_0 + \sum_{k=1}^{K} d_k D_k$. Using this model, its logarithmic form, and their autoregressive counterparts, Tyner and Tweeten estimated equilibrium factor shares for nine individual input categories for five different decades $(K = 4)$.

Comparison of Estimated Equilibrium Factor Shares with Actual Factor Shares

Data for the comparative analysis are from published and unpublished USDA sources as were Tyner-Tweeten's and Rosine-Helmberger's. Estimates are developed for eight farm input categories based on annual U.S. data 1910–76. (Tyner and Tweeten's data were from 1910 to 1961; Rosine and Helmberger's, 1948–70.) Our input categories are similar to Tyner and Tweeten's; we have one less category, as real estate taxes are combined with other real estate expenses.[1]

Average factor shares (actual) over each of six decades and estimated equilibrium factor shares following Tyner and Tweeten's partial adjustment approach are presented in table 1. The partial adjustment estimates were obtained by fitting the following equation for each input

$$(4) \qquad F_t = \beta'_0 + \sum_{k=1}^{5} d_k D_k + \beta_1 F_{t-1} + e_t.$$

Equations in which the lagged dependent variable appears as an explanatory variable frequently exhibit serially correlated disturbance terms and also bias the test for serial correlation in ordinary least squares (OLS) estimation. Consequently, the less restrictive Cochrane-Orcutt model with Cooper's transformation was used to obtain parameter estimates and standard errors with asymptotically desirable properties for these equations.

From table 1 we first notice that all the estimated equilibrium factor shares are, not surprisingly, of the right sign and significantly different from zero at typically acceptable significance levels. The R^2 values ranged from .81 to .94. However, more interesting is the small (in many cases, negligible) difference between the estimated equilibrium factor share and the mean actual factor share for each input for each decade. All of the decade-mean actual factor shares fall within a 90% confidence interval about the estimated equilibrium; 98% fall within a 75% confidence level.[2]

The average percentage difference between estimated equilibrium and actual factor shares is less than 6%. For only eight of the fifty-four comparisons does the percentage difference exceed 10%. The greatest differences are for machinery investment and machinery operating expenditures in the first and postwar decades. Clearly these results do not provide persuasive evidence to conclude that equilibrium factor shares, assumed constant over a decade, differ substantially from average actual factor shares. That is, our empirical results do not provide a basis for rejecting the hypothesis of Rosine and Helmberger (pp. 718–19), *viz.*, that the

[1] Most data used in this paper are from July 1977 *Farm Income Statistics* (USDA, 1977) and from July 1957 and July 1965 *Farm Income Situation* (USDA, 1957, 1965) with appropriate supplementation and adjustment. Some additional expense items are included in a number of the input categories that were not included in Tyner and Tweeten's data. Details concerning data development and sources are available on request from the authors. Factor share for any category consists of actual expenditures on that category divided by farm income for the same year.

[2] The test employed is an approximation. Exact tests require knowledge of the variance-covariance matrix. We know the variance of each and that there is a nonzero covariance, but we do not know the magnitude of the covariance. Therefore, our test is conducted computing a confidence interval around the estimated equilibrium to see if the actual factor share falls within it. We realize that actual factor share is not an arbitrary value but is also a random variable, and we are not considering either its variance or its covariance with the estimated equilibrium.

Table 1. Decade Average Factor Shares and Partial Adjustment Equilibria Estimates for U.S. Agriculture, 1911–76

		Factor Share by Decade

[c] Approximate standard errors (in parentheses) of estimated equilibria are obtained from

$$SE_{\hat{r}_k} = SE\left(\frac{\hat{\beta}'_0 + \hat{a}_k}{1 - \hat{\beta}_1}\right) \approx \frac{\hat{\beta}'_0 + \hat{a}_k}{1 - \hat{\beta}_1}\left\{\frac{\mathrm{Var}(\hat{\beta}'_0) + \mathrm{Var}(\hat{a}_k) + 2\mathrm{Cov}(\hat{\beta}'_0,\hat{a}_k)}{(\hat{\beta}'_0 + \hat{a}_k)^2} + \frac{\mathrm{Var}(\hat{\beta}_1)}{(1 - \hat{\beta}_1)^2} + 2\left[\frac{\mathrm{Cov}(\hat{\beta}_1,\hat{\beta}'_0) + \mathrm{Cov}(\hat{\beta}_1,\hat{a}_k)}{(\hat{\beta}'_0 + \hat{a}_k)(1 - \hat{\beta}_1)}\right]\right\}^{\frac{1}{2}}$$

for the model in equation (4).

assumption, "in each year, the price of an input is equated to its value of marginal product," is tolerably close to the real world.

Accordingly we conclude that if one is going to develop normative estimates of factor elasticities using factor shares as proxies (following either Rosine-Helmberger or Tyner-Tweeten), the most cost-effective research procedure is simply to use actual factor shares for the year(s) of interest. The extent of disequilibrium appears generally to be insufficient to justify effort in estimating equilibrium factor shares, at least for the case of aggregate U.S. agriculture. This finding may be due to either of two possibilities: (*a*) disequilibrium is minor; or (*b*) if disequilibrium is significant, the Tyner-Tweeten partial adjustment model and estimation technique is not sophisticated enough to detect it.[3]

Some Thoughts on Further Research

Other autoregressive alternatives to the Tyner-Tweeten model have been developed by the authors to overcome some of its restrictive assumptions. Empirical results consistent with those reported in this paper were obtained.[4] However, none of these

[3] When estimated equilibrium factor shares are very close to actual and actual prices are used to derive the minimum cost allocation of resources, the implied misallocation is small (Shumway, Beattie, Talpaz).

[4] Two restrictive assumptions of the Tyner-Tweeten model are (*a*) equilibrium factor share is constant over a decade, and (*b*) only the previous and current years' factor shares influence equilibrium factor share in the current time period. The authors developed an autoregressive integrated moving average (ARIMA) model in an attempt to come to grips with these shortcomings, although not accounting for the simultaneous effects of adjustments in all factor shares. The empirical results did not differ in important ways from those of the Tyner-Tweeten model. Fully 91% of actual annual factor shares fell within a 90% confidence interval about the estimated equilibrium; 80% were within a 75% interval. Additionally, previous work applying a polynomial lag adjustment model to the

models accounts for the simultaneity in factor share adjustment that seems obvious on a priori grounds. Since a particular factor share (F_i) is the ratio of expenditure on that factor to total receipts from output produced, a change in expenditure on any other factor, due to a change in its price or technology, indirectly causes a change in F_i. This occurs because the change in a factor's price or technology directly affects its quantity purchased, the quantity of output produced, and, no doubt, total receipts. Clearly, adjustments in individual factor shares and/or factor quantities are not made independently of other factors.

If specification bias due to simultaneity is a serious problem in the Tyner-Tweeten model, it seems unlikely that additional research effort directed toward more completely specified models of factor share adjustment will be fruitful. There is multicollinearity in the factor share data just as there is in the input expenditure data that one would use to estimate production coefficients directly. In fact, for the period of study, the correlation in the factor share data was nearly as great as in the expenditure data, to say nothing of the correlation present in the lagged factor share data. The principal justification for looking to the normative factor share approach in the first place was avoidance of multicollinearity associated with direct estimation. Yet, more elaborate factor share adjustment models formally recognizing factor share interdependencies would be plagued by the same problem in addition to some others.

Conclusion

Relevant options for estimating production coefficients appear to be limited to two major alternatives: (*a*) use of actual factor shares and (*b*) direct positive estimation. Normative estimation based on historical factor share data and fully specified models is fraught with econometric difficulties rivaling those of direct estimation. Further, abbreviated versions of fully specified factor share adjustment models, like Tyner and Tweeten's, do not reveal sufficient disequilibria to substantiate effort in their estimation. Thus, if the factor share approach is followed, the least-cost research alternative of assuming instantaneous and complete adjustment, i.e., using actual factor shares, seems appropriate.

[*Received November 1978; revision accepted March 1979.*]

Tyner-Tweeten data gave decade-average equilibrium estimates that generally were also very close to actual factor shares (Shumway, Talpaz, Beattie).

On Agricultural Productivity Differences among Countries

Dũng Nguyen

The sources of agricultural productivity differences among countries have been examined extensively by Professors Hayami and Ruttan in their important work published in 1971 (Hayami and Ruttan, chap. 5. See also their 1970 article.) Their method involved the estimation of an aggregate agricultural production function based on intercountry cross-section data for the period centered on 1960, using average per farm data and national aggregate data separately. Further, that study involved the estimation of the per worker production function where data for the years 1955 (1952–56 averages), 1960, and 1965 (1962–66 averages) were used either separately or pooled. The estimation with the pooled samples enabled Hayami and Ruttan to test the stability of the agricultural production function over the 1955–60–65 period using the analysis of covariance method.

The main motivations for the present study are as follows: (*a*) the latest data used in the Hayami-Ruttan work were those for 1965. It is, therefore, of empirical interest to incorporate into the analysis the more recent information. (*b*) In an effort to gain more meaningful interpretations of the impact of education (general and technical) on agricultural productivity, we are interested in using certain proxy variables for education which are different from those of Hayami and Ruttan. (*c*) One of the important results obtained by Hayami and Ruttan was that the agricultural production parameters are stable during the 1955–60–65 period. Our attempt to include the 1970 and 1975 data naturally would require additional tests for the stability of the production function because the behavior of the 1970 and 1975 functions may differ from those of the previous years. (*d*) We intend to analyze the stability question more intensively by examining the differences not only in the intercepts of the production functions but also in their regression coefficients.

The objective of this study is thus twofold: first, to estimate the agricultural production function using the data for 1970 (1968–72 averages) and for 1975 (1974–76 averages), the estimation is made using the per capita as well as the national aggregate data; second, to test the stability of the agricultural production function over time using the 1955, 1960, 1965, 1970, and 1975 intercountry cross-section sample.

The Theoretical Framework

For ease of reference, let us state below the form of the agricultural production function as specified by Hayami and Ruttan:

$$(1) \qquad Y = e^{\alpha_1} N^{\alpha_2} A^{\alpha_3} L^{\alpha_4} F^{\alpha_5} M^{\alpha_6} GE^{\alpha_7} TE^{\alpha_8},$$

where Y is agricultural output; N, the number of male workers in agriculture; A, the agricultural land area; L, the livestock; F, the fertilizer consumption; M, the tractor horsepower; GE, the general education level; and TE, the technical education level. Units of measure for all preceding variables are given in the next section.

Equation (1) describes the familiar unrestricted Cobb-Douglas production function. Theoretical justifications for this representation were given in the original work of Hayami and Ruttan. It can be noted that in the present cross-section framework, the existence of the function in (1) implies that all countries are assumed to operate along a common production function. This may not be a sound assumption because the sample consists of various countries with clearly different degrees of economic backwardness. Here we will counter this argument by taking the Hayami-Ruttan position that, while working with the specification in (1), one implicitly assumes the existence of a meta-production function along which technical change would take place in response to changes in relative prices of the production factors. For further discussions on this and related issues, the reader is referred to papers by Griliches, Krueger, and Nelson.

The Stability of the Agricultural Production Function

Covariance analysis has been discussed at considerable length by Johnston (pp. 192–207). Assuming that many results related to this topic are well known to the reader, we wish to make a number of observations as follows: (*a*) The variance analysis appearing in the Hayami-Ruttan work was based

Dũng Nguyen is a doctoral candidate in the Department of Economics, University of Maryland.

An earlier version of this paper was completed while the author was a senior lecturer in economics at the University of the Philippines, School of Economics. He wishes to thank Professors Randolph Barker, Yujiro Hayami, Robert Herdt, and the reviewers of the *Journal* for their encouragement and many helpful comments.

only on the "overall effect" category. (*b*) The "overall effect" represents essentially the Chow test of equality between two sets of regression coefficients (Chow, Fisher). (*c*) The statistical foundation is described adequately in the text by Johnston. However, his "practical procedures" to carry out covariance tests may not prove to be the most efficient. We can obtain the desired results in a much simpler way when viewing the covariance analysis as a linear-restriction problem. However, due to the familiarity of the conventional covariance analysis, we will follow these procedures throughout this paper, while leaving the linear-restriction alternative to the interested reader.

Sources of Data

Data for agricultural output Y, in thousand wheat units, were obtained by extrapolation from those in the Hayami-Ruttan book with the FAO country index numbers of total agricultural production (*FAO Production Yearbook, UN Statistical Yearbook*). The International Labor Office's *Yearbook of Labor Statistics* is the source of data for male employment in agriculture, forestry, hunting, and fishing. Number of male workers in agriculture N, in thousands, is then derived by using the weighting factors provided in the Hayami-Ruttan book. Agricultural land area A, in thousand hectares, is the sum of arable land, land under permanent crops, and permanent meadows and pastures. Data for A are given in the *FAO Production Yearbook.* Data for livestock L, in thousand units, can be found in the *UN Statistical Yearbook.* The figures used in our analysis are five-year averages and three-year averages centered on 1970 and 1975, respectively, after the original data were converted to livestock units by the weights suggested by Hayami and Ruttan. The same UN source also gives data for fertilizer consumption F, in thousand metric tons. Data for tractor horsepower M, in thousand units, are obtained from the *FAO Production Yearbook.* We adopted the Hayami-Ruttan method in computing horsepower units by giving thirty horsepower for a farm tractor and five horsepower for a garden tractor. All figures for F and M are either five-year averages centered on 1970, or three-year averages centered on 1975. The level of general education is measured using two alternatives. General education 1 ($GE1$) refers to the gross enrollment ratio for the primary and secondary levels, whereas that for the secondary levels defines general education 2 ($GE2$). The latter is our newly suggested alternative for a measure of general knowledge. Data for both $GE1$ and $GE2$ can be found in the *UNESCO Statistical Yearbook.* Finally, a proxy variable for technical education (TE) is defined to be the number of graduates from agricultural colleges per ten thousand male farmers. Data for these variables are also obtainable from the *UNESCO Statistical Yearbook.*

Thus, except for $GE2$, all variables are defined exactly in the same manner as originally suggested by Hayami and Ruttan. However, we will be able to point out later that our attempt to redefine another explanatory variable turns out to be empirically unsuccessful. For the regressions on the years 1955, 1960, and 1965, all data in the Hayami-Ruttan book are used.

The Empirical Results and the Analysis

Results of the estimation of the agricultural production function (1) expressed in log form are reported in table 1 for the separate samples of 1970 and 1975, as well as the pooled sample of the period 1955–60–65–70–75. The functions are estimated using only the national aggregate data because Hayami and Ruttan have pointed out that the estimation using the average per farm data did not lead to different results concerning the regression coefficients.

Columns 2 and 3 include the estimation of the production function parameters for the year 1970. It can be observed that the alternative measures of the level of general education as represented by $GE1$ and $GE2$ lead to different results regarding the contribution of general knowledge to the agricultural production process. While the coefficients associated with $GE1$ in column 2 is not statistically different from zero, that corresponding to $GE2$ is statistically greater than zero (at the 80% confidence level). As it turns out, not only for the period of 1970 but for every period running from 1955 to 1975, the variable $GE2$, as compared to $GE1$, proves to be the better measure for general education in the sense that it is capable of producing a meaningful relationship between agricultural productivity of various countries and levels of general knowledge of their respective population. This fact can be understood by recalling the definitions of $GE1$ and $GE2$. It can be argued that, in contrast to smaller variations in the enrollment ratios for the primary and secondary levels among countries, variations in the enrollment ratios for the secondary levels are sufficiently large to be able to explain a significant contribution of general education to agricultural productivity.

Another feature to be noted from columns 2 and 3 is that the 1970 production function still exhibits the characteristic of constant returns to scale. This result was obtained earlier by Hayami and Ruttan for the data of 1955, 1960, and 1965. As we will see, this also remains to be the characteristic for the 1975 agricultural production function.

The coefficients of all conventional inputs and technical education appear to fall into the ranges obtained earlier by the Hayami-Ruttan study. Thus, we will not repeat the economic interpretations for these coefficients. Instead, as an empirical note, we mention that an alternative measure for technical education, defined to be the number of scientists

Note: Recall that all regressions are of the log-linear forms as described in the text. Figures in parentheses are *t*-statistics.

[a] The whole sample consists of the following countries: Argentina, Australia, Austria, Belgium (and Luxembourg), Brazil, Canada, Ceylon, Chile, Colombia, Denmark, Finland, France, Federal Republic of Germany, Greece, India, Ireland, Israel, Italy, Japan, Libya, Mauritius, Mexico, Netherlands, New Zealand, Norway, Pakistan, Paraguay, Peru, Philippines, Portugal, South Africa, Spain, Surinam, Sweden, Switzerland, Syria, Taiwan, Turkey, United Arab Republic, United Kingdom, United States, Venezuela, and Yugoslavia. Data for 1970 and 1975 are available from the author on request.

The following countries are dropped from the complete sample: in 1975: France, India, Mauritius, Paraguay, Philippines, South Africa, Surinam, and Taiwan; in 1970: Mauritius, Paraguay, and Surinam; in 1965: Ceylon, Libya, Mauritius, Paraguay, Surinam, Switzerland, and Yugoslavia; in 1960: Libya, Pakistan, Paraguay, Portgual, Surinam, and Yugoslavia; in 1955: Ceylon, Libya, Mauritius, Paraguay, South Africa, Surinam, Switzerland, and Yugoslavia.

and engineers engaged in research and experimental development of agriculture (per ten thousand male farmers) was used to replace the variable *TE* previously defined in the data section. In the 1970 regressions using this new measure, education coefficients are not significantly different from zero.

The estimation for the 1975 agricultural production function is reported in column 1, table 1. Although the sum of coefficients for all conventional inputs is still very close to unity, it is important to observe that the coefficient for fertilizer has declined to a level which is statistically zero while that for machinery has increased considerably from .133 to .312. One also notes that the coefficient for general education is no longer statistically significant, while that for technical education has been raised to a higher level. Obviously, one would be interested to know whether or not the changes in the regression coefficients for various independent variables mentioned in the preceding discussion are of any statistical significance.

Because the production function is nearly linearly homogeneous, it can be easily shown that the coefficients appearing in columns 1, 2, and 3 are obtainable by running appropriate regressions on the basis of per worker levels. The dependent variable would be per worker output, Y/N; and the explanatory variables would be (A/N), (L/N), (F/N), (M/N), GE, and TE. Similarly, one can obtain almost identical estimates for the coefficients α_i's by working with the variables defined in terms of per area unit levels. We have chosen the latter approach because we believe that it lends itself to some interesting interpretations regarding the process of agricultural development.

Columns 7 and 8 report the empirical results of the estimation of the production function on the per-area unit basis. As can be readily verified, the

coefficients appearing in 7 and 8 are similar to those in 1 and 3. They are exactly identical if $\alpha_2 + \alpha_3 + \alpha_4 + \alpha_5 + \alpha_6 = 1$.

The remaining equations in table 1 are designed mainly for the purpose of the covariance analysis. Columns 9 and 11 show the estimation of the pooled sample which consists of the data for the whole period of 1955–60–65–70–75. Note that columns 4, 9, and 11 are estimated with the constraint that all slope coefficients as well as the intercept are unchanged over the whole period under consideration. On the other hand, the estimation reported in columns 5, 6, 10, and 12 are obtained by imposing the constraint of slope homogeneity while allowing the intercept to vary freely. The dummies for 1960, 1965, 1970, and 1975 thus are included in the set of the independent variables in these equations. Interestingly, the coefficients corresponding to the dummy variables *D*65, *D*70, and *D*75 are all statistically smaller than zero. The immediate implication of this result concerning technological progress in agriculture seems to be that the agricultural production function has shifted downward over time. However, in an attempt to interpret this particular finding, one should note that while the coefficients of the time dummies for 1965, 1970, and 1975 are consistently negative, they are estimated with the assumption of homogeneity in the slope coefficients, an assumption which cannot be justified a priori. Thus, in order to examine the possible shift in the intercept of the production function, one would need a complete analysis of covariance to which we now turn.

The Stability of the Agricultural Production Function

The test for stability of the agricultural production function over the whole period of 1955–60–65–70–75 is based on the analysis of covariance, results of which are summarized in table 2A. The first part of the table reports the test, whether there is any difference in the intercepts of the five groups of production functions (each group corresponds to each year in the whole period). The second part is the test for the homogeneity of the slope coefficients of those groups. S_4 in the table is obtained by fitting a separate regression to the data for each group of production functions and then summing the residual sum of squares over all groups. Finally, the third part of the analysis of covariance is derived to test the homogeneity of the overall relationship (intercepts and slopes) over all groups of production functions.

The low values of the *F*-ratios (F_1, F_2, and F_3) indicate that the agricultural production function as a whole is still stable over time. Thus, one would not reject the null hypothesis that the intercepts of

Sample size: 183; S.E. = .284; *R*-squared = .951.

Note: For convenience, the following notation is used: $Y_a = Y/A$; $N_a = N/A$; etc. . . .

[a] This equation is of the log-linear form; *t*-statistics are reported in parentheses.

the separate groups of production functions are not different from each other. Neither would one be able to reject the null hypothesis that the vectors of slope coefficients as a whole are the same among the groups.

However, one should be careful in interpreting these results. While the F_1-ratio is calculated to test the null hypothesis that the intercepts of different equations are all equal, it fails to help us determine whether or not one intercept is statistically different from another. Similarly, the low value of F_2 in table 2A would not eliminate the possibility that some of the coefficients for the production function may have shifted over time.

Results for a regression in which all the intercepts and slope coefficients are allowed to vary are reported in the equation in table 2B. The notation makes it clear that the estimation was obtained on the basis of per area unit levels. A number of interesting observations can be made about this equation. In comparison to the 1955 intercept, the intercepts for later periods appear to be fluctuating around it but do not seem to show any sign of systematic divergence. This result contradicts those reported in columns 10 and 12 of table 1, where all the time dummies for 1965, 1970, and 1975 are statistically smaller than zero. Recall that we have warned against using columns 10 and 12 for an economic interpretation concerning technological progress in agriculture.

Another important point in the equation in table 2B is the significant difference between the machinery-land ratio coefficient in the year 1975 compared to 1955. One should note that the shift in the machinery coefficient has been positive throughout the period, with the highest level attained in 1975. Finally, from the viewpoint of the history of the agricultural development process, it would be interesting to observe the consistent movement of the coefficients associated with the farmer-land ratio variable. Although all of these coefficients are not different from the 1955 coefficient in the statistical sense, there is little doubt about their uniformly negative trend over the period under examination. This particular result seems to be quite consistent with the well-known proposition that the agricultural development process would eventually reduce the number of active farmers per unit of land, and hence the contribution of farm labor in agricultural producing activities. Thus, it does not seem to be a coincidence to observe the opposite directions in which the machinery-land and the farmer-land coefficients have changed.

Concluding Remarks

Our estimation of the production function for both 1970 and 1975 suggests that constant returns to scale still prevailed in the agricultural production pattern. The use of the variable *GE*1, which serves as a proxy for general education, does not seem to indicate a reasonable contribution of general knowledge to the process of agricultural production. On the other hand, the variable *GE*2 shows the positive role of general education in increasing agricultural productivity. Since *GE*2 is defined to be the enrollment ratio for the secondary levels only, this finding may have the policy implication that education at the high school and college levels must be expanded.

The impact of technical knowledge in agricultural sciences on agricultural production requires an additional comment. The coefficients for *TE*, defined to be the number of graduates from agricultural colleges per 10,000 male farmers, are significantly greater than zero throughout. This indicates a positive contribution of this form of human capital in producing agricultural output. On the other hand, the regressions with an alternative measure for technical education, defined to be the number of scientists and engineers engaged in research and experimental development in agriculture, gave insignificant coefficients for technical knowledge. This difference may have something to do with the question of whether basic research or adaptive research is more relevant in the context of agricultural development. This result of our study seems to suggest that the latter type is more relevant since to a large extent, this type may be represented by the variable *TE* in the production function.

The analysis of variance does not completely conform to our expectation regarding the likely instability of the production function over time which was, we thought, due to the emergence of the Green Revolution as well as to the new developments of agricultural science in the second half of the sixties. We tend to speculate here that, while new developments and technology may have altered the pattern of the agricultural production function, their real effect was implicitly realized through the behavior of the conventional and nonconventional inputs as specified in the production function. More specifically, we are able to detect an upward shift over time in the coefficients associated with the farm machinery-land ratio variable, together with a much less clearly downward shift in those corresponding to the farmer-land ratio variable. It is suggested that the effect of farm mechanization in the process of agricultural development may well have been accounted for on the basis of our study.

The Economics of Adopting Solar Energy Systems for Crop Irrigation: Comment

J. Walter Milon

In a recent article, Katzman and Matlin (KM) present a parametric analysis of the viability of solar photovoltaic systems for meeting crop irrigation energy demands. KM can be commended for developing an analytical model flexible enough to evaluate the considerable uncertainty surrounding solar technology and for pointing out potential applications. However, their analysis obfuscates the distinction between social and private benefits. The proper definition of these benefits has important implications for determining the viability of photovoltaic systems and public policy toward alternative energy systems.

KM define the energy-related social benefits as the difference between farm energy demands for conventional fuels with and without solar photovoltaic power generation—equation (5). Except for an additional tax adjustment, the same definition is used in calculating the private benefits—equation (7). Assuming, as KM do in equation (4), that the photovoltaic performance is reliable enough to eliminate the need for an auxiliary system using conventional fuels (diesel, gas, etc.), the social and private benefits are equal. However, if the photovoltaic system interfaces with an electric power grid using a traditional tariff schedule based on the average cost of service, the benefits are not equivalent. Williamson and Panzar have proved that the welfare-maximizing price for electricity is equal to the electric system's marginal cost. Since electric utility generating plants are used in order of their running efficiency, the system-wide marginal cost curve is upward sloping (Wenders). As a result, the timing and magnitude of changes in the utility's load curve will influence significantly the social benefits from interfacing photovoltaic systems.

Letting *CFX* be the social and private benefits defined by KM and *CFY* the welfare-maximizing price, we can identify some important policy considerations. In areas where farm electricity demand is coincident with system peak demand, photovoltaic generation will substitute for high variable cost (low fixed cost) peaking equipment. As a result, *CFY* will be greater than *CFX*, and social viability may precede commercial viability. An integrated design of photovoltaic systems, storage capability, and regional load-leveling centers could increase substantially the delivery efficiency of the power system. In this situation, public policy should encourage photovoltaic or other alternative energy systems through tax incentives or subsidies.

On the other hand, if farm electricity demand occurs during system off-peak periods when utility energy is least expensive, *CFY* will be less than *CFX* and private viability will precede social viability by a longer period than that suggested by KM (table 1). Under a traditional tariff schedule, a redistribution of income from nonsolar to solar customers would occur as the nonsolar customers compensate for the decline in utility revenue (assuming a constant return to equity regulatory constraint). As suggested by Asbury and Mueller, proper public policy in these regions would encourage power storage systems using the inexpensive off-peak electricity instead of increasing capital investment through acquisition of photovoltaic systems.

The rate design standards outlined in the Public Utility Regulatory Policies Act of 1978 would, if implemented, mitigate the distinction between social and private benefits discussed here. However, the voluntary nature of these guidelines implies that compliance will be slow. The studies cited by Kelly indicate that there are significant regional differences between the performance characteristics of photovoltaic systems. The framework suggested by KM for determining the optimum investment in photovoltaic systems cannot be considered correct unless the proper distinction between social and private benefits is realized.

The Economics of Adopting Solar Energy Systems for Crop Irrigation: Reply

Martin T. Katzman and Ronald W. Matlin

The purpose of our essay was to provide a flexible methodology for evaluating solar technologies in irrigation, with particular attention to identifying the parameters that have the greatest impact on profitability. To avoid complications such as regional variations in sources of power or current tariff structures, the analysis was perhaps more institution-free than some readers would prefer. The solar photovoltaic-power system was compared to a conventional one with onsite generation, a common condition in Texas, Nebraska, and New Mexico. The irrigation benefits were defined as the asymptotic world price of fuel rather than any prices derived from existing tariffs. These asymptotic fuel costs reflect fairly well the marginal social costs of irrigation. Thus, we take exception to the commentator's statement that our framework for determining the optimum period of investment in photovoltaic systems cannot be considered correct.

We welcome Milon's extension of our analysis to conventional irrigation systems powered by the central grid, the common situation in Arizona and California. As Milon shows, calculating social and private benefits is more complicated than under our conditions of on-site generation.

Without performing the calculations, one cannot say whether variations in pricing schemes, under any load-curve characteristics, have as decisive an impact on the viability of solar photovoltaic systems as, say, variations in fuel escalation rates or the cost curve of the array. Anticipating load-curve characteristics or the implementation of the Public Utility Regulatory Policies Act in the 1980s and 1990s in particular regions seems beyond our modest capacities; however, as we approach these years, the calculations suggested by Milon should be undertaken before adopting solar systems in particular circumstances.

Contrary to Milon's statement in paragraph two, social and private benefits are never equal. Depreciation and allowances, investment tax credits, and income taxes result in lower gross and net private benefits than social benefits.

Oligopoly Pricing in the World Wheat Market: Comment

Thomas Grennes and Paul R. Johnson

Alaouze, Watson, and Sturgess (AWS) have recently revived the argument that the world wheat market is oligopolistic. McCalla described the market as a United States-Canadian duopoly, and the innovation of AWS is to convert the club into a triopoly by adding Australia. We are generally skeptical about the ability of oligopoly models to explain the behavior of world wheat prices, and oligopoly appears especially inappropriate in view of events since 1971. We offer two comments concerning the AWS paper. First, variation in market structure is dominated by other variables in terms of explaining the actual variation in wheat prices. Second, the logic of the triopoly model presented by AWS has several shortcomings.

The World Wheat Market as an Oligopoly

The characterization of the wheat market as oligopolistic is motivated by two undeniable facts: (*a*) the large shares of United States and Canadian firms in export markets, and (*b*) historical attempts of major exporters to collude. McCalla alluded to meetings between the United States and Canada, and AWS refer to meetings between those two countries and Australia as evidence of duopoly and triopoly, respectively. Attempted collusion by wheat exporters is not in dispute, because there has been a continuous and overt effort to implement the various international wheat agreements since the 1930s, and a new agreement was being negotiated in early 1979. However, as empirical studies in industrial organization have shown, the desire by firms or governments to collude is not sufficient to achieve a price in excess of marginal cost. One of the reasons that the Organization of Petroleum Exporting Countries (OPEC) has fascinated economists is that its success in disciplining member states contrasts so sharply with the failure of other commodity agreements; international wheat agreements have been notable for their failure to keep prices within the agreed range (Behrman). Because substantial barriers to wheat trade result in price differences across countries, the notion of a world wheat price is somewhat ambiguous. We interpret the U.S. price as the best index of a world price because it is the largest exporter and the U.S. government has imposed the least trade controls (see Grennes, Johnson, Thursby, 1978a, chap. 7–8). The behavior of wheat prices since 1971 is dramatic evidence of lack of oligopoly discipline (see table 1). AWS refer to a stable oligopoly prior to 1972 (p. 173), but they neglect the fact that real wheat prices (money prices deflated by the consumer price index) stabilized in the three previous years at the lowest level since 1932. AWS offer a curious interpretation of wheat prices after 1972. "Since 1972, the world wheat market has been characterized by high, unstable prices and low carryover stocks, indicating that the market has been operating essentially competitively" (AWS, p. 173). There are two problems with this statement. First, prices have not been high since 1972. They increased sharply in 1973 (doubling in one year); but they also declined quickly, so that by May 1977, prices had returned to Great Depression levels ($2.33 in current dollars or $1.30 in 1967 dollars). By the end of 1978, prices had increased slightly to the neighborhood of $1.70; but real wheat prices in 1977 and summer 1978 averaged less than 90% of the previous forty-four years. Substantial inventory accumulation has prevented a larger price decline. The second problem with the above statement is that the sharp price increase in 1973 is hardly convincing evidence that a stable oligopoly had deteriorated into a competitive price war.

Oligopoly is a market structure lying somewhere between competition and monopoly. Presumably those observers who stress lack of competition describe the wheat market as oligopolistic rather than monopolistic because of the number of producers and the periodic occurrence of price wars.[1] However, the more frequently price wars occur, the closer is price to marginal cost, and the more closely the wheat market approaches competitive conditions. Our interpretation of the data is that price cutting has dominated monopoly pricing and that oligopoly is not a useful description of the wheat market. An example of this price behavior is the failure to enforce the minimum price provisions of the International Wheat Agreement. The trend of real wheat prices has been downward since 1947,

Thomas Grennes and Paul R. Johnson are associate professor and professor, respectively, in the Department of Economics and Business, North Carolina State University.

Paper 5881 of the Journal Series of the North Carolina Agricultural Experiment Station, Raleigh.

[1] "We interpret the price wars as indicating an unstable duopoly situation because of the actual or potential erosion of one or both of the market shares of the duopolists by other exporters" (AWS, p. 175). If the duopoly is frequently unstable, there is not much of an excess of price over marginal cost for the duopoly model to explain.

Table 1. U.S. Wheat Prices for Selected Years, 1913–78

Crop year	Current Dollars per Bushel	1967 Dollars per Bushel	Crop Year	Current Dollars per Bushel	1967 Dollars per Bushel
1913	.88	2.96	1957	2.20	2.61
1915	1.29	4.24	1958	2.03	2.34
1917	2.30	5.99	1959	1.98	2.27
1919	2.42	4.67	1960	1.99	2.24
1921	1.33	2.48	1961	2.01	2.24
1923	1.11	2.17	1963	2.18	2.38
1926	1.50	2.83	1964	1.88	2.02
1930	.90	1.80	1965	1.56	1.65
1932	.49	1.20	1966	1.79	1.84
1935	1.04	2.53	1967	1.67	1.67
1939	.76	1.83	1968	1.47	1.41
1944	1.60	3.04	1969	1.39	1.27
1947	2.60	3.89	1970	1.48	1.27
1949	2.15	3.01	1971	1.60	1.32
1950	2.23	3.09	1972	2.26	1.80
1951	2.40	3.08	1973	4.83	3.63
1952	2.39	3.01	1974	4.29	2.90
1953	2.24	2.80	1975	4.08	2.53
1954	2.31	2.87	1976	2.88	1.69
1955	2.26	2.82	1977	2.72	1.50
1956	2.22	2.73	1978[a]	3.44	1.72

[a] 8 Dec. 1978.

and the sharp fluctuation of prices in the 1970s cannot plausibly be explained by changes in market structure.

One can describe the world wheat market as approximately competitive without implying that it is efficient in the sense of Pareto. It is well known that the wheat market is heavily regulated by governments at all levels of activity, and many of these regulations result in misallocation of resources. Nevertheless, many regulations, such as tariffs, price supports, and production quotas, can be represented by competitive models (Grennes, Johnson, Thursby 1978a, Chap. 4; Schmitz and Bawden) while achieving satisfactory empirical results. Thus, the existence of policy-induced distortions in the wheat market does not preclude positive economic analysis based on competitive models.

We find that variation in world wheat prices is better explained by government policy than by changes in market structure, but the two explanations are not unrelated (Johnson, Grennes, Thursby). When government policy calls for export restriction, the resulting increase in the foreign price is consistent with oligopoly behavior by exporting countries. However, when policy calls for export promotion, the resulting price decline violates oligopoly behavior. Our interpretation of policy is that governments restrict or promote wheat exports depending on their domestic agricultural goals rather than trying to maximize national income from wheat exports which would result from oligopoly pricing. A domestic wheat price above the competitive level has been a traditional U.S. policy goal, and export promotion has been a technique for achieving this goal without resorting to direct payments, larger inventories, or production controls. Export promotion has taken many forms including concessionary sales, export subsidies for commercial sales, subsidized export credit, or increasing export quotas. Wheat boards may accomplish this more directly by quietly increasing the amount of wheat offered to the export market or raising the price to domestic buyers. The dominance of domestic policy goals in agricultural trade policy has been stressed for decades by D. Gale Johnson, and evidence from the 1970s continues to support that hypothesis. One of the reasons that oil is a more effective cartel than wheat is that OPEC can restrict oil exports without complaints from domestic producers, but the USDA cannot restrict wheat exports without strong resistance from U.S. wheat farmers. (Recall the discussion of the U.S. "grain embargo" during the 1976 presidential election.) Thus the dominance of domestic policy goals erodes the potential oligopoly power of the major exporters. During periods of downward pressure on world wheat prices, U.S. policy has tended to liberalize Public Law 480 shipments, increase export subsidies (recall the USSR's Great Grain Robbery of 1972), and promote market development. (Greater sales to the People's Republic of China is a prominent goal of the U.S. Agricultural Trade Act of 1978.) These and similar policies have resulted in an export volume which has depressed wheat prices below oligopoly levels.

Shortcomings of the AWS Triopoly Model

Because the AWS triopoly model is vaguely specified, it is not easy to interpret. If loosely interpreted, it cannot be distinguished from competition and if strictly interpreted the model contains logical errors. What distinguishes the AWS contribution from McCalla is the claim that a three-country oligopoly explains more than a two-country oligopoly, but they offer little evidence as to why a quadropoly, for example, would not provide even more explanatory power than a triopoly. In terms of export volume the United States, Canada, and Australia are the largest national exporters, but Western Europe exported more than Australia in crop year 1978–79 (*Wheat Situation*, Nov. 1978), Argentine exports cannot be ignored, and the USSR has been an important exporter until recently. AWS cite a meeting between U.S., Canadian, and Australian officials as evidence of three-country collusion, but there has been continuous contact for years involving a larger group of countries under the au-

spices of the various wheat agreements (a new agreement is currently being negotiated). Their emphasis on the independence of the triopoly leads AWS to refer to the "exportable surplus" of fringe exporters as if this were a fixed amount independent of the triopoly price. Theory and evidence indicate that both the excess supply of other exporters and import demand are responsive to the triopoly price, and the effect is to increase the elasticity of demand facing the three. A related point concerns the optimum triopoly price. AWS state (p. 184) that the triopoly price is greater than the duopoly price, which suggests that adding countries to an oligopoly raises the optimum price. If this is generalizable, then the competitive price (n-opoly?) should exceed the monopoly price, which is an implication contrary to received doctrine. Thus, AWS have not established the superiority of triopoly over either smaller or larger oligopolies.

A second shortcoming concerns the object of the wheat oligopoly. If members were private firms, profits would be the natural object, but government marketing boards and the USDA are not profit-making institutions, and they frequently pursue policies which lower the national income in order to transfer income to particular domestic groups. As mentioned above, when domestic policy goals conflict with oligopoly discipline, the latter tends to be sacrificed. AWS are vague about oligopoly objectives, mentioning maximum revenue (p. 179), stable market shares (p. 175), and maximum exports (p. 174). Costs are ignored as if they were irrelevant or equal for all triopolists, but how can one explain the observed differences in market shares unless costs are different?

Even if the triopolists agreed on an objective, how would they enforce the arrangement? Export or production controls would be required for members, and nonmembers must be discouraged from growing more wheat. Since the industry is characterized by many firms with easy entry, enforcement is a problem.[2] AWS concede that price cutting is difficult to detect because of the many grades of wheat (p. 176), although at another point they assert that wheat is a homogeneous good (p. 174). In either case the triopoly has a problem because heterogeneous wheat causes an enforcement problem and homogeneous wheat increases the elasticity of demand facing the three.

Inventories and stable market shares are said to play an important role in the triopoly model (pp. 181–82), but it is difficult to determine from the discussion of AWS how observations on these variables permit one to distinguish triopoly from competition. For example, the class of constant market share trade models (Leamer and Stern) assumes competitive markets, and those models have the property that market shares remain constant unless relative prices change. What distinguishes competitive from noncompetitive behavior is price relative to marginal cost, and that relationship does not restrict market shares. Stable market shares are consistent with a small total market where price exceeds marginal cost or a larger competitive market where price equals marginal cost.

AWS claim that willingness and ability to hold inventories is a measure of monopoly power (p. 181). The literature on inventories is based on uncertainty about future prices, and most of the work dealing with how hedgers and speculators react to uncertainty assumes competitive markets (see, e.g., Telser on the demand for storage). AWS argue that the depletion of wheat stocks in 1971 caused the triopolists to lose their market power (p. 182). Curiously this erosion of market power resulted in real wheat prices rising to the highest level since 1947. Neither is there much evidence of renewed potency of the oligopoly as stocks have accumulated recently. AWS expect the variability of wheat prices to depend on the level of triopoly inventories (p. 184), but the same relationship holds for competitive conditions. Thus, inventory behavior provides no discriminatory power with respect to market structure.

Despite some descriptive appeal, the class of oligopoly models fails to explain the pattern of world wheat prices, especially in the 1970s. An alternative explanation, in addition to the vicissitudes of nature, is foreign trade policy as determined by domestic agricultural goals. In terms of future research, we would expect a larger payoff to modeling the interdependence of national trade policies than to formulating more complex oligopoly models.

[*Received September 1978; revision accepted April 1979.*]

[2] The discussion of the structure of international wheat trade frequently takes the nation as the appropriate trading unit. This may be proper for countries with state trade monopolies but in the United States wheat is traded by private firms. For a study of the industrial structure of private grain trade, see Richard E. Caves.

Oligopoly Pricing in the World Wheat Market: Reply

Chris M. Alaouze, A. S. Watson, and N. H. Sturgess

Grennes and Johnson (GJ) have criticized our recent paper "Oligopoly Pricing in the World Wheat Market" on several grounds, some of which suggest that they have misunderstood our triopoly model. In this reply we attempt to answer their major points of disagreement and at the same time reemphasize the essential points of our original paper.

In the first instance, we reject comparisons of our paper with results from "empirical studies in industrial organization" or recent experience with oil prices. Our paper was concerned with the year-by-year selling and storage decisions of statutory authorities in Canada and Australia and the analogous problem confronted by the United States—although its essential similarity is masked by the different price support and regulatory mechanisms that have been used. In this sense, to seek "to achieve a price in excess of marginal cost" has nothing to do with the problem at hand. Our analysis is in the spirit of the stock period, as defined by Schultz, when "once the crop is harvested, one is necessarily restricted to the particular stock until the next crop becomes available."

Nowhere in the Alaouze, Watson, and Sturgess (AWS) article is it stated that the triopoly is always operating. In fact, the point of our exercise was to demonstrate how different market structures could eventuate in response to different supply and demand situations over time. Necessary conditions for the formation of the triopoly are outlined (p. 183), and these clearly are not satisfied by the demand and supply conditions of the 1972/73 season. Lack of "oligopoly discipline" plays no part in the breakdown of triopoly pricing. Supply and demand do.

The real wheat prices (table 1) by which GJ judge price levels are not relevant to the analysis because the AWS paper sets out to explain nominal prices. It also should be noted that the nominal price series in table 1 of the GJ paper does support our statement that prices have been high and unstable since 1971 (as compared with preceding years) and that at the time of publication of the AWS paper (May 1978) prices were declining. We must confess, however, that we have an antipodean perception of the course of wheat prices over the 1970s because we think (most of the time) in Australian currency terms. Even if they were relevant, an Australian series of real wheat prices would look very different from those in table 1 of GJ.

GJ argue that oligopoly is not a useful description of the wheat market. The major evidence cited for this conclusion is that the minimum price provisions of the International Wheat Agreement were not enforced. In response, we would like to point out that we provided evidence that the triopoly was operating in the 1968/69 season at prices below the minimum price provisions of the International Grains Arrangement then in operation. Incidentally, the minimum price provisions of the International Grains Arrangement were set (on average) 19¢ per bushel higher than those of the preceding International Wheat Agreement (AWS pp. 176–77). There is no requirement for realism on the part of the participants when drafting international commodity arrangements. We note, however, that subsequent international grain arrangements have not specified minimum prices.

We agree that "the wheat market is heavily regulated by governments at all levels of activity." GJ prefer to represent the pricing outcomes that occur in the wake of these extensive regulations as "approximately competitive." In the world wheat market as we understand it, there are few sellers, there are frequently large publicly held stocks (or private stocks induced by public pricing policies), and there are government-to-government sales. We cannot regard this as "approximately competitive." However, we do not view the intermittent situations which we believe can be interpreted with oligopolistic models in the way that GJ have attributed to us. We do not regard "variation in wheat prices" as being explained by "changes in market structure." Rather, changes in behavior and in market structure are explained by changes in supply and demand in the world wheat market.

GJ have described policies of export promotion which, they argue, depress prices and contradict oligopoly behavior. Such policies include concessionary sales (dumping?), export subsidies for commercial sales, subsidized export credit, and increasing export quotas. We believe these are practices usually associated with less-than-perfect competition. Regrettably, we cannot comment on references to disputes over U.S. grain policies during U.S. presidential elections; nor can we see the relevance to anything in our paper of the passing reference by GJ to the "USSR's Great Grain Robbery of

---

Chris M. Alaouze is a teaching assistant in the Department of Economics, University of Wisconsin, formerly at the University of Melbourne. A. S. Watson and N. H. Sturgess are senior lecturers in agricultural economics at the University of Melbourne.

1972" except that we would point out that we are fully aware that the ambitions of those who seek to regulate markets are not always fulfilled.

In their discussion of the shortcomings of our model, GJ suggest that it is derived from McCalla. In fact, we have attempted to generalize Taplin's model. The extension of our model to a fourth country, such as Argentina, would be straightforward. In any case, we see a clear difference between the situation of the wheat exporting countries and the EEC and USSR. The EEC trades most of its wheat among member countries, which we would not regard as "exports" and occasionally sells (dumps) wheat on the world market. USSR trade is highly volatile while Argentina's trade is small relative to the three major exporters.

GJ confused the discussion on p. 184 of our paper concerning optimal triopoly and oligopoly prices. In our model, the more countries that combine to set prices the closer the situation is to monopoly rather than to competition as suggested by GJ. If countries were "added" to the oligopoly, the residual demand curve facing this new oligopoly would shift outwards. If all countries were added, the residual demand curve facing them would be the industry demand curve. This n-opoly would act as a pure monopolist along the industry demand curve.

We cannot defend ourselves against the charge that we are "vague about oligopoly objectives" because we believe that the weightings given to revenue, market shares, and exports as objectives by individual countries will change over time. Whatever the mix of objectives favored by the major wheat exporting countries, we fail to see how "costs" are relevant, in whatever sense is intended by GJ.

GJ have questioned the enforcement of a triopoly arrangement. We would not suggest that a neat and tidy arrangement could exist or has existed in the past. We note, however, that at various times the principal wheat exporting countries have used production controls and maintained substantial stocks. We dispute that "the industry is characterized by many firms with easy entry" for reasons clear from the above. We could note that our paper arose from the attempt to explain high Australian stocks from 1969 to 1971. Do GJ believe that the policies of stock holding and production quotas pursued by Australia were the sorts of policies that would have been pursued in an "approximately competitive" world wheat market? With respect to "easy entry," if another country starts to become important (as Australia started to be in the late 1960s) then they could be absorbed into the oligopoly. When high wheat stocks exist, threats of price cutting would encourage expanding producers of wheat to join the cartel.

GJ argue that it is difficult to determine from our discussion how observations on inventories and market shares permit our readers to distinguish triopoly from competition. As it happens, our paper on oligopoly in the world wheat market developed from another study (Alaouze, Sturgess, Watson 1978) in which we studied the inventory problem confronting the Australian Wheat Board. Two models were available for the demand side of the model. First, the duopoly models of McCalla and Taplin which led to the conclusion that the demand for Australian wheat was infinitely elastic at the world price. Second, the competitive model in which the elasticity of demand for Australian wheat would be computed using the market share formula—a calculation similar to the application of this formula outlined in AWS (p. 181). Both approaches would have concluded that the demand for Australian wheat exports was elastic. However, the following facts: the 7.2 million tonne Australian carryover in the 1968/69 and 1969/70 seasons, the accompanying silo construction program, and the threat of a price war in 1968/69 (AWS pp. 176–177) were inconsistent with an elastic demand for Australian wheat exports in those seasons, given that the Australian Wheat Board had previously pursued a policy of selling its exportable surplus. Therefore, we were led to reject the two duopoly models and the competitive model as an adequate description of pricing in the world wheat markets after the 1968/69 season.

Furthermore, GJ's criticism of our interpretation of inventories and market shares is based on published works which address issues unrelated to that under discussion. First, their reference to the Leamer-Stern (two-country) model is misleading. The Leamer-Stern market-share model implies a highly stylized supply function in which the supply of a particular good is completely determined by the price of that good alone. Therefore, constant crises imply constant market shares. The market-share equation on which their model is based implies the even stronger assumption that market shares are constant when the selling price ratio is constant. This paradigm clearly is not applicable to commodities such as grain which are typically produced by multiproduct firms using many factors of production. The Leamer-Stern model also ignores yield-induced variations in production. Second, the statement that "most of the work dealing with how hedgers and speculators react to uncertainty assume competitive markets" is irrelevant to the question of the actual structure of the world wheat market.

In conclusion, GJ state that "the class of oligopoly model fails to explain the pattern of world wheat prices, especially in the 1970s." The analysis of our paper included the use of the model to show how the triopoly can break down when faced with an episodic increase in demand (as occurred in the 1972/73 season) (AWS pp. 182–84). Therefore, we are being criticized for a claim we would not make for our work.

Books Reviewed

Bell, Frederick W. *Food from the Sea: The Economics & Politics of Ocean Fisheries*. Westview Special Studies in Natural Resources and Energy Management. Boulder, Colo.: Westview Press, 1978, xxvi + 380 pp., $25.00, $12.00 paper.

Since the U.S. Congress voted to extend the country's exclusive fishing zone to 200 miles in 1976, interest in the fishing industry has grown considerably. Investors and fishermen are eager to cash in on the expected bonanza when fish stocks return to abundance after concentrated fishing by foreign fleets stops. The management of these fisheries resources present interesting problems to both theoretical and applied economists. With the additional interest in fisheries stimulated by the current Law of the Sea negotiations, the time is right for a comprehensive text on the economies and politics of ocean fisheries.

Frederick Bell, active in fisheries economics research for many years, provides in this book a useful presentation of the basic economic analysis of fisheries and of some of the management strategies used and proposed. As well as explaining supply and demand for fisheries products and basic economic analysis for the firm and the industry, Bell examines the potential contributions of aquaculture and underutilized fishery resources to fish supplies. He includes a chapter on recreational fishing which covers standard economic approaches to the valuation of recreational fishing. The problems of applying effective fisheries management and the role of national governments and international commissions in fisheries management are discussed in other chapters. Inclusion of a chapter on the effects of environmental deterioration on fishery resources is unusual but wise; for anadromous species (such as salmon) and for sedentary shellfish (such as oysters), pollution has further depleted stocks which have been severely overfished.

Since the book was written—apparently before 1977—rapid changes have taken place in many U.S. fisheries. Particularly in New England, earnings of fishermen, investment in new boats and restriction of fisheries management have radically altered the economic situation of the fishing industry from that pictured in Bell's book. However, this change provides a foil for the instructor to illustrate how economic incentives alter exploitation patterns. The text's presentation of basic economic analysis in fisheries remains applicable, and Bell's points about the incentives to overexploit a common property resource and about the failings of traditional management techniques are demonstrated anew by current developments in the traditional fisheries.

The book contains some misrepresentations. For example, tuna (a highly migratory species) is explicitly excluded from regulation under the Fisheries Conservation and Management Act. The section on bioeconomic modeling is necessarily limited in its scope; the more interested student should obtain information on more current and complex modeling developments from Lee Anderson or, on a more advanced level, Colin Clark. The author's prose is reasonably clear, though punctuated by curious excursions into levity. These reservations are relatively minor and do not mar the book's basic usefulness.

The book should be useful as an undergraduate text for introductory courses in natural resource economies or fisheries economics. However, some of the economic analysis may be demanding for students with no previous economics, so the instructor should be selective in assigning sections of the book. The comprehensive discussion of applied aspects of fisheries economics provides a review of some basic facts about world fisheries and discusses the economics of various U.S. fisheries in particular; those engaged in fisheries management may find the book a convenient reference for these facts. A few additional tables listing, for example, the various international fisheries commissions, would have greatly improved the book's usefulness as a reference.

This book deserves attention during this time of rapid development of U.S. fisheries management policy, a time when the economic and social aspects of fisheries management are the object of more careful and systematic attention than ever before.

Binswanger, Hans P. *The Economics of Tractors in South Asia—An Analytical Review*. New York: Agricultural Development Council, and Hyderabad, India: International Crop Research Institute for the Semi-Arid Tropics, 1978, 96 pp., price unknown.

The book under review is devoted mainly to the

scope of tractorization in South Asia. The use of tractors in low wage countries has been the center of one of the most virulent and emotional choice-of-techniques debates for the past twenty years. The author has tried to make an analytical review of the scope of tractorization as it is related to agro-climatic, social, labor employment, and economic factors. The benefit of tractors has been discussed from two apparently contradictory views. The substitution view looks at tractors and animals as two power sources which are technically perfect substitutes. The opportunity costs of labor and bullocks have been compared with tractors, also taking into account social and economic aspects. The author also discusses the net contributory view of tractors on production, profit, timeliness, and labor employment aspects, using survey data to aid his discussion. He critically analyzes the benefit-cost relationship of the use of tractors in this part of the world.

After reviewing various empirical studies, the author concludes that tractors are not responsible for the substantial increase in intensity, yields, timeliness, and gross returns on farms in India, Pakistan, and Nepal. Benefit-cost studies also show that the use of tractors does not yield much benefit. Private returns to tractors from agricultural operations are close to zero, or even negative except in situations where area efforts are possible (by renting or buying) or in very semi-arid tracts.

The drudgery of farm work is reduced with the use of tractors, but, in an environment of stagnant or declining wages, although the loss of employment may relieve landless laborers of drudgery, it clearly will increase rather than reduce their overall sufferings. While the data show that tractor farms generally do not use less labor than do bullock farms, this may be due to increased productivity and higher capital use on tractor farms quite aside from the use of tractors per se.

The Economics of Tractors in South Asia is an excellent brief but critical review of numerous papers and reports published by renowned agricultural scientists, engineers, economists, and statisticians of the world at large and of Southeast Asian countries, in particular. The subject matter is presented clearly and the conclusions are argued well. However, the data collected through the survey methods have certain limitations, especially at the adoption stage of modern technology by farmers. The manner in which the author describes the limitations of the data derived from the survey reports which form the main source of reference for the book is much appreciated. It is the final conclusion of the book that tractorization in South Asia may not be of great benefit, taking into account the production, social, and economic aspects at the present stage of agro-socioeconomic conditions.

I wish to add a note from my own observations of the subject. Data obtained at research stations clearly show that tractors as a supplementary source of power will be required if cultivation is to be done on a scientific basis under irrigation. The Indian government is trying hard to increase the irrigated area, thereby cropping intensity certainly will increase. The increased cropping intensity will require more power to complete the job in comparatively less time than in monocropping. For existing farm technology, bullock power is sufficient, and that is one of the reasons that tractors are not profitable. However with the adoption of modern technology and the resultant higher cropping intensity, there will be need of more power. Experiments show that to accomplish farm work in a timely manner it is more economical to supplement power by using tractors rather than bullocks.

Granger, C. W. J., and Paul Newbold. *Forecasting Economic Time Series*. New York: Academic Press, 1977, xiii + 333 pp., $22.00.

The authors of this book, two distinguished statisticians with wide empirical and theoretical experience, are obviously well qualified to write such a text, and the end result of their collaboration is an excellent book which should prove an invaluable tool for econometricians interested in forecasting economic time series.

The first several chapters of the work cover the mathematical prerequisites for the text including a brief survey of the theory of difference equations, autoregressive processes, moving average processes, and mixed autoregressive integrated moving average processes. A brief, but excellent, survey of the methods of spectral analysis is contained in chapter 2. This chapter, however, appears to be extraneous to the main purposes of the text, because spectral techniques are dealt with only infrequently thereafter. As such, this chapter probably could be skipped without too much loss of continuity. Chapter 3 includes a concise discussion of the theory and practical methods of constructing linear time-series models. The remaining chapters deal with methods for forecasting economic time series and forecast evaluation.

The modeling methodology suggested by Granger and Newbold closely follows that proposed by Box and Jenkins in their various works on time series analysis, forecasting, and control. Especially important is the three-step iterative cycle strategy for constructing autoregressive integrated moving average models. The cycle consists of a model identification step, a model estimation step, and, finally, diagnostic checks on model adequacy. This technique allows the would-be model builder an excellent practical method of determining the adequacy of alternative models used to forecast economic time series.

From the forecasting point of view, Granger and Newbold go beyond Box-Jenkins methods by giving particular attention to the concept of combined

forecasting. As illustrations, they discuss the feasibility of combining forecasts generated by a Box-Jenkins type model with forecasts generated by a purely automatic prediction process, such as exponential smoothing, or by stepwise autoregression. By and large, however, the theory of estimation and forecasting presented within this text is fairly classical in nature; the authors rely heavily on the least squares criterion of estimation and evaluation of models for economic time series. Relatively little time has been spent on estimation and forecasting techniques based on alternative criteria which have received increasing attention in the recent statistics and econometrics literature. A particularly interesting example of such work is the recent book by Bibby and Toutenburg. Their analysis starts from the observation that classical statistical forecasting techniques usually are based on accurately estimating the expected value of the time series of concern. By constructing models predicated on estimating the actual value of the time series, Bibby and Toutenburg are able to derive what they term "improved" estimators and hence "improved" predictors. An example of such estimation and prediction procedures is the class of homogenous estimators and predictors. The optimal homogenous estimator in the general linear model can be shown to be a combination of the estimators obtained by the ridge regression procedure and generalized least squares. In many cases, these estimators will perform better than least squares estimators given a different criterion for evaluating model forecasts. This work can be closely aligned with that of Hoerl and Kennard and others on ridge regression and biased estimation. Incorporation of this material into the text by Granger and Newbold would have made an interesting bundle of tools for the practicing econometrician. Although it cannot be expected that authors include all that has been done in previous work, it is suggested that persons seriously interested in forecasting techniques consider complementing the text by Granger and Newbold with a text placing more emphasis on nonclassical procedures.

Granger and Newbold accomplish all of the objectives set forth in the introduction to this text. Not only do they accomplish objectives, but they do so in a manner most profitable to the reader. Any person interested in either the theory or practical aspects of forecasting economic time series would do well to avail himself of a copy of this book. The authors are to be lauded for both undertaking such a complex task and achieving such excellent results.

Bibby, John, and Helge Toutenburg. *Prediction and Improved Estimation in Linear Models*. New York: John Wiley & Sons, 1977.

Grennes, Thomas, Paul R. Johnson, and Marie Thursby. *The Economics of World Grain Trade*. New York: Praeger Publishers, 1978, 129 pp., $16.95.

World trade in grain is of special significance to the United States at this time in history. Concern over the balance of trade (and payments) situation, pressure to increase domestic grain prices, potential for expansion of exports to the Peoples' Republic of China, and uncertainty created by political instability in the Middle East have focused attention on the nature and behavior of international markets.

Thomas Grennes, Paul R. Johnson, and Marie Thursby provide a timely application of a reduced-form modeling approach for analyzing international trade in grain. A principal objective of the book is to demonstrate the usefulness of a model of this type in forecasting prices and in analyzing certain policy initiatives. It is worth noting that this objective is pursued in a strictly positive vein. That is, judgments regarding social welfare and equity implication of trade and trade policy are clearly avoided.

Chapters 1 and 2 provide an overview of the world grain economy and a historic review of trade relations and policy in trading grain. In general, chapter 1 identifies major wheat exporting and importing regions, historic production levels, and U.S. grain price movements. Chapter 2 lends a historic perspective to issues dealt with in later sections of the book. The authors briefly discuss major changes in grain trade policy, particularly from the U.S. perspective. Much of the policy outlined here and analyzed later relates to protectionist initiatives by various grain exporting nations.

Chapter 3 may well be one of the most valuable portions of this work, particularly for readers interested in questions of modeling methodology. In this chapter, the authors provide a concise, yet informative, evaluation of alternative techniques for modeling world grain trade. They review the relative merits of models ranging across the methodological spectrum from spatial equilibrium models to systems dynamics models. A brief discussion of the appropriate application of several modeling formats between these extremes is included. This chapter presents some interesting insights into tested modification of standard modeling techniques aimed at improving their usefulness in analysis of international trade.

Grennes, Johnson, and Thursby have chosen to use the Armington-IMF model for forecasting trade flows and price movements (chaps. 4, 5). The model is used to analyze the price and flow of impacts of changes induced from the supply side and from particular unilateral policy initiatives. Principally, the model is applied to the international wheat market. However, chapter 6 takes the reader through the model as adopted for trade in rice and coarse grains.

The Armington model is not without its faults.

First, several assumptions might be criticized as overly simplistic. This, however, is a perpetual problem encountered in modeling a market as complicated as that for international trade in grains. A more severe criticism of the model is that, in some respects, it fails to perform as well as a much more naive approach. The authors recognize and discuss its shortcomings.

No matter how one views the viability of the Armington model, it is important to note that the authors have attempted systematically and quantitatively to evaluate several trade policy alternatives (chaps. 7, 8). Herein lies the real significance of this book. It presents methodology to address very real and critical contemporary economic issues. The book can act as a departure point for those interested in pursuing additional econometric analysis of the world grain market.

Oregon State University

Hyer, Edgar A., and John A. Rogalla. *Farm Management*. San Luis Obispo, Calif.: Farm Management Publishing Co., 1978, viii + 271 pp., price unknown.

The authors seek to provide a textbook for standard principles of farm management courses. The implication is that this represents an introductory or first exposure farm management course. The book is divided into six parts: (*a*) Introduction—a historic treatment of American agriculture; (*b*) Measuring Financial Success—farm records and income measures; (*c*) Finding Strengths and Weaknesses—efficiency factors; (*d*) Changing the Farm—use of the farm budget and linear programming to evaluate economies of size, input combinations, and choice of enterprises; (*e*) Operating the Farm—management of labor, equipment, the acquisition of capital and input and product marketing; and (*f*) Public Influence in Farming—taxes, farm programs, and environmental and safety programs. The authors indicate that students with six quarter-hours of economics should be able to understand the economic concepts utilized.

There are some problems with using this book as a text in an introductory farm management course. As an example, chapter two considers farm record systems without providing illustrations or examples. This material will have little meaning to the student with no background in accounting. The authors state that the chapter is not complete enough for use in a separate farm records course. However, without illustrations and problems, the material will not be useful to most students. Other sections also lack adequate illustration of the concepts. Instructors adopting this text will find it necessary to provide a substantial number of illustrative examples and problem sets.

The farm records and analysis section (part 2) would have benefited from elaboration on analyzing changes over time. The very common act of "spreading" financial statements was not covered. Use of records as an ongoing control mechanism should be a part of any contemporary farm management textbook. Profit measures in this section and investment decisions in later parts of the book should be based on after-tax results. After-tax treatment was finally mentioned in chapter 14 under the discussion of milk quotas. The omission of "cash-flow" budgeting in the farm budget chapter is a serious exclusion considering the increasing importance of capital management in agriculture.

The inclusion of a chapter on linear programming is desirable, but the type of presentation could be improved. The uninitiated will not be able to follow the material and even those familiar with LP may find the chapter confusing.

Part 5 on operating the farm contains the four best management chapters of the book. The chapter on labor provides explicit treatment of managing with organized farm labor. The separation of obsolescence and use in treating depreciation is presented effectively in the machinery chapter. Failure to treat machinery replacement was a significant omission from this chapter. The capital management chapter would have been strengthened with some treatment of risk.

The part entitled "Public Influence in Farming" (part 4) added an important dimension missing from many farm management texts. The chapter on taxes was well done and covered both income and estate taxes. The authors were rather careful to avoid materials which could be invalidated by changes in IRS regulations. The chapter on farm programs provided a good example of use of budgets by a farmer in deciding upon participation or nonparticipation. The modest discussion of income distribution issues related to federal programs was good. The concluding chapter on environmental and safety regulations was a useful inclusion, but the authors need to be more careful of statements related to what farmers are permitted to do because of differences among state laws and regulations.

In summary, the book covers most of the correct topics at an introductory level. Classroom use will require extensive support in terms of illustrations and examples. There are areas which will require expansion beyond the coverage in this book. It is unfortunate that the book contains a large number of typographical errors which detract from the presentation. The search for an ideal textbook for the introductory farm management course must continue.

Leroy F. Rogers
Washington State University

Lave, Lester B., and Eugene P. Seskin. *Air Pollution and Human Health*. Baltimore, Md.: Johns Hopkins University Press for Resources for the Future, 1977, xx + 368 pp., $22.50.

Lave and Seskin analyze the effect of air pollution on human mortality. The book is the culmination of a ten-year research effort and is written for government decision makers, public health service officials, and other groups concerned with environmental protection.

Controlling for air pollution, socioeconomic characteristics, and meteorological conditions, the authors analyze 1960 mortality data from up to 117 Standard Metropolitan Statistical Areas. The analysis is replicated using 1961 and 1969 data and generally confirms the 1960 results. Regression is used extensively with cross-section, time-series, and pooled data. A single equation model is employed throughout, with several alternative functional forms examined. The authors decided to rely on the linear specification because of its simplicity and ease of interpretation. Although several air pollution variables are analyzed, the major focus is on suspended particulates and sulfates. These two variables are, for the most part, consistently significant, implying an association between air pollution and mortality.

Lave and Seskin draw three main conclusions from their analyses: (*a*) There is a significant association between specific air pollutants and death rates across U.S. metropolitan areas. Although multivariable analysis (author's term) cannot prove causality between air pollution and mortality, the consistent statistical significance between the two factors (plus findings of other studies in the epidemiological literature) lend support to the concept of causality.

(*b*) A benefit/cost analysis supports the abatement of air pollutants from stationary sources (mainly sulfates and suspended particulates). The statistical analysis of mobile source pollutant effects on human mortality is inconclusive. Based on these and other findings, the authors concluded that benefit/cost analysis does not support the current federal program on mobile source emission control.

(*c*) Setting national air pollution control standards to protect the "public health or welfare" is not warranted. Standards should be set on the basis of benefit/cost tradeoff analysis.

A number of criticisms can be leveled at the Lave and Seskin approach (failure to include certain explanatory variables in the models, need for better explanations of why certain variables are statistically significant but have the wrong sign, or why certain variables are included in the models in the first place, etc.). This short critique will focus only on those items which may question or support the study's findings or conclusions.

Overall, the first conclusion is supported by the analyses. Lave and Seskin ran a number of regressions to estimate the association between air pollution and mortality. The regression results are consistently affirmative and are well documented. As mentioned above, however, some of the findings could be discussed in more depth.

Conclusion two is not entirely supported by the authors' analyses. Problems with multicollinearity and probable use of air pollution data containing random measurement errors are the reasons. The issue of multicollinearity is discussed first.

The authors discuss their concern for multicollinearity and its potential for distorting the estimated coefficients. Yet, in part of the analysis, they ignore the multicollinearity problems, or undertake forms of analyses that enhance the problem. The authors omit certain socioeconomic variables from their models. They dismiss these variables by stating that they are concerned primarily with omitted variables which will bias the association of air pollution with mortality (p. 22). Lave and Seskin ignore the fact that poor nutrition and medical care, for example, may be associated with lower socioeconomic status, which, in turn, may be connected with higher levels of air pollution. The poor are likely to live in more polluted areas.

The authors' benefit/cost analysis supporting control of stationary source emissions is questionable. The regression equation (p. 31) used to develop the benefit estimates had significant multicollinearity among the air pollution variables. The resulting nonsignificance of the estimated air pollution coefficients made their interpretation difficult (p. 36). To derive the benefit estimates, the authors summed the elasticities of insignificant, unreliable coefficients. The validity of this process is debatable.

Lave and Seskin appear to have used measures of nitrogen dioxide in their analysis based on the Jacobs-Hecheiser (J-H) method. The J-H method was the initial EPA reference for nitrogen dioxide and was used widely in the United States. However, in 1972 it was found that the method produced significant, random errors. Although the authors recognize the problem (p. 6), they appear to use the J-H values anyway. Since J-H data are unreliable, so are conclusions which are sensitive to these data.

One can chide the authors for advocating use of benefit/cost analysis as a sole criteria for setting environmental standards. It can be argued that EPA should perhaps place more emphasis on benefit/cost analysis. However, there are many environmental effects that cannot be economically quantified, and there are other considerations (political, for example) to account for. At best, benefit/cost analysis should serve as one input into the decision-making process.

Lave and Seskin's treatment of air pollution and human mortality is comprehensive, considering the limited data bases. Their study should be considered as another contribution to the increasing body of literature relating air pollution to human health. One should recognize that their work is dated. This statement is not meant to detract from the research's contribution. When some of Lave and Seskin's initial findings were reported almost ten years ago, they were significant. However, the state-of-the-art has advanced significantly since

then. One would anticipate that future research will build upon their work to yield more precise, reliable estimates. "The regulators cannot wait until the scientists provide all the answers, for there will almost always be some degree of uncertainty in some parts of the data" (Costle, p. 3).

Meister, Anton D., Carl C. Chen, and Earl O. Heady. ***Quadratic Programming Models Applied to Agricultural Policies*. Ames: Iowa State University Press, 1978, 110 pp., $6.00.**

This book describes the adaptation of Iowa State's national agricultural model to a quadratic programming format. It contains eight chapters, the first two of which describe and contrast linear and quadratic programming models while the remainder contain the empirical specifications and applications of the Iowa State model.

In Chapter 1, the information needs of policy analysis are discussed and the information generated by linear and quadratic models is contrasted. Chapter 2 contains mathematical specifications of the linear and quadratic models, the self-dual quadratic models and quadratic models with both symmetric and asymmetric demand matrices. For each model the presentation includes both its optimality conditions and the economic interpretation thereof. This is the best chapter of the book. It provides a brief but rigorous overview of spatial programming models which would be useful in graduate courses in which there is too little time to investigate a detailed treatment like Takayama and Judge.

In Chapter 3, the structure of and data generation procedures for a quadratic model of U.S. agriculture in 1980 are presented. The model represents 10 consuming and 103 crop- and livestock-producing regions within the United States as well as international demand for several commodities.

Results from the solution of a free market model are presented in Chapter 4 for 1980, and contrasted to actual 1965 data. The results include national weighted-average prices (deflated to 1965 dollars), production and consumption, as well as regional data on acreage and/or production; shadow prices on constrained resources; labor, capital and fertilizer requirements, unused land and livestock capacity; and interregional transfers.

In Chapter 5, the implications to domestic agriculture of increased exports of wheat, feed grains and soybeans are investigated by increasing export requirements in the model's constraint set and comparing the resulting solution to the original 1980 solution.

Chapter 6 contains an analysis of a support price policy. The analysis is accomplished by forcing 1975 (deflated to 1965 dollars) target prices for grains and cotton into the 1980 model as minimum prices. No account is taken of either the loan rate or set-aside programs. The results are increased production and surpluses of grain, decreased livestock production, and increased livestock prices.

In Chapter 7, restrictions on fertilizer applications are imposed on the 1980 model to reflect concerns about environmental quality.

Chapter 8 contains a discussion of limitations of the model and data used. The authors conclude that several limitations exist but "the results . . . seem, in general, reasonable and consistent . . ." (p. 99).

I was left with some qualms and questions about the empirical analysis. First, there is no attempt to validate the model against an historical time period. There is, of course, a controversy over validating normative models (see Schaller). In my view, specification of a normative model is neither more nor less than specifying an hypothesis about economic behavior. It should be tested. In this case, the opportunity existed since the data on which the model is based are drawn from the 1960s and a reasonably free market existed in U.S. agriculture after 1972. An historical validation would have allowed for a diagnostic analysis of deviations between real market and the model solution which would have been helpful in either improving the model or in understanding real world behavior.

There are some deviations. First, the free market solution for the equilibrium live hog to live cattle ratio is .54. Over the past quarter of a century, the historical ratio has been approximately .75. Second, the fed cattle price from the 1980 solution (deflated to 1965 dollars) is $27.29 per hundredweight, the price of corn is $.86 per bushel, and the price of 400-pound feeder calves is $19.40 per hundredweight. If the fed cattle and corn prices are inflated by a factor of two and one-half, they are similar to nominal prices for those two products in early 1979 ($68.23 per cwt. and $2.15 per bushel, respectively). Multiplying the feeder calf price by 2½ gives $48.50 per hundredweight. This does not strike me as a reasonable approximation of equilibrium prices. Third, in the 1980 solution, the Pacific and Mountain states are projected to produce no fed beef. This is surprising, given that some fairly significant cattle feeding states are included in these regions. It is even more surprising that there is also no idle fed beef capacity for the Mountain states—which would appear to be an error in logic.

There are additional results which disagree with reality. The number is sufficient to cause skepticism about the model and to expect an explanation from the authors. None is given.

The reasons for these deviations from reality might lie in the model's specification. Again, several questions can be raised. First, export equations are included only for cattle, hogs, and soybean oil. International trade in the remaining commodities is represented by fixed constraints, on the ground that there are "deficiencies in foreign demand data" (p. 98). Other researchers have had reasonable success in estimating trade equations. At least a limited amount of reliable analysis would improve the interaction of the United States with the world market in the model.

Second, the domestic demand matrix—which is crucial in multicommodity models—is obtained by combining Brandow's elasticities with average annual regional prices and quantities demanded during 1963–65 to estimate price coefficients. Then the intercepts are adjusted using time trends to obtain demand functions for 1980. One wonders why George and King's later estimates were not used or even referenced. Also, one wonders why only the intercepts are adjusted and why with time trends. Why are not the intercepts adjusted for changes in income and population and the slope coefficients adjusted for changes in income?

A final comment concerns the analysis of the target price policy. The logic of a higher-than-equilibrium support price for grains resulting in reduced production and increased prices for livestock escapes me. I would have expected the opposite impacts on the livestock sector since increased grain production would drive down market-clearing grain prices. What is not clear from the book is whether the analysis was intended to reflect the true impact of a pure price support policy or whether it was merely a modeling exercise. If the latter, it is not very useful. If the former, it is conceptually incorrect.

In either case, one wonders (since no indication is given) whether the model is sufficiently flexible to analyze the policy correctly and whether it will accommodate more complex policy situations like the loan rate or set aside programs.

This book was written for use as a text in a one-semester undergraduate course. According to the author the "book attempts to give the reader some insight into both the permanent and changing elements of U.S. agricultural policy and some basis for evaluating the impact on the nation and the world of current laws and future proposals" (p. 2).

The book, divided into ten chapters, contains the list of topics one would expect to find in an undergraduate text. It opens with definitions and reasons for studying agricultural policy. Chapter 2, appropriately entitled "Cast of Characters," describes both traditional and new groups in the policy process, with a brief description of how policy is formulated. This is followed by the economic and social background as it affects agriculture (chap. 3), a review of how economists explain farm policy needs (chap. 4), and characteristics of demand, supply, and the marketing system (chap. 5). Chapter 6 reviews agricultural policies of the 1970s with emphasis on changes in the forces affecting agriculture. Chapter 7 puts U.S. agriculture in the rapidly changing world context. "Poverty in Agriculture" is the subject of chapter 8. The chapter (9) on beliefs, values, and goals is a rambling review of materials which can be found with better organization in other books (Hathaway). This chapter also includes a section entitled, "A Framework for Future Agricultural Policy," which more appropriately could be called a policy prescription.

In addition to discussion of the traditional participants, chapter 2 contains relevant information on other organizations not usually recognized as being important in the policy process. Although the chapter is informative, it is long and becomes somewhat tedious in discussion of USDA agencies.

Chapters 3, 4, and 5 might well have been organized in a different way. Chapter 5, with its emphasis on characteristics of agriculture, logically could have followed the chapter on the economic and social environment. This would have provided more basis for understanding the sources of policy problems and why economists try to explain farm policy needs.

The chapter on how economists explain farm policy needs is, as stated, a review of explanations offered by others. It fails to provide a comprehensive framework to the student for analysis of the performance of agriculture and what might be expected of it. This reviewer would like to have seen more emphasis on important concepts in policy such as opportunity costs, rates of return to resources, resource allocation, income comparisons, externalities, and the role of prices in a marketing system. A logical discussion or brief review of these concepts would enable the student to understand policy problems better and be better able to evaluate past policies and policy proposals, an objective which the author stated at the outset of the book.

In places the book contains errors of fact and analyses which are not well supported. For example, the Cooperative Farm Credit System, the Farmers Home Administration, and the Commodity Credit Corporation are classified as public agengies which supplement and compete with private credit institutions such as banks and insurance companies (pp. 131–33). Classifying the Federal Land Banks and the Production Credit System (no mention is made of the Bank for Cooperatives) as public agencies serves no useful purpose and would be considered in error by many, especially the personnel and borrowers of these institutions. The Cooperative Farm Credit System was originally capitalized with federal funds, but the operating units have been fully borrower-owned since 1968. The operating units are supervised by the Farm Credit Administration, an independent government agency whose expenses are paid by the operating units. Loan funds come from the sale of bonds to the public and do not represent government loans as is implied by the author.

The analysis as to why this system was needed is also subject to a different interpretation. Farm businesses are not any poorer credit risks than other businesses. The amount of individual credit needs, timing of availability of funds for repayment, and access to loanable funds, were reasons for development of the cooperative credit system, not that farmers were poor credit risks. Statements in this section are inconsistent. Agriculture is considered to be a "very profitable industry . . ." (p. 131). Two pages later one encounters the statement, "a farmer must earn 9 percent on borrowed capital . . . in an industry which rarely earns more than 1 percent on all capital employed." In addition to lack of consistency, the analysis is not complete.

O'Rourke's policy framework is essentially a free market approach except that a group of "core" farmers would be provided a guaranteed minimum income base. Core farmers are defined as commercially viable farmers chosen on the basis of competitive criteria. If government desired to stimulate supply, it should use a forward contract price. Welfare programs should be taken out of the U.S. Department of Agriculture. His program would also include removal of uneconomic regulations within agriculture or without, and general promotion of competition. The program would include extension to agriculture of the same bargaining rights as unions now possess. This last proposal seems inconsistent with the rest of the approach; however, it is consistent with the viewpoint expressed earlier that other economists tend to overlook many of the imperfections in the markets.

The organization of this book is appealing for classroom use. Each chapter is divided into sections which are followed by key words, central concepts, and study questions. The questions cover material not included in the book and should stimulate discussion and further study. The central concepts part is useful but needs further work in any subsequent edition because several concepts are not clearly presented, e.g.. aggregate effects (p. 7), technology (p. 57), and diminishing returns (p. 90). The book includes a comprehensive index which is of benefit to the reader, and the final chapter includes a comprehensive list of readings which appears to be appropriate for an undergraduate class.

The principal limitations of this book have been illustrated. Possible errors of fact and interpretation have been pointed out. On the other hand, it has many positive attractions, including a style of writing which makes for easy reading. Since it is one of the most up-to-date books available in an area where books quickly become dated, instructors will want to consider it as a text for an undergraduate course and supplement it with sections of other books and other interpretation of parts of the subject matter.

Palmer, John L., and Joseph A. Pechman, eds. *Welfare in Rural Areas: The North Carolina-Iowa Income Maintenance Experiment*. Washington, D.C.: The Brookings Institution, 1978, xiii + 273 pp., $11.95, $4.95 paper.

During the three-year period 1970–73, some 700 low income farm and nonfarm families in rural areas of North Carolina and Iowa participated in a social experiment to help determine the impacts of a negative income tax (income maintenance) program. Impacts which the experiment was to determine included those on hours worked, earned income, payments received, consumption, asset accumulation, job mobility, school performance, and psychological well-being. One control plus five treatment groups were used; treatments varied by the level of guaranteed income and the benefit reduction or tax rate. The rural experiment, which complements similar urban experiments, was conducted by the Institute for Research on Poverty of the University of Wisconsin, and results are published in a final report from the Institute. The book under review is a product of a 1977 conference sponsored by the Brookings Institution to review the experiment, and evaluate both policy and research implications.

Individual conference participants and chapter contributors include: Larry L. Orr, an overview of the experiments and findings; D. Lee Bawden and William S. Harrar, the design and operation of the

experiment; Harold W. Watts and D. Lee Bawden, issues and lessons of the experimental design; Finis Welch, labor supply response of farmers; Orley Ashenfelter, labor supply response of wage earners; Robert T. Michael, consumption effects; Michael T. Hannan, noneconomic outcomes; G. Edward Schuh, policy and research implications; Marvin M. Smith summarizes the conference discussion. Comments by others follow each chapter.

Policy Implications

Few policy implications from the report or the underlying research go unscathed by the rigorous economic and sociological debate. The most damning criticism by the authors is leveled at the experimental design: rigor was sacrificed for budgetary and time considerations. A sample of deficiencies include: a sparsity of families in particular treatments, truncation of the sample, sample selection from only two states, use of a scattered sample approach, and perhaps most important, limiting the experiment to three years. Rationale for the criticisms is vividly portrayed.

Theoretical underpinnings of the original studies are also questioned: general equilibrium effects are not adequately addressed, human capital formation goes unmeasured or poorly measured, the culture of poverty theory is investigated as an afterthought, the definition and farmers' report of income is challenged, and key variables such as the accounting period and the reporting period are not included in the analyses. As one participant indicates, the cost of a national program (one of the key effects of interest) would vary by billions of dollars depending upon the accounting period chosen.

Although most of the criticism goes unanswered, or at least little consensus derives from the proceedings, some may wish to take results of the original research at face value since they are, presumably, the best available. Key findings and implications include: (*a*) for both farm and nonfarm families, there is little change in the work and earnings of the husbands while wives and dependents reduced their work and earnings. This result implies that there is no need to include a work requirement in a tax program and that housewives may devote more time to the care of children and thus nurture human capital formation. The decrease in earned family income implies that total program costs are substantially more than direct transfer payments, and must be recognized in policy considerations. (*b*) Nutrition was enhanced in North Carolina but not Iowa. Some argue, then, that since diets were relatively poor in North Carolina, the tax program is a viable substitute for current food subsidy programs. (*c*) Psychological well-being was not affected and therefore concern that a tax program would diminish self-respect is unfounded. (*d*) The lack of accuracy of income reported by farmers and a failure of participants to understand the program will require administrative action.

Research Implications

Are large-scale, multiyear social experiments an efficient way to obtain policy information? This all important question goes largely unexplored. However, Metcalf, who participated in most of the experimental design, states (p. 76): "As a general strategy, I believe a social experiment of this sort cannot be justified unless the issue at hand is regarded as critical enough to warrant a much larger sample than was funded for the rural experiment. An effective experiment is an extremely expensive undertaking. Unless society is willing to bear the cost, an alternative research strategy should be used."

Aside from the preceeding deficiency, the book is indeed rich in research implications and is "must" reading not only for those who would participate in future social experiments at the national level, but also for those who gather primary data from much smaller populations. Information and implications at several levels of the research process abound. (*a*) Researchers are to use more of their resources to identify the socioeconomic goals of society before beginning research on what just may be a nongoal or nonissue. (*b*) Many aspects of theory are treated either in a critical way by testing theory against the data, by way of explanation, or by way of exhortation for inclusion in future research. Theories treated pertain to conventional labor supply, the new household economics, life cycles, the culture of poverty, general equilibrium, and distribution. (*c*) Experimental design issues, including dispersement of sample, site selection, sample size, sample characteristics, and duration of the experiment are treated, oftentimes in depth. (*d*) Some attention is paid to questionnaire design, content, and administration. The difficulties of defining and then eliciting reliable information on such a basic variable as income is aired in gory, but necessary, detail. And the importance of considering the Hawthorne effect (the effect on dependent variables caused by contact between the staff of the experiment and the participants) is brought forth.

The book is both well-edited and well-written.

Wortman, Sterling, and Ralph W. Cummings, Jr. *To Feed This World.* Baltimore, Md.: Johns Hopkins University Press, 1978, xiv + 440 pp., $25.00.

This book addresses the important questions of world hunger and poverty from a decidedly pragmatic and action-oriented perspective. As the authors state in the introduction, "this report has been prepared from the vantage point of individuals asso-

ciated with the Rockefeller Foundation and the International Agricultural Development Service," two institutions that have been and are actively involved in the development of new agricultural technologies and in the promotion of rural development programs. As such, the book fundamentally consists of (*a*) a description of the world food situation and of the history of the Green Revolution, foreign assistance in agriculture, and specific programs to increase food production and (*b*) the definition of a strategy to accelerate increases in agricultural production and rural incomes.

The departing point for the authors' proposal is the conviction that "for the first time in history we now have an opportunity to deal effectively with the problem" (p. 6) and that this gives "a firm basis for hope that hunger and the associated poverty can be eliminated" (p. xii). This opportunity is based on two factors: the growing "will" of the world's leaders to deal with the issue and the availability of a new technological capability to increase production. The technology-led strategy which the authors propose consists in organizing forced-pace campaigns to modernize peasant agriculture and bring it into the market economy. As they say, "there are two sides to the food problem: one is to increase production; the second is to create purchasing power among the hungry. The effort to increase crop and animal production on the millions of family farms around the world gets at both sides of the equation. It is the only approach which does" (p. 8). Family farms are thus seen to be both the source of the bulk of food supplies (p. 6) and the principal receptacle of poverty and hunger.

The strategy to feed this world consists of two steps: first, to implement land reform where necessary in order to create an agrarian structure of privately owned commercial family farms since "in the absence of effective agrarian reform the results will never reach full potential in terms of either production or income distribution" (p. 9); second, to launch a three-component approach consisting of commodity-oriented production programs, defined-area campaigns (regional development), and synchronized and reoriented government services. These programs are aimed at making technology, instruction, modern inputs and credit, and markets available to smallholders. And they are to be backed by a generous inflow of foreign assistance.

The book has a definite flavor of technological determinism: "We place an especially high premium on the role of technology and the importance of research" (p. xiv). The authors are obviously well-informed and long-time participants in that area of knowledge, and this gives a distinct interest to the book. Thus, the organization of research, the development of new technologies, and the management of diffusion programs are discussed in detail. This will prove useful to readers who want to be familiarized with the history and implementation of Green Revolution technology.

The main shortcoming of the book, however, is that it describes and prescribes but without presenting an explanation of the hunger-poverty crisis in its economic, social, and political causes over the course of history. As a result, the proposed strategy for change is in my view largely utopian and so is the announced basis for hope.

Clearly, the hunger-poverty crisis is not a technological or natural problem but a social product. Key elements of an explanation are rooted in such factors as the economic and social class structure created by colonialism, the economic logic of cheap labor and cheap food policies, the tremendously uneven distribution of the land, the diversion of some of the best lands for plantation and export crops, and the increasing reduction of peasants to the mere function of a cheap labor reserve. In this context, poverty and hunger are not the isolated products of traditional agriculture but the results of a complex set of exploitative social relations.

A strategy for change needs to start from an understanding of these complex economic, social, and political realities and must be oriented at changing their root causes. A program of technological modernization will otherwise almost inevitably lead to increased inequalities and accelerated displacement of peasants. That political change is essential is briefly acknowledged by the authors when they observe that "most relatively successful land reforms have been carried out when the normal political process was suspended" (p. 281). In the strategy they outline, land reform is an essential precondition. Yet, the strategy of forced-paced, technology-led modernization is proposed to avoid social change: "There is no time to lose. The incentives for action are clear: They involve urgent matters of political stability and national security, as well as economics" (p. 3). Social change or status quo? While need for the first is eventually acknowledged, the second is put forward as a goal: "Government leaders are increasingly aware that, unless they take steps to develop their rural areas through widespread involvement of the rural poor, they will likely face unrest, violence, even revolution" (p. 3). Since the latter is to be avoided, forced-paced modernization of peasant agriculture is suggested. The reader is thus left with the unresolved contradiction that social change is needed to create the preconditions for accelerated and socially beneficial agricultural development while agricultural development is simultaneously seen as an urgent need to avoid social change.

In conclusion, the book offers important pragmatic insights into the processes of generation and diffusion of technological change in agriculture. For readers who believe that the hunger-poverty crisis is principally social and political, the book will, however, appear short of out'ining an effective program to feed this world.

November 1979

AMERICAN AGRICULTURAL ECONOMICS ASSOCIATION

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri Columbia, MO 65211

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

Articles

Agricultural Pollution: The Economics of Coordination

Basil M. H. Sharp and Daniel W. Bromley

Institutional design is the major obstacle in reducing agricultural pollution. Cost sharing is being proposed for encouraging best management practices. Two models, one representing an agricultural firm and the other a management agency, are used to illustrate the flexibility and analytic capacity that agencies must have in determining the cost-sharing rules that apply to on-farm abatement practices. Off-farm investment opportunities should also be considered. If water quality is to be improved, these institutional arrangements will need the capacity to generate information, adapt to changing conditions, and reconcile the conflicting incentives of other programs.

Key words: agricultural pollution, coordination, input demand, institutions.

Agricultural activity has been cited as one of the leading contributors to the nation's water quality problems (General Accounting Office). It is now apparent that the federal government will not utilize regulatory constraints as a policy device for achieving the goals of the Federal Water Pollution Control Act Amendments of 1972 (PL 92-500). This direction echoes much of the sentiment expressed at the hearings before the Senate and House of Representatives on bills to provide for the maintenance or enhancement of the quality of water in rural areas (U.S. Congress 1977a, b). It is clear that the formulation of policy instruments at the federal level to enhance water quality will proceed with the minimum interference of individual farmer's activities, thereby reflecting the Jeffersonian doctrine about preserving the independence and virtues of small-scale farming.

Currently, policy makers are attempting to strengthen financial incentives for inducing voluntary participation in conservation-oriented practices. The Rural Clean Water Program (PL 95-217), passed by Congress in December 1977, authorized the Secretary of Agriculture to allocate $200 million for fiscal year 1979 and $400 million for fiscal year 1980. These funds were to be distributed through cost-sharing programs under the direction of the Soil Conservation Service (SCS). Although this program was not funded for fiscal year 1979, Congress intended the funds to have been in addition to the regular Agricultural Stabilization and Conservation Service (ASCS) and SCS programs which received appropriations of $456 million and $497 million, respectively, for 1979 (*Congressional Quarterly Weekly Report*).

Agricultural pollution abatement programs also are being developed at the state level. For example, the authority for water quality management in Wisconsin rests with the Department of Natural Resources and, while major regulatory and grant-in-aid programs focus on point sources, it has been recognized that nonpoint source abatement also must proceed.

The Methodological Setting

A conventional benefit-cost formulation of the environmental quality problem is hampered by the lack of weights (prices) to transform the benefits and costs of water quality into the metric of other economic objectives such as agricultural production. Hence, the usual approach is to utilize a water quality, or a surrogate on-farm, standard as one of the determinants of the feasible set within an optimizing

Basil M. H. Sharp is a research associate and Daniel W. Bromley is a professor in the Department of Agricultural Economics, University of Wisconsin, Madison.

The authors are grateful to Craig Osteen, Wesley Seitz, Earl Swanson, and two anonymous reviewers for assistance on an earlier draft.

This work was funded by the University of Wisconsin Sea Grant College Program under a grant from the Office of Sea Grant, National Oceanic and Atmospheric Administration, U.S. Department of Commerce, and the State of Wisconsin.

framework. As Kneese and d'Arge show, the conditions of Pareto optimality through partially adjusted choice can be met and deemed to have the same normative significance as when achieved under "natural" constraints of scarcity, private ownership, and technological production functions. It has been shown that a tax on emissions, set equal to the shadow price of the pollution constraint, is a fiscal measure satisfying the necessary conditions for minimizing the cost of pollution abatement to society (Baumol and Oates).

Agricultural economists have adhered tenaciously to this methodology, to the extent of being tendentious. Effluent charges on nitrogen irrigation returns have been studied by Horner, a tax on crop and pasture land was proposed by Jacobs and Timmons, and a tax on soil-loss was shown by Taylor, Frohberg, and Seitz to result in the most efficient way of achieving the desired reduction in soil loss. Invariably, however, the primary policy instrument that has emerged is not a tax on emissions, rather it is an on-farm standard, such as tons of allowable soil loss, popularized to connote a regulatory approach to agricultural pollution abatement.

These studies have yielded considerable insights into the implications of land use and land management practices for water quality. In addition, they indicate how agricultural operators can adjust their operations to meet tolerable standards, and, in most instances, that costs to the farming community are considerable. However, these studies, and the methods employed, do not adequately address the needs of policy makers. Subsidies are a reality in nonpoint source abatement programs—emission standards are not—and one of the most pressing issues facing local and state units of government is the allocation of scarce federal, state, and local funds in a manner conducive to the attainment of the goals of PL 92-500.

In this context, financial incentives assume the pivotal role of inducing the application of pollution abatement technology on an individualistic basis rather than playing the role of dampening the financial burdens associated with meeting tolerable loadings. More specifically, program design must become more concerned with the sensitivity of the agricultural operator's input demand function for these systems of management with the view of structuring these incentives to achieve the targets of water quality. To this end, a more comprehensive framework for viewing the agricultural pollution process is proposed.

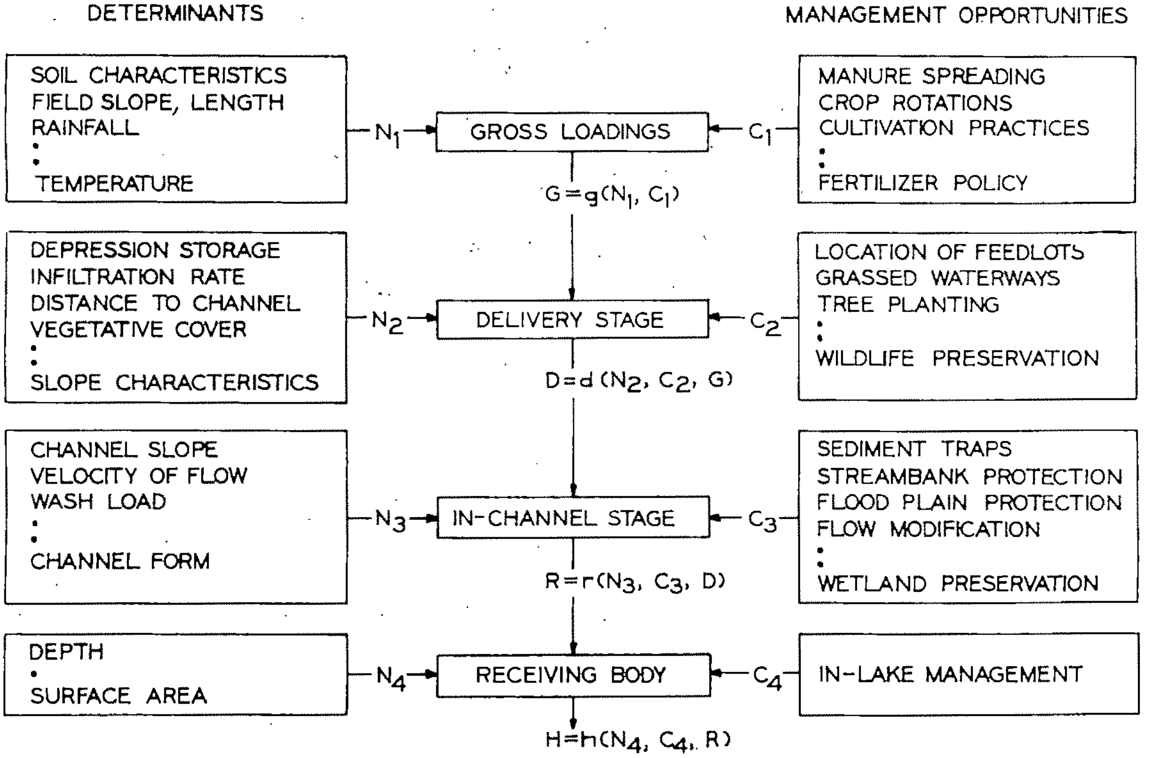
The Pollution Process

The flow diagram in figure 1 traces the stages of the agricultural pollution process, commencing with a set of determinants that initiate it, through the various transformations, to the quality of the receiving body of water. Hence, the first stage relates to practices, such as cropping and manure spreading, which result in the generation of pollutants at the farm level. For example, G may be taken as a vector comprising soil loss, nitrate-nitrogen, ortho-phosphorus, and so on, the levels of which are determined by a vector-valued function g.

These gross loadings are then transported, and transformed during the delivery stage, to a water channel. This stage essentially represents the overland flow phase of delivery and the transformations that occur are represented by the function d. Once in the water channel, the pollutants further interact with the components of the in-channel system eventually to impact the level of water quality entering the receiving body of water, as identified by the function r. Finally, there are a multitude of in-lake phenomena, such as nutrient transport, depth, and surface area, which jointly determine the level of water quality at any particular time.

It is important to appreciate that at each stage of this process there exist a number of management opportunities which can reduce the flow of nutrients, sediments, and other pollutants into receiving waters. These opportunities are identified as control vectors (C_j) with the subscript ($j = 1, \ldots, 4$) referring to the stage at which the controls are implemented. The effectiveness of the controls at any time is determined by the number of "givens" (N_j) in the system, some of which are amenable to change. For example, infiltration rates can be increased over time by using good soil husbandry, channel form can also be modified, but other components such as the distance to channel and channel slope are not so readily changed.

Any analysis that emphasizes adjustments at the farm level necessarily omits many feasible management alternatives. The current focus on best management practices (BMPs) stems from the fact that agricultural activity



Source: Sharp and Berkowitz

Figure 1. The pollution process

augments, and initiates, the flow of pollutants from the land resource. It is the practices of plowing, fertilizing, harvesting, and manure spreading that provide the inputs into a process which is essentially driven by hydrological phenomena. But, the delivery systems and the receiving bodies of water are also amenable to change. Actually, the only requirements placed upon the set of locally determined BMPs is that they be the most effective and practicable means of preventing or reducing the amount of pollution generated by nonpoint sources to a level compatible with water quality goals (*Federal Register*).

Similar results, in terms of water quality, may be achieved by disrupting the flow of nutrients within the lake proper. For example, aeration, biotic harvesting, lake bottom channelization, and various forms of chemical treatment have been proposed. Also, aeration and mixing systems can be installed in influent water (Speece, Murro and Yeaple). Structural changes, such as diversions, channel grade controls, serrations, sediment traps, and dry ponds can help dissipate the energy of surface runoff thereby allowing the sediment-nutrient complex to settle out. It is conceivable that more predictable changes in water quality may be obtained at a lower cost to society from the use of these alternatives.

One rationale behind the establishment of BMPs lies in the use of *T*-values to determine an upper bound on the management factors in the universal soil loss equation, factors which satisfy the maximum rate of soil erosion permissible for high levels of crop production to be sustained indefinitely (Wischmeier).[1] Soil-conserving systems of management will reduce agricultural emissions to the extent that the soil resource is kept in place and the energy potential of surface water is reduced. These practices therefore serve a dual role in conserving the soil resource and reducing the contribution of agricultural activity to water pollution. However, their adoption under a voluntary program will depend upon the value

[1] The soil loss equation ($A = RK\ LS\ CP$) estimates the average annual soil loss from sheet and rill erosion (A), in tons per acre, for specific combinations of rainfall (R), soil type (K), topographic features (LS), crop system (C) and supporting erosion control practices (P). *T*-values are assigned to a given site expressing a tolerable limit of average annual soil loss. The permissable CP is determined by substituting for A in the equation: $CP = T/R\ K\ LS\ P$. This establishes an upper bound on the set of feasible management practices.

which individual farmers place on the soil and nutrients lost. Current financial constraints may lead farmers to place short-run profits ahead of long-run productivity.

These observations have implications pertinent to abatement programs which rely upon the voluntary participation of individuals for the achievement of water quality goals, the benefits from which are shared by many. Agencies charged with designing programs to control agricultural pollution must appreciate that management opportunities exist outside of on-farm adjustments of the type so commonly found in analyses to date. This is important for the efficient use of public funds; it also has profound distributional implications. In the analysis which follows the control vector **C** will be partitioned as follows:

$$\mathbf{C} = [\mathbf{X}Y]. \tag{1}$$

The vector **X** represents an array of on-farm decision variables which will be referred to as BMPs, some of which may be soil conservation-oriented, and a set of off-farm management options Y reflecting those control measures which may be initiated outside of the farm decision-making environment.

A Framework for Analysis

Institutional change in a socioeconomic system is driven by some concept of desired performance. A society can be said to possess some collective will—however imperfectly defined and acted upon—with respect to such things as the level of water quality, the minimum level of income, and the like. From this view, the policy issue becomes one of finding a set of institutional arrangements which induces behavior on the part of individuals that is consistent with desired performance. Such institutional arrangements may exist through (*a*) the pricing mechanism, (*b*) nongovernment collective action, or (*c*) the government acting as an inducer (cost-sharing), a facilitator (extension education and technical assistance), or an enforcer (regulation). This suggests the following idealized framework: institutional arrangements influence the behavior of individual actors within the system, the aggregate of which leads to certain beneficial and some adverse consequences, thereby influencing judgment of the performance of the system and, so, the institutional arrangements that define its structure, and motivate its actors.[2]

As an illustration, consider the concern in the 1930s with increased soil erosion, along with the attendant problems of blowing dust and silted-in streams and reservoirs. With the expectation that altered behavior would lead to improved performance (less erosion), a new set of institutional arrangements, and an organizational structure, was devised. Specifically, cost-sharing for certain conservation practices was introduced, along with the provision of technical advice. These new institutional arrangements altered the relative benefits and costs of prevailing practices and so rendered new behavior more attractive (profitable) to the individual farmer.

The problem, then, is one of adjusting incentives for decision makers such that the resulting behavior is consistent with, or rather results in, socially desired performance. The essence of efficient policy for dealing with agricultural pollution, where efficiency comprehends not only least-cost abatement at the firm level but also the allocation of scarce public funds, is that of coordinating the actions of two primary actors: the agricultural firm and the management agency. That is, the important question is how public policy can create a set of institutional arrangements which will alter and strengthen incentives for private decision makers to adopt voluntarily systems of production. The complexity of this coordination problem is at once realized when one considers the existence of numerous programs which directly, and indirectly, influence the incentive structure of agricultural firms. Some programs may reinforce existing incentives to incorporate less polluting technology, for example the Agricultural Conservation Program (ACP); while others, such as price support programs, may run counter to the goals of PL 92-500. Signals perceived and patterns of behavior so induced may not correspond with the specific and more narrow objective(s) of any one individual program.

The Agricultural Firm

An agricultural operation may be viewed as a multiproduct firm with the production of q_i

[2] This performance-institutions-behavior model is inspired by the work of Schmid.

achieved by allocating n variable inputs x_{ij} and r fixed factors z_{ir}. The total quantity of the fixed factors Z_r is assumed to be constant and the allocations z_{ir}, among the i products, must satisfy these constraints. However, it is possible to transfer units of these factors from one product to another and readjustments of this nature give rise to switching costs $S(z_{ir})$ (Pfouts). The market price of the products p_i and inputs w_j are assumed constant, although the subsidy rate θ_j on some inputs (BMPs) will lower the market price by $(1\text{-}\theta_j)$. The Lagrangian function for the profit maximization problem is

$$(2)\ L = \Sigma p_i q_i - \Sigma\Sigma w_j(1 - \theta_j)x_{ij} - S(z_{ir}) + \Sigma\mu_r(Z_r - \Sigma z_{ir}).$$

To make the following discussion more transparent without losing any generality, we will assume that the decision variable x_{ij} represents a BMP. An interior solution for this practice is characterized by

$$(3) \qquad p_i \frac{\partial q_i}{\partial x_{ij}} = w_j\,(1-\theta_j).$$

This states the well-known condition that the value of the marginal productivity of the abatement alternative equals its factor price, which in this case is net of the subsidy rate θ_j. Therefore, under these conditions the operator will invoke BMPs commensurate with privately determined benefits.[3] For example, an improved manure management plan will be adopted in accordance with the net value of the nutrients saved. Clearly, any plan that effectively conserves manure nutrients will also reduce pollution loadings; the particular system adopted, however, may not result in the desired level of pollution reduction. For higher levels of pollution reduction, it may be necessary for the agency to increase the subsidy, thereby lowering the relative price of the input which, in turn, lowers the cost of manure nutrients vis-à-vis commercial sources.

Turning to the fixed factors of production z_{ir}, an interior solution is characterized by

$$(4) \qquad p_i \frac{\partial q_i}{\partial z_{ir}} = \frac{\partial S(z_{ir})}{\partial z_{ir}} + \mu_r.$$

Here, the relevance of the fixed factors of production becomes clear because (4) requires an equality to exist between the value of the marginal productivity of z_{ir} and the sum of the marginal switching costs and the imputed value of utilizing Z_r in the production of q_i. Asset fixity is a real consideration in the design of institutional arrangements to reduce agricultural pollution. Any reallocation of these resources inevitably will involve costs; for example, planting equipment may require modification for use within a conservation system of management. Considerations of this nature not only determine the flexibility available for adjustment, but also translate into financial constraints which may alter the responsiveness of agricultural systems to cost-sharing incentives.

As stated earlier, the central concern of the agency is the sensitivity of the farm-firm's input demand function to perturbations in the subsidy rate θ_j. For example, what is the response that will be elicited if the cost-sharing rate is increased from 20% to 50%? To portray this response, the following input demand function will be utilized. It is expressed as a function of output prices, input prices, and unit subsidy rates with subscripts suppressed,

$$(5) \qquad x = x[p, w(\theta)].$$

Neoclassical theory suggests that this function is downward sloping with respect to input price; its elasticity is an empirical question. Current policy models are mandating the use of a BMP, at a level x', to satisfy tolerable loadings. But the critical issue, given the legislative intent not to impinge upon the independence of the farming community, is whether or not the level adopted by voluntary action x^* will lead to socially desirable levels of agricultural pollution. In this setting, government has two options: the price of agricultural products can be altered and/or the price of the inputs can be adjusted to induce the incorporation of BMPs.

The Management Agency

Our model of agricultural production focused upon the alternative aspects of on-farm decision making. In terms of figure 1, only those control instruments which are applicable at stages 1 and 2 of the pollution process were addressed. A management agency can however introduce controls y_{ts}, each costing v_t, at various stages s and it can also influence the adoption of BMPs at the farm level through its choice of the subsidy rate θ_j. Each of these

[3] As used in New York State, a BMP is a conservation practice or management technique that will result in the opportunity for a reasonable economic return within acceptable environmental standards (Loehr et al., p. iii).

instruments will result in administration costs A, a factor which must be recognized in the development of efficient programs.

It will be assumed that the agency wishes to maximize water quality subject to a budget constraint B. Water quality is a multidimensional concept and the functions given in figure 1 are all vector-valued, comprising such indicators as sediment, phosphorus, nitrogen, and toxic chemical concentrations. In view of this, the techniques applicable to multiobjective analysis are necessary (Cohon and Marks). We will assume that a scalar function h represents the notion of water quality.

The agency's principal concern is, therefore, to select that combination of off-farm strategies and on-farm subsidies that yields the highest level of water quality subject to the budget constraint. The Lagrangian for this problem is

$$(6)\quad L = h(y_{ts}, x_{ij}; N) + \beta[B - \Sigma\Sigma v_t y_{ts} - \Sigma\Sigma w_j \theta_j x_{ij} - A\ (\theta_j, y_{ts})].$$

The interdependencies that exist between the agency and the agricultural firm are clear: it is through the choice of the subsidy rate that the agency influences the adoption of the BMP x_{ij}, which in turn impacts the level of water quality h. However, the agency can have more direct control over the level of water quality by employing y_{ts} which influences the off-farm transportation and transformation of pollutants. The relevant equilibrium conditions are

$$(7)\quad \frac{\partial h}{\partial y_{ts}} + \frac{\partial h}{\partial x_{ij}} \cdot \frac{\partial x_{ij}}{\partial y_{ts}} = \beta(v_t + \frac{\partial A}{\partial y_{ts}}), \text{ and}$$

$$(8)\quad \frac{\partial h}{\partial x_{ij}} \frac{\partial x_{ij}}{\partial \theta_j} = \beta(w_j x_{ij} + \frac{\partial A}{\partial \theta_j}).$$

Equation (7) requires the sum of the marginal direct and indirect effects of employing off-farm controls to equal the sum of their purchase price (or marginal factor cost) and the marginal administration costs that result from their use weighted by the shadow price associated with the use of scarce public funds. This condition must hold for all controls at each stage of the process.

Similarly, if a subsidy is to be used as a means of controlling pollution, then equation (8) states that the marginal reduction in pollution must equal the sum of the on-farm expenditures ($w_j x_{ij}$) and the marginal administration costs weighted by the shadow price β.

The agency can, therefore, utilize an indirect means of inducing pollution abatement through its choice of the subsidy rate and it can use a more direct approach by investing in off-farm practices. The rate at which subsidies and off-farm investments can be substituted, while still achieving targeted levels of water quality, should be recognized if scarce public funds are to be allocated efficiently in pollution abatement programs. In addition, the magnitude of the administration costs incurred by the instruments also should be given consideration in program design. Administration costs may be made lower and water quality responses higher and more predictable through the use of off-farm strategies rather than relying solely on subsidies to induce the adoption of BMPs at the farm level.

The Coordination Problem

These two models are coupled, and by the very nature of the interaction between the firm and the agency, some form of coordination is necessary so that the decisions of these actors are in harmony with the goals of society. Subsidies are the driving mechanism in a voluntary program and the problem in designing such programs revolves around synchronizing the supply with the demand for public funds (Mesarovic, Macko, Takahara; Wismer). The essential ingredients of the coordination problem are presented in figure 2. Here, an input demand function for a BMP, as depicted in equation (5), is illustrated in quadrant I. The level of water quality H is shown in quadrant IV to be influenced by the level at which the BMP is adopted at the farm level. Recall from figure 1 that this option corresponds to the early stages of the pollution process and, given that the chemical form and toxicity of pollutants change over time and space, the technical information necessary to establish the causal linkages between these two quadrants is considerable. Different management strategies may be warranted depending upon the proximity of polluting activity to the receiving body of water and agency action with respect to off-farm controls (y_{ts}).

The water quality indicator is then made a function of the cost-sharing rate in quadrant III, with the final connection between the subsidy and the adjusted price of the input being established in quadrant II. Therefore, if H' is the targeted level of water quality, this can be achieved by inducing agricultural operators to employ BMPs at a level x' through a cost-

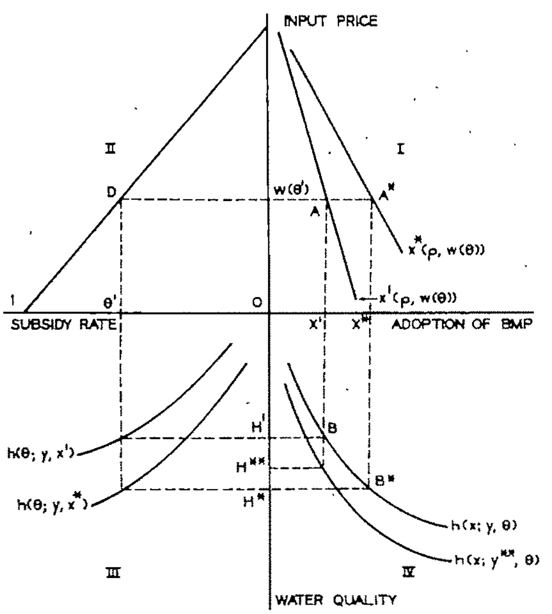


Figure 2. Voluntary abatement programs: the coordination problem

sharing rate of θ'. A lower rate is necessary if the water quality objective is lower.

The agency, however, does have another option: it can invest in off-farm practices y, such as streambank protection and wetland preservation. This form of investment will influence the marginal productivity of on-farm practices in terms of improving water quality and can be extended to include projects designed explicitly for nonagricultural pollution abatement. In figure 2, the effect of increasing these activities from y to y^{**} is shown to shift the water quality indicator resulting in, for example, a higher level of water quality H^{**} and a different marginal productivity for the abatement practice x'.

A number of considerations emerge from this general coordination model which are relevant to the design of agricultural pollution abatement programs. First, the optimal cost-sharing strategy is inextricably linked to the crops that are grown, and, in fact, it is specific to the local conditions of production and the way in which these activities impact water quality. This implies that local control over the determination of these rates is desirable, if not necessary, if scarce public funds are to result in the maximum possible improvement in water quality.

Second, similar cost-sharing rates are likely to induce different responses, in terms of adopting BMPs at the farm level, depending primarily upon the elasticity of the input demand function for the practice. In general, this function is likely to be more elastic, the more readily substitutes can be found. On the other hand, demand will be less elastic, the less important is the part played by cost of x_{ij} in the total cost of production; provided i has a price elasticity exceeding the elasticity of substitution (Ferguson). Therefore, if chisel plowing comprises a small part of the budget for corn production and if the price elasticity of corn exceeds the elasticity of substitution between chisel plowing and a conventional alternative, then the response to changes in the cost-sharing rate will be smaller. A more elastic input demand function x^* is illustrated in figure 2 which results in a higher level of pollution abatement behavior given the same level of cost sharing θ', a shift in the water quality indicator in quadrant III, and a change in the marginal productivity of the policy instrument itself.

It is also possible to illustrate the multiobjective nature of the problem by incorporating a long-run soil productivity goal into figure 2. Assuming that H' is the targeted level of water quality, the issue now becomes whether or not x' exceeds, or is exceeded by, the recommended T-values (x^t) for that soil. If, for example, $x' < x^t$, then the water quality goals will be met if the soil productivity goals are met, *mutatis mutandis*, if $x' > x^t$. While the existence of multiobjectives adds further complications, an early recognition of the dominant concern and the channeling of funds into these practices may assist in the achievement of other objectives. In the event of different agency's being involved, the coordination effort must transcend the boundaries of all actors in order to take advantage of any complementarities that may exist.

This section has highlighted the pivotal relationship that exists between the choice of a subsidy and the adoption of pollution abatement practices at the farm level. There are of course other factors to consider. For example, rules that establish limits on the total subsidy received will influence response as will attempts to discriminate between the components of a BMP that qualify for a subsidy. Therefore, the tailoring of incentives to induce abatement behavior at the farm level is extremely complex. These are issues that economists can address by reorienting programming models to analyze the allocation of scarce public funds within a program which relies

upon voluntary participation. Statistical analyses also may assist in the identification of input demand functions for BMPs. For example, it has been shown that relative prices explain most of the variation in fertilizer consumption (Griliches) and the ACP cost-sharing policies stimulate lime usage at the farm level (Swanson).

Implications for Program Design

The technology capable of achieving substantial reductions in agricultural nonpoint source loadings exists (BMPs); as do the off-farm techniques that can influence the pathways of these pollutants in the environment. However, the distance that exists between the actions of individual farmers and the concomitant impact on water quality has not been fully appreciated by policy makers. The response of water quality to BMPs may not be as great as some off-farm investments—this is a relevant consideration in the efficient allocation of scarce public funds. In dealing with the technical and behavioral uncertainties in a stochastic environment, a common-sense approach would recommend a spreading of the abatement effort between on-farm and off-farm practices.

If the goal of fishable and swimmable water is to be met in reasonable time, the major hurdle is not technology; rather, it is the design of institutional arrangements to encourage the incorporation of this technology into ongoing farming systems. Cost-sharing will play a pivotal role in inducing the adoption of BMPs at the farm level and we are suggesting, based on the above analysis, that an iterative approach be adopted. The institutional arrangement for effecting a program of this nature must have the capacity to (*a*) generate relevant information with respect to performance, (*b*) adapt over time to changing conditions, and (*c*) reconcile the often conflicting incentives of other programs which may dampen the incentives for pollution abatement.

It is almost axiomatic that funds be allocated on a "worst-first" basis during the initial stages of program implementation. Once in operation, the response of the farming community to the incentives and the attendant changes in water quality should be monitored on a periodic basis, at least in representative watersheds. Information of this nature could be obtained in conjunction with the conservation needs inventory that is conducted in most states every five years. In particular, we will need to be able to identify the practices that are most readily adopted, the motivation behind their adoption and what they mean in terms of water quality. These data then become the basis for any adjustments to be made in the incentive structure over time. It is imperative that the agency follow up on the practices installed because the objective is to foster a continuing abatement effort and not a one-shot response.

The adaptive properties of an institutional arrangement will depend to a large extent upon the ability of planners to foresee and prepare for the future. For example, it has been estimated that 1 million acres of high-quality agricultural land is being lost each year to urbanization (Dideriksen and Sampson). Prior to urbanization this land is usually subdivided into smaller part-time operations which crop the land intensively, thereby exacerbating the loadings from these areas. There is little incentive for these individuals to participate in voluntary programs, and special arrangements will have to be made if this form of behavior is to be changed; many counties are considering regulations to deal with this problem. Flexibility is therefore one aspect of adaptation; the other relates to expectations. Expectations are strongly linked to institutional change—decisions made now are based upon what we expect the institutional arrangement to be in the future. This means that there should be a very clear statement about the nature of future changes in the program if a voluntary approach fails to elicit desired behavior. Obviously, participation will be slower if the cost-sharing program is altered frequently—that is, it might prove profitable for farmers to wait for the expected increase in the incentive.

Perhaps the most formidable barrier to be addressed concerns the need to tailor the incentive structure according to local conditions. As indicated by the above analysis, efficient allocation of funds requires differential (discriminating) cost-sharing programs; the response of the farm-firm will depend upon the nature of the technology currently employed, resource availability, and financial considerations. To induce the adoption of BMPs, it may be necessary to vary the per farm limit and the subsidy rate according to local agricultural conditions and water quality. Currently, there does not exist the analytic

capacity to adapt the incentive structure to local conditions.

There are a number of other pressures impinging upon agricultural systems from the national level. The continued policy of stimulating production is leading to more intensive use of land that is marginally suited to cropping, along with a conversion to row crops. The U.S. Department of Agriculture has estimated that between 1972 and 1975, harvested cropland increased by 41 million acres, largely in response to increased foreign demand for grain. This trend, coupled with the loss of high-quality agricultural land, will result in more pollution from agricultural activity over time. Many other programs offer the opportunity for inducing the application of BMPs. For example, the Small Business Administration's loan program and state and federal tax incentives can be tailored to reduce financial constraints. In addition, it may be possible to adapt the wetland and wildlife preservation programs of the Department of the Interior toward meeting the goals of PL 92-500. These avenues have largely been unexplored, yet there seems to exist significant opportunities for reconciling the often conflicting environmental implications of each.

The existing organizational structure for controlling soil erosion would seem to have the potential for playing a significant role in agricultural pollution abatement. In many instances the objectives are complementary and the agencies currently involved have the benefit of experience, particularly in providing technical assistance. However, if the pollution control program evolves as a nationwide fixed cost-sharing effort relying upon voluntary participation, the above analysis suggests that this narrow approach would compromise the efficient use of public funds designated for improving water quality.

A Conceptual Framework for the Empirical Analysis of Peasants

Carmen Diana Deere and Alain de Janvry

To assist in the design and analysis of the many empirical studies currently conducted on peasants and their changing status in third world countries, a conceptual framework is presented and illustrated with data from Cajamarca in Peru. The framework identifies the key variables to be measured and processes to be analyzed at three levels: the organization of the peasant household in terms of production, circulation, and reproduction; the mechanisms of surplus extraction; and the class position and differentiation of groups of peasants within particular social formations.

Key words: peasants, Peru, social relations.

In recent years the economic and political significance of peasantries in the third world has received increased attention. The active role of peasants in postcolonial struggles has drawn attention to their political importance in the transformation of many third world societies. The economic importance of peasants has been highlighted by the dimensions of the food crises of the 1970s and by the recognition that they are often cheap food suppliers and a source of cheap labor for agriculture and industrial development. The consequence has been an explosion of both research and programs oriented to the peasant question: research to observe, describe, and understand the economic and political logic of peasants, as well as their changing position and functions in broader society, and programs to increase the productivity of labor in peasant agriculture and to promote political stability in spite of massive poverty. Thus, a large number of empirical studies have been conducted, frequently in the context of the search for new technologies adequate for peasant farming or the design of rural and community development projects.

The research effort has demystified many of the concepts that dominated much of the early work on peasants, such as cultural traditionalism, economic backwardness, and the autarky of subsistence production. Yet, the absence of an adequate conceptual framework for the study of the peasantry too often has prevented these studies from isolating the key variables required for analysis and from organizing the empirical information in terms of the central processes that characterize peasant households and the forms of their insertion into the wider economy. For the economic analysis of the organization of peasant households, reliance typically has been placed on either the Chayanovian theory of utility and demographic differentiation (Chayanov, Archetti) or on strict neoclassical principles derived from the theory of the capitalist firm (the formalists in anthropology—Tax, Nash, Leclair; the new household economics—Becker, Benito). For the analysis of the insertion of the peasantry into the broader society, either a phenomenologist and cultural vision of partiality has been used (Kroeber, Redfield) or the conceptualization of specific noncapitalist peasant modes of production has been relied upon (Servolin; Vergopoulos 1971, 1978).

In this paper it is argued that the analysis of peasantries must be based on the specification of the relations of production in which peasants participate. We reject both Marxist and non-Marxist attempts to define a peasant mode of production or peasantry as a specific sociocultural or economic type and focus on the mechanisms of surplus extraction which describe the relations of production between direct producers and appropriators in class societies.

We take the situation where the capitalist mode of production is dominant in the econ-

Giannini Foundation Paper No. 535.

omy at large and focus our inquiry on the forms of integration of peasants into the social formation. This framework highlights the conditions under which peasant households become integrated into markets as suppliers of products or of wage labor. We argue that the integration of the peasantry into the labor market, as suppliers of wage labor to capitalist units of production or as buyers of wage labor in the process of capitalization, most closely characterizes the process of class formation among direct producers and, hence, their incorporation into the dominant capitalist mode of production.

The conceptual framework developed here attempts to account for the variation in the material conditions of peasants as well as for the dynamics of their transformation by interrelating three levels of analysis: (*a*) the organization of the peasant household, (*b*) the mechanisms of surplus extraction, and (*c*) the class position of different groups of peasants within particular social formations. The framework is illustrated with data describing the Cajamarcan peasantry of the northern Peruvian sierra.

Organization of the Peasant Household

In order to highlight the interrelated social processes that characterize the peasant household, Marx's categories of production, circulation, reproduction, and differentiation are drawn upon. What distinguishes the peasant household from other domestic units (such as the household in advanced capitalism) is that the household is both a unit of direct production and a unit of reproduction of familial labor power on both a daily and generational basis.

At a given moment in time, the stock of family labor in relation to the household's access to the means of production is reflected in the particular division of labor by sex and age embodied in the household labor process. Household labor power is used in the home production process or sold as wage labor on the labor market where it participates in what is termed as the wage labor production process. A continuous spectrum of combinations between the two pure extreme types of households—purely agriculturalist and purely proletarian—can be identified.[1]

Household labor dedicated to home production generates a gross product which is either retained as a use value by the household for home consumption or sold on the market as a commodity (the circulation process). Here, again, a continuous spectrum between pure subsistence household production with no marketable surplus and the pure commercial farm that is exclusively producing for the market can be identified.

The sale of commodities and the wages received from the proletarian labor process constitute the gross monetary income. This income, after deduction of the various monetary costs involved in production, generates a net income which permits the purchase of means of consumption for reproduction of the household and means of work for replacement and net investment.

Means of consumption and means of work thus derived from both home production and purchase sustain the reproduction of the household as both a consumption and a production unit (Meillassoux). Reproduction includes both daily maintenance to restore the capacity to work and generational reproductive activities reflected in the size, age, and sex composition of the household.[2] The scale of this reproduction, in turn, determines the pattern of social differentiation and the consequent changing class position and composition of peasants.

The four key processes identified characterize the organization of the peasant household—home production process, wage labor production process, circulation process, and reproduction-differentiation process. They are schematized in figure 1. In the left-hand column,the stocks of means of production at a particular point in time are identified. They include raw materials (land and water), means of work (seeds, trees, animals, tools and implements, fertilizers, and fuels), and family labor (number, sex, and age of members). In the right-hand column the monetary variables that characterize the circulation process on both the supply and demand sides are presented: gross cash income from sales,

[1] For the sake of simplicity, we abstract from the myriad of home production processes (such as artisan production, small merchant trade, etc.) which might be a complement or substitute for the agricultural/wage labor duality.

[2] While production is ultimately the determinant of reproduction in a relative sense in that the level of the outcome of productive activities determines the household's consumption possibilities and, hence, the level of living at which family labor power can be reproduced (nutritional level, fertility, etc.), the peasant household's reproductive strategy also conditions the productive activities in which it may engage (Mamdani, Folbre).

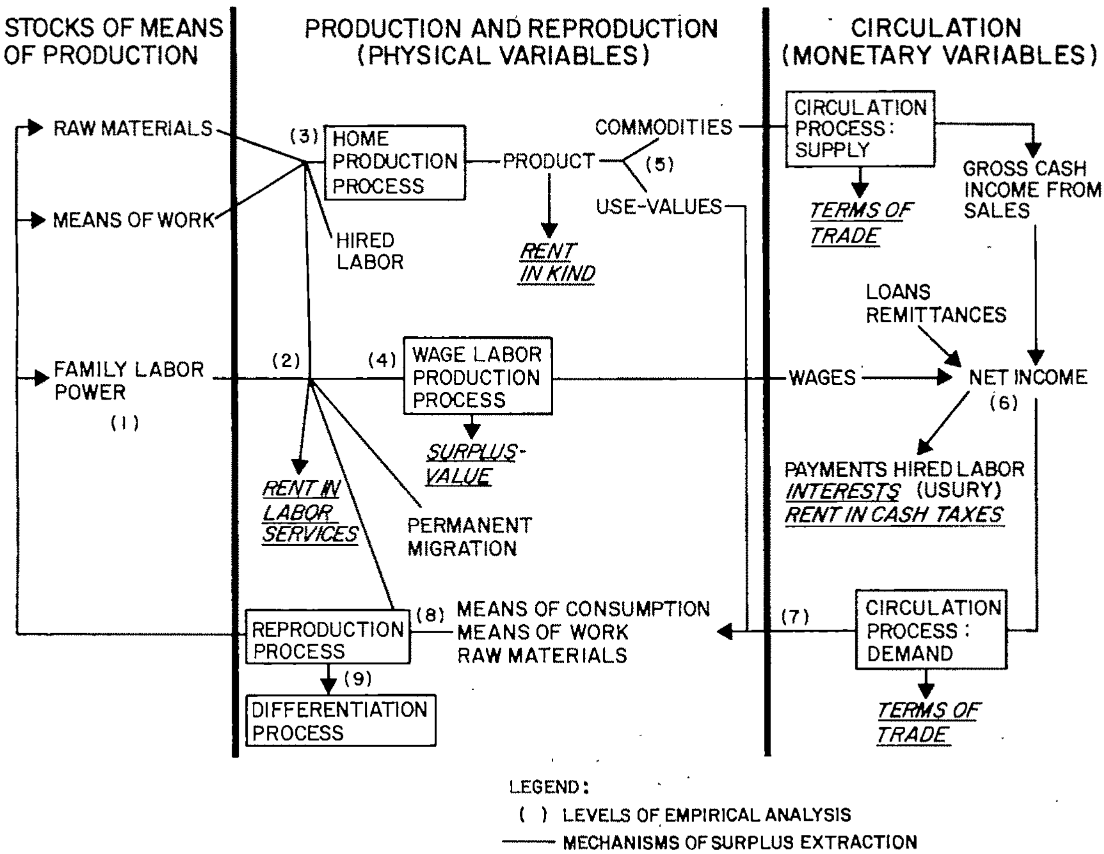

Figure 1. Organization of the peasant household

wages, net income formation, and purchase of means of consumption and work. The center column highlights the two fundamental processes of production (home and wage labor) and reproduction (of the consumption unit and of the means of work). These two key processes are partially mediated through circulation in terms of the formation and disposition of net income but also directly reflect the social relations of production.

From figure 1, nine key sets of variables can be identified for the empirical analysis of the peasant household. These variables correspond to the different nexuses which indicate that either a process of choice and decision making is taking place or that an accounting identity can be established. They are (1) the stocks of means of production at time t; (2) division of labor by sex and age in the household process; (3) choice of activities (products and technologies) and allocation of resources in the home production process; (4) choice of activities and job search in the wage labor production process; (5) disposition of the product between sale (marketing) and retention for home use; (6) the formation of net income (sources of income); (7) effective demand—disposition of net income; (8) reproduction of the consumption unit (family labor) and of the means of work, acquisition of raw materials; and (9) the level of stocks of means of production at time $t + 1$ which provide the basis for the analysis of social differentiation.

Organization of Peasant Households in Cajamarca

The Cajamarcan peasantry is a *mestizo*, Spanish-speaking peasantry resident in the most populous Peruvian Sierra Department. As table 1 illustrates, access to the means of production among the peasantry is highly unequal.[3] Some 72% of the total number of rural

[3] The data presented herein were derived from two sample surveys representative of the distribution of land ownership in 1972. The 1973 Cajamarca Income Survey was carried out by the Socio-Economic Study Group of the Cajamarca-La Libertad Project under the direction of Ing. Efrain Franco. The survey included 1,500 observations on peasant households in 13 districts of the provinces of Cajamarca and Cajabamba. The data presented herein is restricted to 1,050 households in the province of

[a] The correlation coefficient between land held in property and total land used is .9822.
[b] The mean value of the means of work includes the present value of tools and equipment and the market value of work animals (donkeys, mules, horses, and oxen). Valuation is in 1973 dollars.
[c] The mean value of total assets includes the present value of buildings and equipment and land in pasture as well as the total stock of animals.
[d] n indicates the number of observations.

households have access to less than 3.5 hectares of land each, the minimum—given the ecological and technical conditions of production—that is required for a peasant family to be able to produce its full subsistence requirements. Middle and rich peasant households with sufficient land to be viable agricultural units constitute only 25% of the total number of rural households; their landholdings average 6 and 16 hectares, respectively. The commercial enterprises of the farmers make up only 3% of the total number of units and, when added to the large landholdings in the area (over 100 hectares), control more than 50% of the total land surface.

The highly unequal pattern of access to land is also reflected in the unequal distribution of other resources. The majority of peasants do not own oxen, the principal draft animal in the area. The average middle peasant household owns one ox, whereas only rich peasants and farmers own an average of two oxen, the number required for plowing. The unequal ownership of draft animals is reflected in the data on the average value of the means of work and in the value of total assets of the different social strata. Finally, there is a positive relationship between the household's access to resources and the average household size.

Household composition and structure interact with a given stock of the means of work to determine not only the division of labor by sex and age within the peasant household but the number and composition of activities in which a given household may engage. The specific division of labor by sex and age will vary over the family life cycle and according to the range of activities which the household may pursue (given their access to the means of production) as well as with the social valuation of male and female labor. Tables 2 and 3 give a static picture of the division of labor by sex in productive activities and the differing rates of household participation by social strata in a series of income-earning activities.

Table 2 presents the data on the principal family member that is charged with the re-

---

Cajamarca. The 1973 survey provided the population for a follow-up survey of 105 households; the 1976 Peasant Family Survey, focusing on the familial division of labor by sex, was carried out by the authors.

[a] Includes cases where mother and father share responsibility for the activity, where other family members carry out the activity, and where parents and children carry out the activity with equal responsibility.

sponsibility for directing and carrying out the series of household activities aggregated over all social strata. Mothers, principally assisted by daughters, carry out the myriad of activities which are required to reproduce familial labor power on a daily basis. But women also play an active role in home production activities. In the majority of households, women are charged with animal care in addition to agricultural processing and artisan production. Men, in contrast, are the principal agriculturalists. In the majority of households that participate in the labor market, fathers and/or sons are the wage workers. However, commerce is an off-the-farm activity that is generally in the female domain.

As table 3 indicates, there is significant variation in the composition of income-generating activities in which different strata of the peasantry engage. Whereas the overwhelming majority of peasant households participate in direct agricultural production or in animal-raising activities, the salient feature of the table is the different degree of participation in the labor market by social strata. Whereas the majority of landless and smallholder households have at least one labor market participant, only one-third of the upper strata of

peasant households engage in the sale of wage labor. The differing access to the means of production is also reflected in the rental of productive resources and in animal-raising activities.

While the majority of peasant households engage in agricultural production, there are significant differences by social strata in the purpose of production (use values versus commodities) and in the magnitude of the activity in terms of the composition of net household income. As table 4 illustrates, an insignificant portion of the agricultural production of landless peasants is sold on the market. Even among smallholders and middle peasants, less than one-third of the total imputed value of agricultural production is sold on the market. Only the rich peasants appear as principally agricultural commodity producers. The farmers are primarily commercial dairy producers. For all strata of the peasantry, cash income from the sale of animal products is relatively more important than that from agricultural production.

While the bulk of agricultural production of the poorer strata of the peasantry is dedicated to use value production, the Cajamarcan peasantry certainly cannot be characterized as "subsistence" producers divorced from the wider economy. Over 80% of the total gross income of the landless and smallholder strata is in the form of monetary income generated by their participation in the product and labor markets. Only the middle peasants exhibit any important degree of "self-sufficiency," although only one-third of their total gross income is derived from home production activities. The data indicate the importance of the integration of the peasantry into capitalist commodity relationships.

Table 5 illustrates that the majority of the peasantry relies on nonfarm sources of income to reproduce their livelihood. Only the middle strata of the peasantry and the commercial farms of the rich peasants and farmers rely on farm activities for a majority of the net mean annual income. The importance of wage income for the landless and smallholder strata is evident and correlates with the high degree of labor market participation of these strata. The data support the proposition that access to the means of production is a key to determining the form of integration of the peasantry to the wider economy: the majority of peasant households with insufficient access to land are increasingly integrated as proletarians, whereas only among the upper strata of the peasantry with their greater control over the means of production is commercial farming a viable activity.

There are important differences in the levels of income generated by different strata of the peasantry. The estimated median net income by social strata is presented in the last column of table 5. The greatest disparity in income levels characterizes the rich peasants and the farmers at one pole and the landless peasants and smallholders at the other pole. The gross median income of the farmers is 22% greater than that of the rich peasant strata, 99% greater than that of the middle peasants, 158% greater than that of the smallholders, and 116% greater than that of the landless peasants.

In 1973 the median net income was on the order of U.S. $156. If the legally defined minimum wage is taken as an indicator of the "moral and historical" minimum subsistence requirement of a worker, the magnitude of rural poverty becomes clearly apparent. In

[a] Based on 1973 dollars.

1973 the minimum legal daily wage in rural agricultural employment in the district of Cajamarca was U.S. $1.00. A full-time proletarian working 250 days a year would earn approximately 60% more than the annual net median income of the peasantry. Only the rich peasants and farmers earn income above that socially defined minimum required to reproduce the labor force. The other 89% of the peasantry falls below this threshold.

The implications for the development of the home market are clear. While most of the net income of peasant households is generated in monetary form, the low absolute income level restricts the magnitude of effective demand. For the overwhelming majority of the peasantry, net income is destined for the purchase of means of consumption to reproduce their level of living. Aggregated over all strata of the peasantry, the composition of consumption expenditures is dominated by the expenditure on processed foodstuffs (cooking oils, sugar, and flour) followed by expenditures on fuel (kerosene, candles, matches, and wood) and clothing and then on education and health and, finally, on housing and household equipment. Only among the rich peasants and farmers is investment in new means of production significant, primarily in increasing the size of animal stocks.

The level of outcome of the production and circulation processes in which different strata of the peasantry engage determines both the level of consumption possible to reproduce familial labor power as well as the family's access to means of work and raw materials in the next productive period. This, in turn, is the basis for social differentiation to which we will return shortly.

Patterns of Surplus Extraction

Appropriation of part of the product of peasants by other social groups has been identified as a defining characteristic of peasantries by Marxists and non-Marxists alike (Wolf). Within Marxist discourse, the social relations of production in which peasants participate are, in fact, defined by the manner in which the surplus labor time of direct producers is appropriated by a nonproducing class. From an empirical standpoint, we must first identify the mechanisms through which surplus extraction occurs in order to analyze the relations of production into which the peasants enter. In this manner we can then single out different groups of peasants. The model of the organization of the peasant household presented above can be used for this purpose. In figure 1, seven mechanisms of surplus extraction are identified: three operate via rents that result from private appropriation of the land (rents in labor services, kind, and cash), three operate via the markets (for labor, products, and money), and one through the state (taxes).

(*a*) Rent in labor services (*corvée*): family labor is forced to provide unpaid labor services on the landlord's estate in order for the peasant household to acquire the usufruct right to land from which to produce its subsistence consumption. This type of rent characterizes semifeudal or servile relations of production.

(*b*) Rent in kind (sharecropping): the direct producer gives to the owner of the land a predetermined amount or a fixed share of the product in exchange for access to the land and occasionally to some means of work. Rent in kind is a direct subtraction from the gross product before the residual is divided into use values and commodities. Rent in kind also may characterize semifeudal relations of production or represent a form of land acquisition and surplus extraction among different groups of peasants.

(*c*) Extraction of surplus value: in capitalist relations of production, labor power is sold for a wage to those who own the means of produc-

tion. In the production process, labor generates a product, the value of which is greater than the costs of replacement of the physical capital resources and the wage labor used in production. A profit is thus generated which results from the "exploitation" of labor power in the production process. Semiproletarian peasant labor can, however, be further exploited indirectly because the wage level can fall below subsistence needs (for maintenance and reproduction) as part of these needs are provided by the family in the home production process. Cheap peasant labor, extracted through "functional dualism" (de Janvry and Garramon), is thus a major source of exploitation of peasantries under capitalism in the third world.

(*d*) Extraction via the terms of trade: unfavorable prices for the commodities sold relative to the commodities purchased (means of consumption and means of work) is the dominant form of surplus extraction from independent peasant producers. Once capitalist commodity relations have developed, low agricultural product prices may result from a variety of causes including competition with capitalist agriculture, international transmission of prices, cheap food policies, and monopolistic merchants capturing high profit margins.

(*e*) Usury: the instability of peasant agricultural production often results in peasant indebtedness to local moneylenders (merchants, landlords, and rich peasants) who charge usurious interest rates. The money market thus becomes an important source of surplus transfer.

(*f*) Rent in cash: with full development of a money economy, the rental of land is increasingly paid in cash. The peasant farm thus needs to be increasingly commodity-oriented and specialized. In contrast to the other forms of rents, production and price risks are shifted completely from the landowner to the peasant producers.

(*g*) Taxes: taxation assumes different forms —head taxes, land taxes, market taxes, export taxes, and income taxes—with differential impact upon the peasant economy. All represent important sources of fiscal revenues for the state and usually a transfer of surplus from the peasantry to other classes in the social formation.

Once the mechanisms of surplus extraction have been identified, the controversy over the economic logic of peasant households becomes essentially trivial.[4] Simple reproduction of the peasant household (its inability to accumulate) is not based on a given behavioral determination (that peasants prefer to produce only their necessary subsistence requirements) but, rather, must be located in the relations of production that presume surplus extraction. What is key is the dominated class position of peasants within different social formations.

The empirical analysis of the mechanisms of surplus extraction in a given social formation necessarily requires historical analysis because distinct relations of production are maintained by a complex interaction of political, ideological, as well as economic elements. To illustrate, in the Cajamarca area the hacienda system was the dominant rural institution well into the 1950s. Peasants gained access to land on the hacienda through the provision of rent in labor services, in kind, and in cash. An important characteristic of semifeudal or servile relations of production in this area was that the various mechanisms of surplus extraction through rent were superposed, and landlord-peasant arrangements exhibited a combination of forms. Nevertheless, three groups of peasants can be characterized according to their main form of rent payment (Deere).

The *colonos* were the peasants who paid the predominant form of their rent in labor services; the most common arrangement called for an approximately equal division of time between labor services required by the landlord and the familial labor time left free for the family's own subsistence production. The group of peasants called *partidarios* or *medieros* were generally sharecroppers; the

[4] Few controversies have generated less insight than that concerning the economic logic of peasants: do peasants engage in the calculus of economic maximization in the allocation of scarce resources among alternative ends or are there specific economic rules that characterize peasant economic behavior that, in particular, negate expanded reproduction? In anthropology the conflict has assumed confrontation proportions between formalists (Firth, Tax, Nash, Leclair) who assume the former position and substantivists (Polanyi, Dalton, Sahlins) who assume the latter. Agricultural economists, with their neoclassical heritage, have nearly all stood on the side of the formalists (Schultz, Hopper, Lipton).

For empirical purposes, specification of the peasant's economic objective function is indeed important, but the characteristics of the particular social formation within which peasants are inserted must be specified first. Once this specification has been made, the controversy becomes essentially trivial. Each mode of production clearly has its own ideology and economic rules which, when reflected at the level of the social formation, condition economic behavior and the economic possibilities for peasants to reproduce themselves as direct producers.

landlord provided the land and the seed and sometimes the oxen for plowing, while the peasant family provided the labor. The crop was usually divided into equal shares. The *arrendires* on the hacienda were the peasants who paid their rent in cash; this arrangement was most common for the rental of grazing land. Notwithstanding the payment of rent in kind or in cash, these latter two groups of peasants also provided labor services to the landlord which ranged from two weeks to three months of labor services per year, depending on the personalized landlord-peasant relationship as well as the labor requirements of the landlord.

Other mechanisms of surplus extraction on the hacienda focused on the landlord's control over any marketable surplus that the peasants may produce after the payment of rent. On many haciendas, the resident peasants were required to sell any of their surplus production directly to the landlord; at other times, certain specified quantities of produce or animals were to be sold to the landlord at an established price. On many of the larger haciendas, the landlord also operated a country store where peasant families were required to purchase their nonproduced necessities. These commodities were often provided on credit for payment at harvest time at prices set by the landlord.

With the dissolution of the traditional hacienda system in the 1950s and 1960s, the majority of peasants were expelled from hacienda lands and became independent peasant producers—owners of their own plots of land acquired from the division and sale of marginal hacienda lands. The haciendas themselves were transformed into large-scale commercial farms using wage labor. With the change in the relations of production, rent was no longer paid directly to the landlord, and the landlord no longer controlled the circulation of commodities. But as the peasantry became increasingly integrated in the product market, they became more dependent on the upper strata of the peasantry and the farmers who now were to serve as both the primary providers of credit and petty monopolists in rural markets. In addition, the rapid integration of the peasantry into the labor market assured that low wages would become a principal source of surplus extraction as the rural areas became the storehouse of surplus labor.

For the rural sector at large, the unfavorable terms of trade between agricultural and manufactured products constitute an important source of surplus transfer. In the 1973 to 1975 period, the terms of trade were deteriorating at a rate of 8.6% per year (Acevedo). While quantitatively the bulk of commercial agricultural suppliers are found among the upper strata of the peasantry and the commercial farms, these sectors are able to face deteriorating terms of trade only due to the plentiful supply of cheap labor available from the poorer strata of the peasantry. The poorer strata are squeezed at both ends: as wage workers, they receive a wage significantly less than the value of what they produce; and, as producers, they are faced with deteriorated prices for the commodities they sell to insure cash needs.

The Class Position of Peasants and Differentiation

Having characterized the organization of the peasant household and the patterns of surplus extraction through which peasants are exploited, we move on now to locate the peasantry as a social category within the broader society of which it is a part. Doing this implies taking sides in the debate opened in Russia at the turn of the century between Bolsheviks and Populists regarding the specification of a unique peasant mode of production. This debate has been reopened actively in recent years as an understanding of the future economic contribution and the political role of peasants requires the conceptualization of their position in the economy and in society (Ennew, Hirst, Tribe).

The debate is more than rhetorical, as it leads to markedly different interpretations of (*a*) the economic logic of peasants and (*b*) the future of the peasantry. For those who argue the existence of a specific peasant (or simple commodity) mode of production, peasant economic behavior is not guided by the motive of accumulation but by the objective of simple reproduction. The usual description highlights the family labor farm as the basic unit of production and private property in land which is distributed on a relatively equalitarian basis among households who form a single class. Wage labor is generally not employed, and the production of commodities has as its ultimate goal only consumption. While Marx developed the concept of petty commodity mode of production as a theoretical abstraction in *Capital*, those who employ the concept as a histor-

ical reality (Servolin; Vergopoulos 1971, 1978; Amin; Gutelman) argue that it is observed as articulated to and dominated by other modes of production to which it is functional, surrendering a surplus. The implication, however, is that this peasant mode does have the wherewithal to reproduce itself over time, resulting from its capacity to resist internal differentiation into social classes because accumulation is presumably not a behavioral objective of peasants.

There are, in our opinion, two objections to the use of the peasant mode of production concept. The first is that the specific form of organization that corresponds to peasant households and the existence of mechanisms of surplus extraction are not sufficient to constitute a peasant mode. As a theoretical category, a mode of production implies the specification of a determinate set of social relations and an ideological-political superstructure that remain here unidentified. The mechanisms of surplus extraction are not immutable but, to the contrary, assume a wide variety of forms that correspond to the particular social formations in which peasants are encompassed.

The second objection concerns the observed economic condition of simple reproduction. Do peasants want simple reproduction, or is it that they cannot overcome simple reproduction due to surplus extraction that cancels accumulation? In our opinion, the fact—simple reproduction—is wrongly given explanatory capacity on a behavioral basis while the essence—surplus extraction—is omitted. Clearly, under feudal and communal modes, the possibilities of accumulation and differentiation are severely reduced by the nonexistence of labor and land markets. However, when these markets prevail (i.e., when both labor and land have become commodities under the capitalist mode), the empirical observation of concentration of the land by some peasants and increasing proletarianization of the many—whenever economic and social conditions permit retention and accumulation of a surplus—is a clear contradiction of the peasant mode concept.

For those who oppose the notion of a specifically peasant or simple commodity mode of production, peasants are conceptualized either as a class within a given mode of production (e.g., serfs under feudalism) or as elements of a class under capitalism (Marx, Lenin, Kautsky, Preobrazhensky). Under feudalism, the peasantry was the essential class of direct producers subject to the appropriation of their surplus labor by a nonproducing class—the lords. Under capitalism, peasants are a transitory and differentiating class in a process of decomposition and absorption by the essential classes—proletariat and bourgeoisie—of the mode of production. In the analysis of a specific social formation characterized by heterogenous relations of production, the patterns of surplus extraction are the most revealing indicators of the elements of class: rent in labor services and kind under feudal or servile relations of production; and appropriation of the surplus through circulation (terms of trade) and labor process (wage) under capitalist relations of production.

As the development of capitalism progresses in agriculture, the feudal and communal modes decompose, releasing their peasantries which become incorporated in the capitalist mode as a highly unstable class of direct producers subject to differentiation based on their access to the means of production and the subsequent sale or purchase of wage labor. Following Lenin's characterization of the "farmer road" to capitalism, a few are able to employ wage labor and thus capitalize their production process, and become increasingly specialized as commodity producers, whereas the majority must increasingly rely on the sale of their labor power as they lose access to the means of production. In figure 1, changes over time in the levels of reproduction of the means of subsistence and work give the economic basis of differentiation.

Among the lower strata of the peasantry, the low income level continually encourages permanent migration from the household of sons and daughters old enough to capture their own opportunity cost on the labor market. In many cases the deteriorating level of income attained from the combination of home production and wage work in the rural areas or from temporary migration requires the whole family to leave for the urban environment where temporary work may be easier to find, notwithstanding high rates of unemployment. In Cajamarca approximately 2.2 households per hundred leave the rural area annually for urban centers. In many cases these households continue sharecropping their meager land parcels with neighbors or family members but, after a while, sell out.

Conceptualization of the peasantry within the capitalist mode of production as oscillating elements of class between proprietor and worker is also revealing of the political posi-

tion of peasants. The upper peasantry, with its petty bourgeois character, is tied economically to the bourgeoisie but ideologically to the mass of peasants. It thus constitutes a buffer class between bourgeoisie and proletariat in the increasingly polarized rural population. In recent years, a number of reforms promoted by the state have attempted to recreate this category for the purpose of political stabilization. Land redistribution, settlement schemes, and efforts at rural development have this significant—if not always explicit—political dimension.

In our analysis, the peasantry as a producer of commodities is thus only a transitory social stratum under capitalism. Transition does not, however, imply a particular pace. Indeed, this transition can last for a long time; and the absolute number of peasants in the third world still may increase for a long time to come under the double force of the demographic explosion and the decomposition of feudal and communal modes that eject their peasantries into the capitalist mode of production. Yet, these peasants differentiate and are reproduced increasingly as wage workers: the majority gradually lose their status of producers of commodities while attempting to maintain that of producer of use values as a necessary complement to wage earnings in insuring household subsistence. This, at least, is what the peasantry of Cajamarca is currently undergoing.

Present and Prehistoric Problems of Natural Resources

Ernest W. Grove

The currently developing crisis in natural resources is put in historical perspective as one stage in the ongoing agricultural-urban revolution. This started after the last ice age, when rising seas covered much land while rising populations needed more. Agriculture was not discovered by hunter-gatherers; it was their last resort when game and wilderness became scarce. The result was conflict and near-slavery for most people. Better conditions came with the fossil-fuel (industrial) revolution, but may prove temporary as the natural resources crunch raises questions not unlike those faced by hunter-gatherers some 10,000 years ago.

Key words: agricultural revolution, energy crisis, natural resources, population pressure.

The Fellows Lecture by M. M. Kelso, probably the best so far, presents the development of a land economist in admirably frank and personal terms. It also presents, clearly and unmistakably, the terrible dilemma that what we have learned to call "modern civilization" has only just begun to face. There is even the implication of a possible Armageddon in the not-too-distant future, although Kelso downplays it by referring only to the "apocalypse" (pp. 814, 819).

As many informed citizens are beginning to realize, there is reason for concern, even alarm, about what might happen in the relatively near future—"near" at least in relation to geological time and the 15-million-year evolution of the human race. In fact, the present-day apocalypse, based on seemingly unchecked population growth, has become almost commonplace in recent years. See, for example, Brown's *The Twenty-Ninth Day,* which refers to the next-to-last time period in a potentially disastrous geometric progression.

The Agricultural Revolution

On the other hand, the explosive changes that took place before, during, and after the initial stages of the agricultural revolution some 10,000 years ago are just beginning to be understood. And we should all of us, including agricultural economists, learn as much as possible about the recent findings of archeologists and anthropologists so that the present-day apocalypse, as articulated by Kelso and others, can be put in its proper historical and prehistorical perspective.

Role of Rising Seas

The main point that needs to be made is that the current, obviously precarious situation is just another stage—not the last—in the ongoing agricultural-urban revolution, which probably had its inception some 20,000 years ago after the peak of the last ice age. Melting ice resulted in rising seas, which eventually covered much of the previously available land surface. So Pleistocene hunter-gatherers were confronted with a gradual but inexorable decline in the area of wilderness land—a formidable problem in natural resource economics, even by present-day standards.

According to Pfeiffer, human population had been increasing gradually for ages, but a land squeeze also began about 20,000 years ago. So much water "was locked up in polar ice caps and glaciers that ocean levels stood 250 to 500 feet lower than they stand today. Hunter-gatherers exploited herds roaming over the continental shelf . . ." (p. 69). As the melting started, shorelines receded at a rate of

Ernest W. Grove is Deputy Director, Producer Associations Division, Agricultural Stabilization and Conservation Service, U.S. Department of Agriculture.

a mile or more per century, and a fifth of the total land surface was probably lost in the end.

Role of Population Growth

As to the increase in population, Cohen devotes his whole book, as its subtitle indicates, to a marshaling of the evidence and arguments for an active rather than a passive role for population growth in human history. In other words, and Malthus to the contrary notwithstanding, population growth generally has been the cause of technological change, not the result. Cohen cites Ester Boserup as the originator of this heretical view, and says "in her analysis of agricultural systems she argues that it is not so much technological progress as population density that determines what type of agriculture will be employed. She argues, in fact, that the relative efficiency of various agricultural technologies is largely a function of population density, and that the various known technologies represent a continuous series of more or less elastic responses to growing population" (p. 13).

Cohen summarizes his own views as follows: "I intend to argue that human population has been growing throughout its history, and that such growth is the cause, rather than simply the result, of much human 'progress' or technological change, particularly in the subsistence sphere. . . . By approximately 11,000 or 12,000 years ago, hunters and gatherers, living on a limited range of preferred foods, had by natural population increase and concomitant territorial expansion fully occupied those portions of the globe which would support their lifestyle with reasonable ease. . . . [Beginning about 8,000 B.C.,] populations throughout the world, already using very nearly the full range of available palatable foods, were forced to adjust to further increases in population by artificially increasing, not those resources which they preferred to eat, but those which responded well to human attention and could be made to produce the greatest number of edible calories per unit of land" (pp. 14–15).

Life and Skills of Hunter-Gatherers

Cohen's arguments following this summary are quite convincing, as are also those of Farb, Harris, and Pfeiffer on the same general subject. Earlier theories of agricultural origins held that agriculture was "discovered" about 10,000 years ago when some exceptionally observant individual noticed seeds sprouting in a refuse heap near camp and drew the appropriate conclusion. But this "Eureka theory" grossly underrates hunter-gatherers. "It assumes that they had exploited wild plants for several million years without learning what happens when seeds are placed in the ground" (Pfeiffer, p. 69). Farb also points out that the few remaining present-day hunter-gatherers are almost the equal of professional botanists in their practical knowledge of the plants they are exploiting. Thus, it must be assumed that the knowledge was there all along, but that domestication made no sense in a normal hunter-gatherer context.

There are two reasons why this is so. First, the diet of hunter-gatherers was superior to that of farmers or city dwellers at almost any stage of development. This hardly requires demonstration, since the human organism evolved for millions of years in a hunter-gatherer context, and developed a need for a variety of proteins, vitamins, minerals, and trace elements that were readily available in that environment. And the second reason is that the hours of work required for a decent lifestyle were much less for hunter-gatherers than for primitive farmers.[1] The lifestyle of present-day hunter-gatherers may have little appeal for "civilized" humankind, but they enjoy more leisure than most of us.

Thus, the shift to agriculture could have been made at any time, but it was not a desirable change for advanced hunter-gatherers to make under normal circumstances. Why, then, did the shift take place at approximately the same time all over the world? The answer is: There were too many hunter-gatherers; they were on the verge of starvation, in some areas at least; and there must have been ever-growing conflict among hunter-gatherer bands—which previously had been part of the "peaceable kingdom."

Disappearance of Megafauna

The disappearance of many species of large game animals (megafauna) during the Late Pleistocene constitutes important supporting

[1] This may not have been true when game animals had become scarce, just before the agricultural revolution. But it was certainly true before that. The life of primitive men and women was not "nasty, brutish, and short."

evidence. The possible reasons for this disappearance have been the subject of some controversy, with older theories holding that the extinctions resulted from drastic changes in climate and resulting disruption of food supplies and reproductive patterns (Martin and Wright). But the latest theory, strongly advanced by Martin (1967) during the last decade, is that the extinctions resulted from "overkill," not "overchill." In other words, man the superpredator destroyed his own primary source of food.

The overkill theory now seems to be gaining general acceptance, not necessarily as the sole cause of extinctions, but certainly as an important contributing factor. Martin's main arguments, in fact, are not likely to be successfully refuted. He points out (*a*) that the large mammals had survived previous advances and retreats of polar ice, (*b*) that megafaunal extinctions occurred at different times in different parts of the world, whereas climatic changes were approximately simultaneous worldwide, and (*c*) that, "when examined on a global basis, in which Africa, North America, Australia, Eurasia, and the islands of the world are considered, the pattern and timing of large-scale extinction correspond to only one event—the arrival of prehistoric hunters" (1967, p. 36).

Megafaunal Extinctions in America

Martin (1973) has even developed a model or hypothesis concerning the discovery of America in which megafaunal extinctions are a key element. "At some time toward the end of the last ice age, big game hunters in Siberia approached the Arctic Circle, moved eastward across the Bering platform into Alaska, and threaded a narrow passage between the stagnant Cordilleran and Laurentian ice sheets" (p. 969). "By analogy with other successful animal invasions, one may assume that the discovery of the New World triggered a human population explosion. The invading hunters attained their highest population density along a front that swept from Canada to the Gulf of Mexico in 350 years, and on to the tip of South America in roughly 1,000 years. . . . The model generates a population sufficiently large to overkill a biomass of Pleistocene large animals averaging 9 metric tons per square kilometer. . . . It requires that, on the front, one person in four destroy one animal unit (450 kilograms) per week, or 26 percent of the biomass of an average section in one year in any one region. Extinction would occur within a decade. There was insufficient time for the fauna to learn defensive behaviors, or for more than a few kill sites to be buried and preserved for the archeologist" (p. 973).

If Martin's model for the New World survives future findings, it means that the first North American "frontier" was not the westward agricultural frontier of the nineteenth century, but rather the southward hunting frontier from about 9,500 to 8,500 B.C. In any case, there can no longer be any doubt about the important role of primitive hunters in the large animal extinctions of the Late Pleistocene. Men always had hunted cooperatively in groups, and it is certain that, during the successive advances and recessions of polar ice, these hunting groups had become extremely efficient.[2] The hunters, however, were not conservationists—just the opposite, in fact. Whole herds could be destroyed to provide only short-term sustenance for a small group of people. One method was encirclement with fire. Another was to stampede the herd over a high cliff, with women providing the coups de grace at the base of the cliff. The conservation of natural resources is an idea that imposes itself on the human mind only as a last resort.

Slow Development of Domestication

Agriculture developed slowly and spasmodically in different parts of the world, and reversion to the hunting life probably occurred whenever possible. For example, the Plains Indians had settled down to agriculture because of a scarcity of accessible game animals long before the Spaniards arrived. But when the horse became available again—it had previously been killed off for food by the Indians' ancestors—there was a prompt and enthusiastic return to the hunting life, with the large and previously too formidable buffalo herds as the target. Because the hunting life is still so ingrained in all of us, it seems quite clear that agriculture could have developed only at a time when the comparative advantages were overwhelmingly in its favor.

Domestication of crops provided more food for more people. But domestication of ani-

[2] The bow and arrow may have been invented when the growing scarcity of game animals had made spears relatively ineffective.

mals, in its early stages, could provide no more than was already there. Why did it occur? According to Cohen, "severe territorial competition among human groups," and their growing commitment to sedentary behavior, made it increasingly difficult to exploit wild herds. Domestication of animals was "primarily a means of subjecting them to the requirements of an exploitative system geared more and more to intense exploitation of spatially limited vegetable resources. . . . The only other alternative for human population, as demand for calories and protein continued to grow, would be to eschew the vegetable resources and follow the herds in the fashion of nomadic pastoralists; but this alternative would be available only to a very few" (p. 60).

Importance of Animal Domestication

Thus, animal domestication may have been more a matter of expediency than of sheer necessity; but it was a very important step nevertheless. In the Old World, domestication occurred before all the suitable species had been killed off; and Harris calls this "the greatest conservation movement of all time" (p. 27). "The domestication of sheep and goats was followed rapidly by that of pigs, cattle, camels, donkeys, and horses" (p. 29). These species are herbivores and ruminants, and they thrive on grass, stubble, leaves, and other plant foods which human beings cannot digest. Thus, they were important additions to the new agricultural system, and provided the basis for additional technological advances.

In the New World, on the other hand, Pleistocene extinctions had resulted in an almost complete absence of such species. And this in turn, according to Harris, set the New World on an entirely different path from that of the Old World, and at a much slower pace. Thus, the inadequate diet of the New World "explains why it was that Columbus 'discovered' America and Powhatan did not 'discover' Europe [and why] Cortes conquered Moctezuma rather than the other way round" (p. 29).[3] Humankind is omnivorous by nature, and the elimination of meat from the diet exacts a high price.

The Ongoing Revolution

To summarize, the principal theme that emerges from the arguments and evidence presented by Pfeiffer, Cohen, Harris, and Farb is that humankind is still involved in a revolution that started some 10,000 years ago when its earliest lifestyle, its original traditions, and its established ethics began to crumble. This revolution got started as a response to the threat of extinction—nothing less could have brought it about. According to Pfeiffer, "slowly rising seas and slowly rising populations represented a kind of pace-setting system or background pressure, broad forces on a world-wide scale that brought about the agricultural revolution" (p. 69). The way of life of hunter-gatherers was failing, and gradually more and more of them fell back on their previously "useless" knowledge of plant and animal domestication. "Never before has the life-style of a species . . . changed so utterly and so swiftly. For some 15 million years, members of the family of man foraged as animals among animals. The pace of events since then has been explosive" (p. 28).

The Consequences

Also according to Pfeiffer, some consequences of the agricultural revolution were: (*a*) People had to stay put, so conflict reached new levels of intensity. (*b*) Resulting from increased population, reduced mobility in turn resulted in further and faster increases. (*c*) People concentrated in larger groups, raising the problem of order and security, both internal and external. (*d*) This led to the creation of elites and "absolute divine authority invested in men on earth" (p. 41), part of the price paid for stability. (*e*) Religion was elaborated and enforced as a back-up for this system. (*f*) Emergence of the state required an absolute ruler, preferably divine, to serve as an intermediary between his people and the gods. (*g*) "People were being domesticated along with their plants and animals" (p. 436). (*h*) In particular, the taming of the human male is a slow process that is still going on. And (*i*) "agriculture confronted [the male] with a kind of technological unemployment, a loss of status and self-esteem" (p. 464), and it is possible (though not proved) that this in turn led to contempt for "women's work" and the downgrading of women. As agricultural economists, we should add one more consequence:

[3] It also explains why ritual cannibalism developed as an important feature of the Aztec religion, whereas religions in the Old World developed eventually in the direction of mercy, reconciliation, and atonement. In his two chapters on "The Cannibal Kingdom" and "The Lamb of Mercy," Harris is quite convincing on this score. He even provides a cost/benefit analysis of state-sponsored cannibalism!

(*j*) the development of agriculture made land valuable, and was thus the beginning of a new kind of trouble.

Elaborating on items (*f*) and (*g*) above, Harris points out that the rise of the state meant slavery for most people. "For the past five or six millennia, nine-tenths of all the people who ever lived did so as peasants or as members of some other servile caste or class. With the rise of the state, ordinary men seeking to use nature's bounty had to get someone else's permission and had to pay for it with taxes, tribute, or extra labor. . . . Under the tutelage of the state, human beings learned for the first time how to bow, grovel, kneel, and kow tow. In many ways the rise of the state was the descent of the world from freedom to slavery" (pp. 69–70).

In other words, the agricultural revolution destroyed hunter-gatherer institutions which were, as far as we can tell, reasonably democratic in nature, even egalitarian. The result was autocracy and slavery, or near slavery, for the masses. It took 8,000 years for a very limited form of democracy to reappear in the Greek city-states, and much longer for democratic institutions to reappear in a few modern nations. This resurgence of democracy may have been associated, in part at least, with the so-called "industrial revolution" of the last 200 years. But this is itself best viewed as just one short phase in the ongoing agricultural-urban revolution. And now an "energy revolution" seems to be on its way, bringing stresses and strains not now anticipated by the general public, but convincingly forecast by the experts (e.g., Hayes). Will the coming struggle over energy plunge us back into a new kind of autocracy? Only time will tell.

The Current Crisis

In any case, we apparently have reached a point now where we must reassess our approach to the basic necessities of life. In addition to the unprecedentedly concurrent problems of unemployment and inflation, there are new problems relating to environmental pollution and the rapid deterioration of natural systems throughout the world, the realization that supplies of fossil fuels are inherently exhaustible, and the further realization that there is a growing scarcity of agricultural land and other natural resources. We seem, in other words, in danger of forgetting the lessons of sustained yields and killing the goose that lays the golden eggs.

The Question of Economic Growth

In view of all these problems, the question inevitably arises as to the desirability of further economic growth. But the question may not be ours to decide, for economic growth already has slowed down substantially. Denison has pointed out and measured the recent adverse effects on output per unit of input of "(1) new requirements to protect the physical environment against pollution; (2) increased requirements to protect the safety and health of employed persons; and (3) a rise in dishonesty and crime" (1978a, p. 21). He concluded that there was a significant impact, reducing potential gains in output per unit of input by from 20% to 25% in recent years. Elsewhere (1978b), Denison discussed the "puzzling drop" in labor productivity, as measured by national income per person employed, and concluded that a continuation of the "new and much lower growth path" would be disastrous (p. 12).

Brown stated that "the global engine of economic growth is clearly losing steam" because of humanity's relationship to the carrying capacity of biological systems and to the dwindling reserves of several key nonrenewable resources such as oil" (pp. 188–9). Hayes has twisted the screw even tighter by (*a*) showing that "energy and the gross national product have grown hand in hand at 3 to 3½ percent a year for almost 40 years," (*b*) demonstrating that the growth in energy from all sources has slowed down considerably in recent years, and then (*c*) reaching "the dismaying conclusion that energy growth will all but stop in another decade" (p. 233). Jensen is similarly pessimistic in discussing "Limits to Growth in World Food Production." And finally, Train sounds the alarm on the natural environment: "I am struck by the fact that the real 'bottom line' is the maintenance of life on this earth. Time is running out on the natural systems of the earth, and particularly on the survival of species" (p. 201).

But what will happen to a growing world population without a growing world economy? Pfeiffer insists that the agricultural-urban revolution is still in its early stages. "Man, the postponer supreme, has postponed the task of limiting his numbers . . . for the better part of 10,000 years, primarily because of a succes-

sion of advances in agriculture. He is beginning to realize that this delaying action must come to an end" (p. 23). Other species were "adapted" to their environment, and so were human beings until 10,000 years ago. At that time, our ancestors started to "cheat" by changing the environment. "It still remains to be seen whether or not they [or we] will get away with it" (p. 434).

Scenarios for the Future

What of the future? Will we get away with it? Human nature is such, even among scientists, and the nineteenth century idea of "progress" is so thoroughly ingrained in all of us, that a "positive" answer seems almost inevitable until the force of circumstance proves otherwise. Or, as Tiger puts it (p. 15), "anticipating optimistic outcomes of undecided situations is as much a part of human nature, of the human biology, as are the shape of the body, the growth of children, and the zest of sexual pleasure." Of the five authors cited who have considered the problem, one is essentially noncommittal, three are optimistic in varying degrees, and one is a pessimist.

Pfeiffer is the least inclined to prediction. He says only that, "whatever the future, man is moving into it faster and faster . . . " (p. 19). And he concludes his study as follows: "The great problem was always, and still is, to break away from patterns of repeated conflict, of insults and face-savings and victories and defeats—and to devise manmade environments as secure and abundant as the best of the old and all-but-vanished natural environments of hunter-gatherer times" (p. 476). Easier said than done.

Farb is unconvincingly optimistic, basing his hopes for the future on the rather nebulous concept of "modernization," which is loosely defined as "technology interacting with biological and social systems" (p. 452). Technology has admittedly failed us in recent years, but Farb feels that it has only gone "temporarily out of balance" (p. 452). On agriculture, Farb's views do not jibe with those of Brown and Jensen. He states that "technology is already in existence for a very high-yield agriculture, for intensive farming of the sea to produce algae and shellfish, for developing varieties of plants with high protein content, and for cultivating major new crops" (p. 461). But he does not recognize the likelihood of energy shortages and higher costs as any handicap to the achievement of such high technology. In short, Farb believes "that modernized humans will invent new techniques to meet new needs, as they always have in the past" (p. 471). Maybe so, maybe not.

Cohen is essentially optimistic, as indeed he has to be if he is to remain consistent with his previous analysis. He used a Boserupian demographic stress model, documented archaeologically for hunter-gatherer groups, to explain the nearly simultaneous emergence of agriculture on a worldwide scale. Population pressures induced technological advance; but the latter was (and is) more of a "holding action" than the great measure of "progress" we have thought it to be. The idea of "progress" stems only from the last century, and the "prospect of altering our food supply might be more constructively faced if we realized that it is the prevailing notion of 'progress' rather than the contemporary 'crisis' that is the historical anomaly. Perhaps it will aid us in our economic transition to realize that human populations once faced the notion of eating oysters and later the prospect of eating wheat with much the same enthusiasm that we now face the prospect of eating seaweed, soy protein, and artificial organic molecules" (pp. 285–6). But is Cohen's model still valid in the present situation? Or do changes in circumstances render it invalid? Only time will tell.

Brown is ostensibly an optimist. But he states the problems so well the reader hardly believes him when proposed solutions are advanced. His optimism seems utterly forced. Noting first that managing current problems "will require an exceptional exercise of political will and human ingenuity" (p. 11), Brown suggests that "The Inevitable Accommodation" (chapter 10) to nature's limits will require a "planetary bargain" to include "three components—reform of the international order, social reform at the national level, and the overall accommodation of human needs and numbers to the earth's resources" (p. 300). A tall order.

Brown states that the ethic of economic growth must give way to the ethic of "accommodation" (p. 323). He thinks that national security is becoming less dependent on military strength and more dependent on the various natural resource systems for which he seeks an "accommodation" (pp. 294–6). But nowhere does he seem to recognize that an aggressive nation might decide, on rational

grounds, to use its military forces to produce its own accommodation—on its own terms. In view of the history of military aggression since the agricultural-urban revolution began, how can Brown seem to so thoroughly discount the likelihood of its continued recurrence?

Harris is the outright pessimist, although he does not seem so gloomy as the "Global 2000 Study," sponsored by the White House Council on Environmental Quality and reported by Jack Anderson. Harris argues that cultures assume their characteristic forms in response to available resources. As the demands of growing populations eventually exceed these resources, cultures undertake increasingly intensive forms of production until the original resources reach the point of depletion. Then, if the culture is to survive, it must create a new technology, and the cycle of production, overpopulation, intensification, and depletion repeats itself.

In other words, Harris takes the demographic stress model, used by Cohen to explain the emergence of agriculture, and applies it in elaborated form to subsequent developments as well, right down to the so-called industrial revolution—which should have been called the fossil-fuel revolution. Living standards for ordinary people dropped sharply with the coming of agriculture and did not begin to rise again until early in the nineteenth century. Gains over the last 150 years, resulting from the increasingly intensive use of fossil fuels, have largely represented "a regaining of standards that were widely enjoyed during prehistoric times" (p. x). And the current energy crisis raises a question: Will these gains ultimately prove to have been only temporary?

"As coal and oil become scarcer, their costs will go up. And since virtually every product and service in industrial society depends on large energetic inputs derived from these sources, inflation will steadily reduce the ability of the average person to pay for the goods and services now regarded as essential for health and well-being. . . . Food production, to take the most critical example, has now become totally dependent on our oil supply. Agricultural traction, lifting, hauling, and transport were captured first. Now we have reached the stage where the conditioning of the soil through chemical fertilizers and the defense of plants through herbicides, pesticides, insecticides, and fungicides have also become totally dependent on an ever-increasing supply of petrochemicals. The so-called "green revolution" is an oil revolution. . . . The bubble-like nature of this mode of production can be seen from the fact that, if the rest of the world were suddenly to adopt the energy ratios characteristic of U.S. agriculture, all known reserves of petroleum would be exhausted in eleven years" (Harris, pp. 188–9).

Harris fears the most probable technological solution to our energy problems—nuclear power. This is already associated with the military, and it would require only a few very large plants for efficiency. Thus, with power concentrated in both senses of the word, there could be the danger of a new "energy despotism," which would be similar to the despotism of early civilizations based on control of water.[4] There is also some evidence that "after a society has made its commitment to a particular technological and ecological strategy for solving the problem of declining efficiency, it may not be possible to do anything about the consequences of an unintelligent choice for a long time to come" (p. 163). We live in critical times.

Conclusion

Continuing inflation in the foreseeable future, caused in considerable part by the natural resources crunch, is likely to result in a stalemate for the "American Dream." Beyond that, if world population is not soon checked, there could be a real checkmate, not just for the "American Dream," but for humankind as a whole.

An upbeat ending to this survey, therefore, does not seem entirely justified. It is true that, in the infinitesimal time of recorded history, humankind has managed to muddle through some very serious scrapes with its humanity still recognizable if not exactly intact. But the scrapes have been outlasted largely through the services of the four horsemen—war, famine, pestilence, and death. With these population checks more unacceptable now than ever before, what, if anything, can be substituted for them? For a time it was thought that nuclear weapons might induce the ulti-

[4] In so-called "hydraulic societies," the ruler controlled irrigation water—and through it everything else. He could also expand his rule through conquest.

mate extinction of the human species. Could it be that, instead, they will be merely the agent for weeding out redundant humanity—like the suicidal frenzy of the lemmings—and bringing the human population down to a sustainable size?

But this is speculation. Two firm conclusions seem justified. First, the pace of change in the affairs of humankind has quickened markedly during the last 10,000 years and gives every evidence of becoming even more rapid in coming years. And second, there is nevertheless a recognizable continuity in human affairs which we ignore at our peril. In the current crisis, it is terribly important that humankind should compromise its internal differences, insurmountable as they now seem, and get on with the job of deciding what can be done—and then doing it. We cannot count on muddling through this one.

On the other hand, if we insist on muddling through, the only hope for humanity as a whole probably rests in the inevitable fact that "hope springs internal" in the human species (Tiger, p. 147). Many, perhaps most, will not survive. But the survivors, be they few or many, will feel vindicated. They always have, and they always will. It may be in this sense only that there is "hope" for the human race.

In the meantime, however, and in any case, present-day analysts of the natural resources situation, including agricultural economists, should bear in mind the traumatic experiences of the last 10,000 years in their interpretations of current data and in their formulation of appropriate policies.

Product Competition and Consumer Behavior in the Food Industries

D. I. Padberg and R. E. Westgren

Conventional hypotheses regarding product competition and consumer buying behavior are inappropriate for examining these processes in the modern food system. Some new hypotheses about product development, consumer behavior, and their interface are presented. Marketing of new products is not driven by new technology but consists of incremental changes in the existing marketing mix. Adoption of products by consumers is not characterized by analytic consumption behavior, but by risk aversion and preference for incremental changes in the consumption set. Implications for the public interest in these processes are discussed.

Key words: consumer buying behavior, marketing mix, product development, public interest.

Food product competition, particularly with emphasis on product evolution and new product introduction, is of great importance to agricultural economists. A substantial portion of science in the food sector is applied here. Competitive rivalry between major firms occurs at this interface. Structure and behavior of the industries which purchase farm outputs are determined as a result of this process. Dietary patterns and public health, the attitudes of consumers, and the nature of food politics are extensively influenced by these initiatives. Despite the importance of this topic, relatively little attention has been given it. In the instances where agricultural economists have addressed this topic, analysis has been guided by the most primitive hypotheses.

As the public interest in agriculture changes from a focus on the farmer as a disadvantaged interest to include food policy and consumer interests, the attention of agricultural economists must be drawn to these issues. Evidence of increasing public concern with the role of the food industry in consumer welfare is demonstrated by the growing demand for comprehensive national and international food policy and a heightened interest in food safety. (The aspects of the 1977 Farm Bill dealing with human nutrition are a significant example.) These developments will lead to expanded analysis of food product evolution and competition by food scientists and economists. In preparation, this paper will present conventional hypotheses (and explore their implicit roots) and develop some new ones which may be more useful. Examples will be drawn primarily from the food system.

Conventional Hypotheses

A useful beginning may be the identification of hypotheses formed by our experience and thought. Perhaps the most durable of these are the notions within the old quote, "If you build a better mousetrap, people will beat a path to your door." (A similar statement is attributed to Ralph Waldo Emerson. While it is not very useful in economics, it may be judged as quite delightful poetry.) There are two implicit maxims in this quote embraced by economists. The first is that new technology drives product evolution and new product introduction. If the technical advance is significant, product introduction is trivial. A corollary is the maximizing notion that the larger the advance, the greater the welfare increase and faster the uptake of the new technology.

The second maxim is that the other elements of the marketing mix (communications, distribution channels, and pricing) are not integral to the process but merely sales lubricants. Tacitly, the greater advance requires less lubricant. This implies that the measurement

D. I. Padberg is a professor and R. E. Westgren is an assistant professor in the Department of Agricultural Economics, University of Illinois, Urbana.

of the economic value of advertising, for example, evaluates its lubricative capacity. Effects of advertising on the product characteristics purchased by consumers are disregarded. To what extent does advertising provide psychic characteristics (e.g., information, security, status) to the buyer? The naive view of advertising offers no insights into the relationships between product technology and advertising in defining product characteristics.

Another conventional hypothesis is the efficacy of small business held by economists and the public. A great effort is expended to persuade the superiority of small business in new product development. (See, for example, works by Jewkes, Sawers, Stillerman, and Mansfield. Topics are chosen seemingly to avoid consumer products. Most of the innovations are of significance to industrial markets.) The argument centers on the proposition that innovation occurs more frequently in an environment unfettered by bureaucracy. Significantly, this argument is generally used in describing the discovery of a new product or process rather than its introduction to the public. The nexus of this hypothesis with the previous one is the perceived centrality of the technological advance. It has been argued by Galbraith that product competition between firms occurs across all elements of the marketing mix in the introduction of new products, and larger firms have significant competitive advantages in this larger process.

A third conventional postulate that has guided economic analysis is consumer sovereignty in the marketplace. The consumer is characterized by an ability to rationally and completely order consumption bundles. This means the consumer must be able to recognize, evaluate, and rank the characteristics of market goods to achieve maximum satisfaction. This consumer seeks information and makes autonomous and analytical choices. Style or keeping up with the Joneses must be insignificant. This consumer is willing to give sufficient time to this search and comparison process.

Some Hypotheses for Future Research

The following discussion is an effort to extend the accumulation of conventional wisdom into current conditions of consumer affluence, industrial structure, and typical behavior patterns of firms and individuals. Some conventional hypotheses are enhanced, others appear discounted. The following are offered as a tentative outline of significant hypotheses.

(*a*) Product evolution is a broad marketing process spanning changes in product physical characteristics (technology), communications policy, and marketing channels. This process is supported by market research and production methods research. (i) Physical product characteristics and the potential for changing them are often the least significant, least expensive, and least limiting factors in product evolution. (ii) Large organizations may or may not have scale economies in product technology but have advantages in introducing new or differentiated products to consumers—particularly in promotions to the distributive trade and in advertising. (iii) New knowledge about physical product alternatives may contribute little to product evolution because there is no certainty the new product will be introduced. At any point in time there is a stock of product characteristic bundles which does not stimulate the huge investment required for introduction (Skinner). This may be called "redundant technology."

(*b*) Consumers are incrementalists. They want new products similar to familiar goods. They have no scientific or comprehensive standards for evaluating changes in products or judging new products. Big changes are risky and have less value than small changes. (i) Consumers cannot articulate their wants because of the complexity of their choices. They may be able to express the directions of their preferences but no more. Their wants are often only determinate in groups. (ii) Consumers see themselves in a symbiotic relationship with food manufacturers and advertisers. Advertising promotes confidence in purchases by reducing the risk of making choices deemed unsuitable by their reference groups.

(*c*) Public interest in product evolution concerns integrity in communication, sensitivity to collective as well as individual values, waste, conservation, and product safety. (i) Product evolution is an integral part of a society with highly developed scientific capability. Policy should not attempt to minimize or maximize it but try to improve its balance of social and individual effects. (ii) Unregulated product evolution appears sensitive only to individual values. Collective values of conservation, public health, nutrition education, etc., should be encouraged. (iii) Some public interest must be directed toward the enormous

economic power vested in the broad marketing process. The scope of the organizations involved, the vast sums of money spent, the effect on firm growth and decline, and the impacts on consumers are symptoms of this power.

There are three prominent implications to be drawn from the new hypotheses. (*a*) The role of technology-induced product development is muted in the new scenario. (*b*) The role and determinance of consumer behavior are significantly different from conventional analysis. (*c*) The identification and nature of public interest are departures from tradition. These implications merit careful consideration. This paper will not consider these issues empirically but present evidence from other research and recent experience which seems to reflect the new scenario.

Implications for Product Competition

Moving from the concept of a technology-centered process to a model based on extensive redundant technology is a substantive change. Food science offers a vast methodology for altering characteristics of foodstuffs, including taste, form, nutritive content, and preparation. If the cost of introducing one of these changes is large, the firms controlling this technology will be selective in its introduction. What are the criteria for its selection? Little is known about this process in the aggregate. The firm level decision must be based upon (*a*) financial risk of providing capital for production, (*b*) ability to advertise in the matrix of product attributes of competing products, (*c*) possible cannibalization of existing product sales, (*d*) alternative resource use, and (*e*) possible regulatory repercussions.

Attributes of newly introduced products are generally only incrementally different from existing products. The introduction of products closely resembling successful products is seen by firms as less risky than radical changes. Firms are cognizant of the consumer's aversion to radically different goods, and they respond to this preference. Both attempt to minimize risk. This interactive selection process may have more influence on diet and consumption patterns of consumers than the pattern of available technology. Is there a high level of communication integrity linking producers to consumers, thereby making this selection process in the public interest? This position may have validity, but the question is too important to be left to assumption.

The concept of redundant technology needs further elaboration. Is there evidence of a backlog of unused technology for product development and introduction to consumers? Two recent examples are the experiences of Green Giant's boil-in-the-bag technology and the brewing industry's introduction of "light" beers. Both of these technological advances had been explored previously but failed miserably in the market place. With the support of additional market research, new trade promotion and advertising messages were developed. The newly defined marketing mix created successful products. Green Giant and the innovators in the brewing industry showed significant gains in earnings and market share (Bengston, *Business Week*).

The expansion of the definition of product development to include the other elements of the marketing mix represents another departure. This is illustrated by a comprehensive work by Simon which treats advertising as completely independent from product innovation but regards it strictly as a sales lubricant. The process of differentiation and advertising's role in the definition or evolution of product characteristics are not addressed. The confluence of product characteristics and message is evident in consumers' perceptions of products (Silk). To ignore this confluence in assessing the effect of advertising will lead to erroneous conclusions regarding its social significance.

What size of firm is most capable of, and motivated to, innovation? It is indeterminate whether small firms have a competitive advantage in research and development. When innovation is defined as adding to the set of products available to consumers rather than adding to technological inventory, the advantage may be with large, complex firms. Most of the elements of the marketing mix require large investments and have scale economies (Skinner, Marple, Handy and Padberg).

The Role of Consumer Behavior

The consumer role in product evolution is hypothesized differently from tradition. The traditional household provided relatively unsophisticated labor to the assembly line economy and assumed a major role in the processing of food for home consumption. The tasks

of home production required some degree of knowledge and effort in combining purchased inputs. With rising affluence, the complexity of production increased, and the household provided more education, experience, and effort to market labor tasks. Concurrently, consumption activities became relatively less complex. More processing occurred outside the household. Purchased inputs became more diverse. As the value of market labor increased, the value of household time for leisure and consumption activities grew, and the household allocated less time to low valued consumption activities (Schultz).

The assumption of strongly autonomous tastes that related to an economy with limited product choices is inappropriate for the dynamic markets of the second industrial revolution. The plethora of product variations, advertising methods and messages, and distribution alternatives presents the consumer with a confusing set of choices. Choice behavior retreats to habits and impulses with increasing alternatives and decreasing effort allocated to shopping.

The theory of consumer purchasing behavior is considered in its infancy (Woodside, Sheth, Bennett). Cognitive theory suggests the consumer initiates a search process to limit the set of product alternatives from which to make purchase decisions. This search process includes external search in public or social sources and internal search from memory. The complex cognitive processes that assimilate and evaluate this information lead to several manifestations of consumer awareness and behavior. These are discussed at length in Engel, Kollat, and Blackwell; and Sheth. Recent investigations conclude that consumers face an "information overload" in the search process (Jacoby, Speller, Berning; Scammon). The dimensionality of the choice process is too large to construct a complete and ordered set of preferences. The consumers cannot match their perceived product characteristics demand with the product set. This reinforces habituation and limits new product experimentation.

Two inferences can be drawn from the information overload research. Jacoby, Chestnut, and Silberman tested the proposition that as the number of pieces of information on the nutritive content of food products increased and the number of food items shopped for increased, the consumer used fewer nutritive characteristics for decision criteria. Results supported this inference. The second is that the consumer will rely on media advertising as a source of presorted information as the shopping task becomes more complex.

Consumers prefer only incremental changes in new products for two broad behavioral reasons. (*a*) Information overload prohibits the assimilation of all new information. Therefore, it is easiest to appraise the new product in the context of familiar products. (*b*) Consumers seek to minimize the risk associated with new, especially radical, products (Bauer). The consumer takes cues from his environment, particularly from people the consumer associates with or patterns his behavior after, in measuring the appropriateness of product choices. Rothenberg describes this process:

> Why are an individual's tastes deemed worthy of serving as a criterion for his welfare? In an earlier era his tastes could be thought to be a unique representation of what was indissolubly his. The membrane distinguishing the individual from his environment was deemed solid. Social science in the last thirty years has changed this view. Tastes, even personality itself, are now seen made and unmade by the social nexus. The bounding membrane is alarmingly porous. The tastes of an individual—even if we depreciate the effect of advertising—are not nearly so heroically his. They, and he himself, are "only" a relatively stable structure of organized interchanges with a social environment. (p. 281)

The inertia caused by the group nature of consumption pattern determination leads to the introduction of new products with similar characteristics to existing ones. Mass media advertising is implemented to reach a significant portion of the consuming public and convince them of the acceptability of new products and to reinforce the choices for old products.

Consumer reaction to new products often lacks sufficient urgency to elicit analytic behavior from the consumer. Therefore, the novelty factor is often an important aspect of the new product's meaning to the affluent consumer. Scitovsky illustrates several examples of incremental consumer behavior. The Wundt curve suggests that too little variation is boring—but too much is confusing (Scitovsky, p. 35). Again, our communication patterns have considerable redundancy—mixing some new thoughts in usual patterns (so that a friend can finish a sentence when we are half through it). This may seem inefficient, but it would be confusing to get a communica-

tion of all new thought without any familiar comparatives or context (Scitovsky, p. 47).

If educated consumers approached each new product as a matter of sufficient importance to require analysis and preparation, they might be able to react to many of them on the basis of their intrinsic merit. As we retreat into habits, thumb rules, and impulses when confronted with thousands of new products, our reactions take on the patterns usual in reacting to communications and other stimuli. These patterns deal with the new only in small steps and in the context of the old—an incremental process.

Public Interest in Product Competition

Public interest in product evolution and the nature of product competition is unfocused and undeveloped. Two weaknesses in regulatory design are contributory to this. First, monopoly regulation was designed to protect consumers from anticompetitive practices in limited product-line, staple-goods industries. Firm growth and marketing strategies of the second industrial revolution are sufficiently different from turn-of-the-century markets to make most forms of antitrust legislation obsolete. Product competition may have profound (good and undesirable) effects on society, but antitrust does not reach it. Second, past patterns of regulation have been technology-centered, while significant product evolution occurs in other facets of the marketing mix. The Federal Trade Commission alleges that intensive advertising, market channel dominance, and product differentiation are used by breakfast cereal industry leaders to prohibit entry by small firms (Bloom). Bloom argues that the question of efficacy of these industry practices cannot be answered without developing performance criteria for consumer well-being. These practices may be justified by the nature of the product, distribution techniques, and consumer behavior characterizing this market. However, the development of norms for such analysis is tenuous in light of the dynamics of the affluence and socioeconomic changes accompanying the second industrial revolution (Padberg). Economic efficiency norms may be the least important in assessing market performance.

Perhaps questions of advertising integrity and nutrition education have been posed only recently because the public once regarded these issues as concerns of the private domain. Advertising messages and quality were a matter between the consumer and the advertiser. The sovereignty of the buyer was assumed to be sufficient protection from malfeasance. The buyer could vote his preferences by withholding payment and switching to alternatives. Similarly, it was presumed the consumer controlled enough knowledge to make nutritionally optimal purchases.

If these new hypotheses prove valid in explaining consumer and firm behavior, our posture concerning competition policy may change. We may be less inclined to consider advertising categorically wasteful. We may expect less from investments in product technology (which may be redundant). We may define a "public interest" dimension in the whole product evolution process which would require setting public guidelines for directions it might take.

Conclusions

The tendency widely illustrated for researchers to measure technological progress by some quantitative count of technical options and achievements (e.g., patents) appears less than satisfactory. This may identify behavior patterns inappropriately by concentrating on nonlimiting factors in product evolution. Fifty years ago this may have been more appropriate, but present and future usefulness may be secondary.

Arguments regarding advantages of small business in technical achievement are probably irrelevant. Purely technological advances will accrue to the stock of redundant technology and may not result in product advancement in the marketplace. This matter is more related to the marketing event occurring in the other elements of the marketing mix rather than technical product change. The nature of these marketing functions dictate the scale necessary for successful introduction of new products, and the acquired social preference for small organizations and rugged individualism must yield to the pragmatic.

As the roles of advertising and other marketing functions become better understood in the consumption process, consumer behavior research and industrial behavior research will advance. Concurrently, the rationale and justification for regulation of these functions in product competition will emerge. By address-

ing these issues, agricultural economics research will contribute to an efficacious, comprehensive national food policy.

Estimates of Consumer Loss Due to Monopoly in the U.S. Food-Manufacturing Industries

Russell C. Parker and John M. Connor

Three independent methodological approaches and data sets are used to estimate the consumer loss due to monopoly in the U.S. food-manufacturing industries for 1975. They include estimates (*a*) built up from previously estimated components of consumer loss, (*b*) derived from a regression analysis of the relationship of market structure to industry price-cost margins, and (*c*) derived from regression analysis of the market structure determinants of national brand-private label price differences. All three estimates converge to the $12 to 14 billion range. Virtually all of the consumer loss is attributed to income transfers; 3% to 6% is due to allocative inefficiency.

Key words: consumer loss, food manufacturing, industrial organization, market structure, price performance.

The essence of market power is the ability of a firm to raise the price of its product above the level that would obtain if its market were more competitive. Of the numerous, still tenable theories of oligopoly developed by economists over the last 140 years, all predict higher long-run average prices where seller concentration is high (Weiss), product differentiation is effective (Comanor and Wilson), and/or barriers forestall the entry of new businesses into the market (Bain). The major empirical tests of these hypotheses have generally established statistical relationships between the aforementioned market imperfections and higher profits, an indirect effect of raising prices.

The empirical estimation of the direct losses to consumers due to monopoly prices heretofore has been quite imprecise because of inherent methodological difficulties and lack of appropriate data. The processed-foods industries may be an exception.

Most major industrial groups are composed of industries which produce mixtures of high and low priced products of varying durability and which employ diverse channels of distribution. Food and Kindred Products manufacturing, on the other hand, is characterized by low-unit-priced, high-turnover consumer products sold mainly through grocery stores. To the extent that some of the food industries sell to other industries, such as flour and sugar, customers are mainly other food industries. These characteristics, plus the fact that imports and exports are slight, mean that the Food and Kindred Products industries as a group are largely self-contained and do not present the empirical researcher with the need for complex model specification.

A review of the elements of market structure and performance of the food-manufacturing industries provides ample support for the likelihood of substantial departures from pure competition (Connor, Parker 1976). Not only are market shares, sales concentration, advertising, other product differentiation expenditures, and profits high, but also they have been increasing steadily over the last three decades. The processing and

Russell C. Parker is visiting professor in the Department of Agricultural Economics, University of Wisconsin, and an economist with the Bureau of Economics of the Federal Trade Commission. John M. Connor is adjunct assistant professor in the Department of Agricultural Economics, University of Wisconsin, and an agricultural economist with the Economics, Statistics and Cooperatives Service, U.S. Department of Agriculture.

Both authors completed this research while members of the Food Systems Research Group of North Central Research Project NC-117. The research results presented in this paper do not necessarily represent the views of the authors' respective agencies.

The authors wish to acknowledge the invaluable computational assistance of Robert Wills, Pam Bloch, and Mike Murr, and the helpful comments of John J. Siegfried and Michael Gorham. They also received much useful criticism from the discussants and participants of sessions at the AAEA summer meetings in Blacksburg, Virginia, and at the winter meetings of the Allied Social Sciences Association in Chicago, where earlier versions of this paper were presented.

manufacturing of food products occurs in some forty-seven four-digit industries whose competitive structures are quite varied, but in the main they are consumer products industries dominated by companies with high market shares. Increasingly, these leading firms have become consolidated, through merger, into the hands of a few, very large, conglomerate enterprises. Just fifty firms accounted for 64% of food manufacturers' assets in 1978, up from 41% in 1950. Concentration of profits, sales promotion activities, and the holding of leading positions by these fifty firms is substantially higher, ranging upward to 90%.

The weighted average four-firm concentration ratio for all national-market food-processing industries in 1972 was 43%, which is slightly higher than the average of national market industries in the remainder of manufacturing. Adding local market industries (fluid milk, ice cream, animal feeds, bread, and soft drink bottling) and substituting average local for national concentration, the shipments-weighted-average food industry concentration ratio was 52%, indicating a significant degree of oligopoly and potential for competitive problems.[1] Scherer, in his review of the effects of concentration on market performance, concluded that "when the leading four firms control 40 percent or more of the total market, it is fair to assume that oligopoly is beginning to rear its head" (p. 60).

Promotional activities have accounted for a significant increase of the costs of food manufacturers since World War II. Some methods of sales promotion, such as coupons and free samples, provide consumers with price discounts while creating consumer loyalty. Other promotional devices, such as cooperative advertising allowances, special in-store displays, shelf-stocking services, delivery, and information, reduce the costs of retailers or wholesalers. If passed on, these devices would also represent price reductions to consumers. But the bulk of promotional activities currently used for food products (market surveys and test marketing, package design and elaborate packaging materials, point-of-sale advertising, direct mailings, and media advertising) are largely self-cancelling and simply add to distribution costs. IRS data indicate that in 1975 total U.S. advertising expenditures (which include some nonadvertising promotional outlays) by food manufacturers were $4.1 billion;[2] media advertising (TV, radio, magazines, newspapers, and outdoor) of food typically accounts for more than 60% of total food advertising expenditures (Connor). Media advertising of processed foods has risen by an average of 10% per year 1950–75. Because advertising expenses have increased at a much faster rate than sales, the advertising-to-sales ratio of food processors has increased also, from only 1.1% in 1947 to about 2.5% in 1975, with most of the increase accounted for by television advertising.

Persistently high profit rates are another index of monopoly pricing. The profits after taxes, as a percentage of stockholder equity of food manufacturers, have experienced a quarter-century increase of more than 50%. They also have risen relative to profit rates in the rest of manufacturing, itself hardly a model of competition.

The central purpose of this paper is to compute and compare annual "consumer loss" estimates for the U.S. food-manufacturing industries, using three different and independent methodological approaches.[3] These procedures also make use of widely different data bases, two of which have never previously been employed for computing monopoly losses. The estimates display a significant convergence, $12–14 billion for 1975. These large dollar amounts suggest a high payoff for increased public policy attention to competitive problems in the food-manufacturing industries.

Monopoly Loss Theory

Analysis of the welfare effects of monopoly extends back to Dupuit in 1844. Marshall re-

---

[1] Local market industries are more important in food manufacturing because of product perishability or high weight relative to value. There is actually a continuum from completely national to highly local markets, but based on an index of geographic dispersion these five industries are all clearly more dispersed than the other food industries (except for beer).

[2] This figure includes nonfood advertising by the companies but excludes a substantial amount of food advertising by soap and drug companies, other manufacturers, conglomerates, food wholesalers and retailers, and others.

[3] We use the terms "total consumer loss due to monopoly," "monopoly loss due to market power," and similar variants interchangeably. "Monopoly" is intended to encompass not only the 1-firm case but oligopoly as well. The phrase "consumer overcharge," however, is properly used to mean only the income transfer from consumers to the monopolist. Although consumer overcharge excludes the so-called deadweight loss, our estimates indicate that in the food industries most of the total consumer loss consists of consumer overcharge.

fined the concept of consumer surplus, and Lerner extended Marshall's analysis to monopsonists as well as monopolists and to different cost conditions.

Following the framework established by this literature, consumer loss due to monopoly is defined here as the area under the demand curve DD' between the competitive price P_c and the monopoly price P_m (figure 1). To simplify the analysis, we assume that (a) the demand schedule DD' is linear, (b) the monopolist does not price discriminate, and (c) there are constant average costs of production. With increasing marginal costs, both the social-welfare-loss triangle and the monopoly-overcharge-transfer rectangle are enlarged. The total monopoly loss to consumers is represented by the trapezoid P_mP_cCM. The trapezoid has two basic areas: a rectangle P_mP_cRM, which is the sum of overcharges on quantities actually purchased, and the triangle MRC, which is a deadweight or allocative loss incurred by consumers for quantities they would have purchased had the price been the competitive price. Were there a competitive price, consumers would have purchased the additional quantity R to C and would have enjoyed the additional consumer surplus MRC. At the monopoly price P_m, consumers are given price signals that are higher than the opportunity costs for this additional quantity. Thus, consumers are led to consume products they would have regarded as less desirable substitutes were the monopolized food products priced at competitive levels. The triangle MRC is a net loss to society as a whole. No part of it is a transfer as in the case for the overcharge rectangle (P_mP_cRM).

Just how much of the overcharge rectangle P_mP_cRM is an income gain to the monopolist depends on how much higher the monopolist's average costs (X) are compared to the competitive level (P_c). More than 200 years ago, Adam Smith described monopoly as the great enemy of good management; by that he meant that monopolists do not have as strong incentives to minimize their costs of products as do competitive firms. More recently Comanor and Leibenstein have referred to the higher costs of monopolists (rectangle XP_cRE) as "X-inefficiency." These higher costs reflect not only lax management but excessive expenditures on advertising, excess plant capacity, or other costly strategies which protect the monopolist's position from encroachments by competitors. Moreover, monopolistic firms often allow managerial withdrawals in the form of fancy offices, corporate jets, and other inessential perquisites. The monopoly profit rectangle (P_mXEM) that remains after covering the higher costs should correspond to reported before-tax profits in the monopolist's profit and loss statement. However, as suggested by Levinson and Bell, the correspondence is often reduced when firms earning monopoly profits share their gains with their employees through higher wages.[4]

A more rigorous explanation of monopoly loss would relate the area P_mP_cCM to a social welfare loss, defining that as a loss of consumer surplus. No attempt will be made here to reproduce steps and caveats of the traditional proof that the loss of consumer surplus equates to a loss of consumer welfare (see Currie, Murphy, Schmitz). A rigorous calculation of monopoly welfare loss requires assumptions above interpersonal comparisons of consumer utility functions, consideration of the welfare gain of the monopolist, and knowledge of production functions of the products and of their substitutes. However, excluding consideration of the income transfer to monopolists from consumer loss is correct only if income redistribution has no weight in the social welfare function or if there were costless means of offsetting the income distribution effects of market power (Comanor and Wilson).

A full economic articulation of net monopoly welfare loss would adjust the wel-

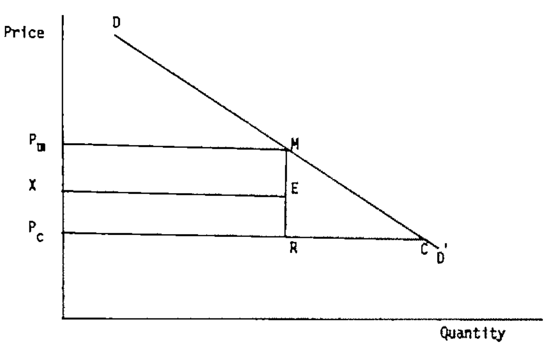

Figure 1. Components of consumer loss due to monopoly

[4] If in a given food industry workers have relatively low incomes and greater equity is a societal goal, then this will reduce further the loss to society that arises from the profit transfer from consumers to the monopolist. However, their incomes must be low relative to both the other claimants on firm monopoly profits (owners and managers) and the consumers of their product to ensure a movement toward greater income equality. Perhaps canned truffles is a product that meets these specifications.

fare loss of consumers (as consumers) by the welfare gain of the monopolist (as consumer) to derive a net welfare loss. Data required for this exercise would include the income distribution of consumers of various products, the income distribution of the various claimants on a firm's rents (owners, managers, government, and possibly workers), and a scale for making interpersonal utility comparisons.

In calculating the following estimates, the increased welfare of the monopolists is ignored, though the omission may not be important if one believes that social equity is served by not increasing material inequality. Food is a basic necessity (a wage good) consumed by all roughly in proportion to dietary needs regardless of income or wealth. On the other hand, the income transfers to monopolies go to a relatively few, higher income individuals whose increased welfare likely would be small in comparison with the welfare loss to all. Indeed, a charter member of the "Chicago School," Richard Posner, has developed a model that assumes that all expected monopoly rents are transformed into gross social costs.

Our estimate of monopoly loss also is overstated by the value received by consumers because of food manufacturers' advertising on information and entertainment media. The value received by consumers from these media is not directly measurable because it is not expressed in a market. Expenditure levels and content are not made in accordance with consumer preference; rather, they are chosen by companies to maximize advertising effectiveness (Doyle). Although advertising expenditures may be efficient in producing private benefits for this purpose, they are likely very inefficient in producing social benefits (Dixit and Norman). Therefore, the authors have made no attempt to adjust their monopoly loss estimates.

Our framework for estimating consumer loss assumes that food product advertising affects only intraindustry preferences for brands and the condition of entry. It ignores all effects on shifting demand between product categories. The authors have substantial reservations regarding this assumption. Comanor and Wilson have found that consumer product demand functions are more responsive to changes in advertising expenditures than changes in relative prices. When changes in interindustry demand schedules occur, additional modifications ought to be made for measuring allocative inefficiency and *X*-inefficiency. The advertising of soft drinks likely has reduced the consumption of milk and fruit juices; the advertising of breakfast cereals probably has caused a decline in the consumption of traditional breakfasts; and the advertising of snack foods and processed foods in all likelihood has caused them to be substituted for fresh products and commodity-type processed foods. Each of these interproduct shifts could well be raising processing costs for food as a sector above minimum necessary levels and may be imposing additional costs on consumers due to health problems aggravated by reduced nutritional levels.[5]

History of Estimation Attempts

There have been very few empirical studies of the loss to consumers due to monopoly, probably because of the general reluctance of economists to deal with questions of equity and technical efficiency. Harberger appears to have been the first to employ the concept of consumer's surplus to quantify the welfare effects of monopolies. Because he considered only the "deadweight" loss triangle (triangle *MRC*) and did not estimate *X*-inefficiency or the profit transfer to monopolists, his estimate was quite small, 0.1% of U.S. national income. Stigler, commenting on Harberger's study, wrote: "If this estimate is correct, economists might serve a more useful purpose if they fought fires or termites instead of monopoly" (p. 34). Subsequent estimates of the "deadweight" loss for the United States generally came to similarly small amounts. One exception is Kamerschen, who, in an innovative paper which considered advertising outlays and employed actual elasticity estimates, arrived at a net welfare loss of 6% of national income. However, his calculations appear to contain a serious arithmetic error (Siegfried and Tiemann). Scherer, however, argues that Harberger's approach subsumes several questionable and restrictive assumptions; more reasonable assumptions would raise the U.S. deadweight loss to a number in the range 0.5%–2.0% of the gross national

[5] Changes in eating habits recommended by the dietary goals (U.S. Congress) have been estimated to enable a family of four to save an annual average of up to $400 on food purchases, roughly eight times our estimates of consumer loss (Peterbin).

product (GNP), with a best-guess estimate of about 1.0% (p. 404).

Scherer estimated total consumer loss for the entire U.S. economy. His estimate included not only allocative or deadweight loss and income transfer but several X-inefficiency components as well. He suggested that the combined total of the X-inefficiency losses was 10% of costs in some industries highly insulated from competition (p. 405). Leibenstein (1978a) cited several industry studies that found excess costs of about 10%, and for all stages of production combined he ventured that he "would be amazed if X-inefficiency wasn't around the 20 percent level for the economy as a whole" (p. 209). With the addition of monopoly profits and deadweight loss, therefore, it is quite possible that the consumer loss could exceed 10% of sales in many industries.

There have been a few estimates of consumer loss in selected industries. Comanor and Wilson applied the results of a profit-market structure regression analysis to a sample of broadly defined industries in the consumer goods-manufacturing sector for the 1954–57 period. Their approach yielded an estimated monopoly overcharge to consumers of 5.5% to 6.0% of value added (p. 242). Unlike all the aforementioned studies which use accounting cost and profit data as their starting point, there are a number of estimates of overcharges based upon price data. For example, Parker (1969), using Bureau of Labor Statistics price data, computed a 15% price-fix overcharge which for the decade 1955 to 1965 cost consumers of bread in western Washington state $30 million annually. Marion, using a structure-price model of metropolitan area food-retailing markets, calculated a 1974 loss to consumers of $662 million nationally due to monopoly in the food-retailing industry.

We have calculated the monopoly loss to consumers of processed foods using three different approaches. These are (*a*) the "loss-components" method; (*b*) price-cost margin estimates; and (*c*) the national brand-private label food price difference method. The three overcharge estimation approaches differ widely and make use of distinct data sets.

The Loss-Components Estimates

Scherer's preeminent textbook in the field of industrial organization presented a set of estimates of the total consumer loss due to market power in the U.S. economy circa 1966 that have been widely cited. He arrived at a total loss figure by considering separately ten different components of consumer loss. His percentage loss for each component was based on an exhaustive review of individual industry studies. Admitting it to be inherently "iffy" and subjective, his "conservative best-guess estimate . . . of the efficiency losses attributable to collusion, the exercise of market power, and related breakdowns of competitive pricing process" was 6.2% of U.S. GNP (p. 408). In addition, he estimated that the redistribution loss of consumers due to monopoly profits is on the order of 3.0% of GNP (p. 409).

Scherer's estimation categories and some of his percentages were adjusted for the U.S. food-manufacturing industries for 1975 (see appendix A of Parker and Connor for details). A summary is shown in table 1. The first component, the income transfer from consumers to monopolists, was calculated by making use of prior regression estimates of market structure-profit relationships for food manufacturing (Federal Trade Commission 1969), substituting, however, the most recent structural data and value of shipment weights. A competitive profit rate was for an industry with 40% four-firm concentration, equal market shares among the top four, and a media advertising-to-sales ratio of 0.5%. The second category, wasteful promotional activities in food, was based on estimates calculated from actual food advertising data for 1975. The procedure involved calculating an advertising-to-sales ratio for the competitive food industries. The competitive advertising rate (0.5%) was then subtracted from actual rates and the remainder defined as excess. The remaining categories of loss due to X-inefficiency were Scherer's estimates adjusted upward on the assumption that X-inefficiency is proportional to the relative degree to which average concentration in the food-manufacturing industries exceed that of all manufacturing. On the basis of both weighted concentration and relative advertising intensities, food manufacturing is more oligopolistic. Two categories of losses were omitted because they do not apply to food processing: deadweight losses in the regulated industries and deficient cost controls in the defense and space industries. The last component, the "deadweight" loss, is among the smallest of the categories. We have deflated Scherer's deadweight loss estimate by assuming a much less elastic demand for food

Table 1. The Loss-Components Estimates of Total Consumer Losses Due to Market Power in the U.S. Food-Manufacturing Industries, 1975

Type of Loss	Scherer's Original Estimate as a Percentage of U.S. GNP, circa 1965	Adjusted Estimates for the Food Manufacturing Industries, 1975: Percentage of Value Added	Percentage of Shipments	Consumer Losses ($ Millions)
1. Income redistribution due to monopoly profit transfers	3.0	7.5	2.1	3,613[a]
2. X-inefficiency due to excess and wasteful advertising and promotional expenses	1.0	8.3	2.3	4,000[b]
3. X-inefficiency due to				
a. lack of cost controls in firms insulated from competition	2.0	6.0[c]	1.7	2,890
b. production at suboptimal scale	0.3	0.9[c]	0.3	430
c. cross-hauling costs and nonoptimal location decisions due to collusive pricing	0.2	0.6[c]	0.2	290
d. chronic excess capacity due to cartelization, collusion, or other monopolistic behavior	0.6	1.8[c]	0.5	870
4. Deadweight and X-inefficiency in the regulated and defense industries	1.2	0.0	0.0	0
5. Deadweight social welfare loss due to monopolistic overpricing and underproduction, unregulated sectors.	0.9	0.9[d]	0.2	430
Total	9.2	26.0[e]	7.3	12,523

[a] Estimate for 1975-based regression equation from Federal Trade Commission (1969).
[b] Assuming $CR4 = 40\%$ as a rough competitive standard, food industries meeting that standard had a media advertising-to-sales ratio of 0.40% (or 0.53% for a total advertising-to-sales ratio). After netting out 0.53% of total domestic sales to consumer processed foods from total advertising expenditures for processed foods, the result is $2,800 million in excess advertising. Because advertising accounts for about 70% of all promotional expenditures, the latter is estimated to be $4,000 million.
[c] All inefficiency components are assumed to be proportional to excess concentration. All of manufacturing has a weighted four-firm concentration ratio ($CR4$) of 44%, or 10% above the assumed competitive standard of 40%. However, food manufacturing's $CR4$ is 52%, which is 30% above the competitive standard, or three times the rest of manufacturing.
[d] Scherer assumed that the long-run price elasticity of demand for an industry's output was −2.5. Studies of comparable elasticities for manufactured food products defined at approximately the four-digit SIC level range from −.3 to −2.8, but most fall within the −.5 to −.8 range. A conservative assumption is −.5.
[e] Expresses consumer loss as a proportion of industry value added. It is the best value measure generally available for comparing the relative economic importance of manufacturing among industries (BOC 1972). Yet the authors realize that some of the sources of the overcharge are not part of industry value added. Examples would include purchased advertising services, packaging materials, cross-hauling by independent truckers, and all of the allocative loss.

(−0.5) than he did for other industries in the economy (−1.0). The aggregate of these component estimates is a consumer loss amount that represents 7.3% of food industry shipments, or $12.5 billion in 1975.

Scherer himself placed a confidence band about his estimate of consumer loss that implied a range of about 5% to 18% of GNP. We feel that because of the two direct estimates made (61% of the total overcharge amount), the total estimate presented in table 1 has a smaller range of error. The components of X-inefficiency adjusted from Scherer contain some assumptions on which reasonable men might differ, but it is extremely unlikely that the levels of X-inefficiency in food manufacturing are less than those of the rest of manufacturing. Price-fixing is rife in many local-market food-processing industries (Marion). The soft drink industry has territorial restrictions that effectively segment markets. Cross-hauling and nonoptimal location decisions are characteristic of several food industries, such as milk. And excess capacity for strategic reasons is known to be serious in the beer industry and others with high fixed costs. For these reasons, we are quite confident that this approach yields a total consumer loss estimate of $12.5 billion that is accurate to within $3 billion.

Price-Cost Margin Estimates

In a 1968 monograph, Collins and Preston examined the relationship between market structure and price-cost margins in food manufacturing. They found a close statistical relationship between the lack of competition and high

price-cost margins in thirty-two food and kindred products manufacturing industries using 1958 Census data. Because higher margins are included in the prices purchasers pay, the present authors have defined the excess in margins due to the lack of competition as the consumer overcharge.

Price-cost margins (*PCM*) are the total dollar amount of value added in an industry less payroll and other direct costs (U.S. Department of Commerce 1972). Therefore, included within the price-cost margins are returns to capital, executive salaries, and expenditures for advertising and other contract services. The overcharge portion of a price-cost margin would include monopoly profits, high salaries of executives, excessive advertising, and costs due to inefficient utilization of capital equipment and contract services.

Collins and Preston used the four-firm industry concentration ratio (*CR*) as an index of monopoly in their model. The present authors accept this role for concentration and define monopoly overcharge as the amounts of interindustry variation in the price-cost margins explained by variation in concentration, other factors held constant. In computing overcharges from the regression models, industries with four-firm concentration levels of up to 40% are considered effectively competitive. As with the loss-components approach, only margin amounts greater than that which corresponds to the competitive level of concentration are considered overcharges.

The variables used to control for other factors in the Collins-Preston model were a capital-output ratio (*K/Y*) and a geographic-market index (*GEOG*). The capital-output ratio was introduced to adjust for differences in capital intensity among industries. The geographic-market index was introduced to take account of the fact that national concentration ratios understate actual levels of concentration in industries whose markets are local or regional in character.

When the model was fitted to the 1958 data using multiple regression analysis, the coefficients in the Collins-Preston equation all had the expected signs and were statistically significant. The best fit of concentration was the nonlinear form involving both *CR* and CR^2. The equation shows that the lowest price-cost margin occurs when *CR* equals 20%, which is half the level the present authors assume as the competitive level. The least squares estimates are shown in equation (1), with *t*-values given in parentheses.

$$(1)\quad PCM = \underset{}{15.699} - \underset{(-1.45)}{.274\,CR} + \underset{(3.75)}{.007\,CR^2} - \underset{(-4.62)}{.121\,GEOG} + \underset{(3.68)}{.250\,K/Y}.$$

The present authors refitted the Collins-Preston model to 1972 Census data for forty-one food-manufacturing industries (appendix table C.1 of Parker and Connor). The coefficients again had the expected signs and were statistically significant except for the linear term of *CR*. The refitted equation (2), which explained 80% of the variation in *PCM*, also shows that the lowest *PCM* occurs when *CR* equals 20%.

$$(2)\quad PCM = 22.096 - \underset{(-.69)}{.211\,CR} + \underset{(1.78)}{.00054\,CR^2} - \underset{(-3.16)}{.117\,GEOG} + \underset{(3.52)}{.178\,K/Y}.$$

In addition to refitting the Collins-Preston model in its original form, the present authors augmented the model by adding several variables suggested by more recent research (Rhoades and Cleaver, Weiss, Strickland and Weiss, and Kwoka). The Parker-Connor model is shown in equation (3). Variables for advertising as a percentage of sales (*ADS*4) of the four largest firms in each industry and for industry growth (*GROW*) were added. The coefficients of all of the variables in the equation had the expective positive signs. In addition to the above, the coefficients of two other variables measuring economies of scale and the intensity of TV advertising had the anticipated signs (negative and positive, respectively), but were not included in the estimating model because they were not statistically significant.

$$(3)\quad PCM = 4.48 + \underset{(3.49)}{.191\,CR} + \underset{(3.64)}{3.695\,ADS4} - \underset{(-1.80)}{.168\,\mathrm{ADS4}^2} - \underset{(-3.07)}{.085\,GEOG} + \underset{(5.97)}{.232\,K/Y} + \underset{(.90)}{.0638\,GROW}.$$

Each of the three equations was used to derive percentage overcharge estimates. The coefficients of the structural variables in the equations were used to calculate the extent to which a price-cost margin for an industry was above that predicted for a competitively struc-

tured industry. The dollar value of overcharge for the industry was calculated by multiplying the percentage overcharge by the industry's 1975 value of product shipments. The total overcharge for all food and kindred products industries was the sum of the individual industry estimates. Table 2 summarizes these estimates.

In order to show the sensitivity of the estimates to the choice of competitive level of concentration, three estimates were calculated from each equation (table 2). In each of the equations *GEOG* is set at 100, which is its modal value for industries that have not been identified as local market industries (National Commission on Food Marketing 1966a). The competitive value of *ADS*4 was set at 0.5%. *K*/*Y* and *GROW* are held constant at their sample means because they are not market structure variables. The predicted values of overcharge therefore abstract from differences among industries due to variations in capital intensity and growth.

The total overcharge estimates from three estimating equations, using 40% as the competitive concentration ratio, range from $12.2 billion to $13.6 billion. The highest estimate is from equation (3). Equation (3) is the most completely specified and also shows the least variability in overcharge amounts due to the choice of the level of concentration defined as competitive. Although the authors believe that the estimate from equation (3) is superior, they wish to maintain a conservative stance by choosing the simple average of the three estimates, $12.9 billion. The deadweight loss that is added to it to arrive at an estimate of total consumer loss is based on the further conservative assumption that demand elasticities in each industry are −0.5. With this assumption the deadweight loss calculates to $823 million and brings the total consumer loss amount to $13,756 million.

Table 2. Total Dollar Amounts of Monopoly Overcharge in the Food-Manufacturing Industries, Estimated from Three Price-Cost Margin Regression Equations, 1975

	Estimated Total Overcharge Amounts when the Competitive Level of 4-firm Industry Concentration is		
Regression Models	35%	40%	45%
		($ billions)	
(1) Collins-Preston equation (1958 parameters)	15.1	13.0	10.4
(2) Collins-Preston equation (1972 parameters)	13.8	12.2	10.2
(3) Parker-Connor equation	15.0	13.6	12.7
Average	14.6	12.9	11.1

National Brand-Private Label Price Difference Estimate

In this method, prices of food-chain private labels are considered to approximate competitive prices; the amounts by which manufacturer brand prices exceed private label prices for the same items and which can be attributed to departures from perfect competition are considered to be estimates of monopoly overcharges. The dollar overcharge for a product category is the percentage of overcharge times the wholesale value of manufacturer-brand sales. The overcharge is attributed only to manufacturers. Only to the extent retailers might pyramid or absorb the manufacturers' overcharge would retailers affect the value of the overcharge. It is assumed that over-pricing by retailers due to local market monopoly positions held (Marion et al.) would apply equally to national brands and private labels.

The private label-national brand price-estimating method cannot be easily applied outside of the grocery products area. In addition to the availability of comparable private label-manufacturer brand price data for a large number of different products, the analysis of the data is made possible by the fact that both national brand and private label products are often manufactured by the same firms to the same specifications, move through market channels in a parallel manner, and encounter few differences in transportation, inventory, warehousing, or in-store merchandising.

Manufacturer brands predominantly are sold nationwide and are supported by large-scale national advertising. In this paper we use the terms "advertised brand," "national brand," "manufacturer's label," and similar variants interchangeably. We also regard "house brand," "controlled label," "retailer brand," "distributor's brand," and "private label" as essentially equivalent terms. "Generic" products, which are packaged items displaying no brand name of any kind, are a special form of private label, but these items did not exist in U.S. grocery stores in

1975. Akin to the generics are the "fresh" meat and fresh produce items in grocery stores, virtually all of which are unbranded items.

Private label products clearly account for a large portion of U.S. grocery store sales. Based on the records of grocery warehouse shipments, the private label share for all processed foods was 16.4% nationally in 1975. If one adds all fresh meat and produce (virtually all private label products) and all nonfood products sold through grocery stores (about 8.2% private label), then fully 39.3% of all U.S. grocery stores sales consisted of private label (or unlabeled) products in 1975.

We recognize that some private labels have achieved wider geographic national distribution than some manufacturer's brands. Also, some private label lines are occasionally given advertising support by the retailers that own them, while a few brands of leading national manufacturers go unadvertised. Nevertheless, in almost all cases the distinction between nationally advertised brands and private labels is unambiguous.

It is assumed that national brands sell at premiums which manufacturers set in accordance with the strength of preference created by advertising and other promotion. Their ability to achieve such prices is enhanced when sales of manufacturer brands are concentrated within a few firms. Advertising is also a principal barrier to entry into food-manufacturing markets. The blockading effect of the advertising barrier is buttressed when the advertising is mainly on television and when it is controlled by large diversified firms who can coordinate it with the activities of large field sales forces. An important problem related to advertising and promotion is the difficulty faced by smaller food manufacturers in obtaining shelf space. In the struggle over shelf space, the small manufacturer faces nearly insurmountable odds (Walzer et al.). Heavy introductory advertising and couponing presell the products of large manufacturers to consumers, virtually forcing retailers to carry the products. Retailers who control shelf space have great discretion in allocating it to their own private labels.

Although large food chains do a considerable amount of food manufacturing, most private label products are purchased. Suppliers are mainly medium-sized and smaller food manufacturers, and purchases are made with price as the primary factor. Food chains have considerable information concerning quality and most of their purchases are bought strictly on a specification basis (NCFM 1966b, p. 133). It is assumed that retailers can obtain private label items at or near the minimum necessary costs of production.

Private label products are usually advertised only in newspapers, with these ads generally featuring price. The average advertising-to-sales ratio for private label products is judged by the authors to be substantially less than the total food chain advertising-to-sales ratio of about 1%, which includes advertising for nonmanufactured products, the company name, coupons, and other store merchandising programs. The actual private label advertising-to-sales ratio probably would be in the neighborhood of the 0.5% calculation used above as the competitive level of food advertising for national brands.

To the extent there are physical quality differences between private labels and national brands, the differences in their prices would imperfectly reflect monopoly overcharges. Available studies comparing quality have concluded that average quality differences are minimal (Federal Trade Commission 1933, Bureau of Economics and Business Research, Jafri and Lifferth, and NCFM 1966b). A painstaking review of several quality tests concluded that "distributors' and manufacturers' brands are essentially equal in quality" (Applebaum and Goldberg, p. 47). Most of these studies are rather dated, and Jafri and Lifferth is based on a rather small sample. Also, in the present authors' judgment, the studies have been biased toward commodity-type products, like canned fruits and vegetables, leaving open the possibilities that quality differences exist between private labels and national brands of highly processed products or that private label products have more variability in quality.

The authors believe the magnitude of such a potential bias is limited by the fact that the food industries are generally low-technology industries whose plants are not significantly affected by scale requirements. Thus, entry by larger retailers is not forestalled by scale barriers. Further, studies of actual private label policies have found that a high quality image for private label merchandise is considered important: "normally retailers' top-line private label merchandise is intended to be of a quality equal to or better than the quality contained in national brands with which they

compete in their marketing area" (NCFM 1966b, p. 133). This finding still leaves the possibility that second-line private label products are of somewhat lower average quality. The very recent introduction by grocery chains of so-called generic products, which are of distinctly lower grades, illustrates this possibility (Walzer et al.).

The combined sales of truly national brand and private label products account for nearly all food product sales through grocery stores (NCFM 1966c, p. 35). The only significant exceptions are several food-processing industries which are organized through local markets because of high perishability of products or high transportation costs. For products like fluid milk and bread, there are often local brands which have "consumer franchises" as strong as the leading national brands of the product.

The data used as measures of the price differences between private labels and manufacturer brands, and also private label market shares, are from a special study of 1976 prices by Selling Area-Marketing, Inc., a subsidiary of Time, Inc. (SAMI). From SAMI data, it was possible to tabulate average manufacturer brand price premiums and private label sales shares for forty-one 5-digit food product classes (Siegfried. These data and details on all other variables discussed can also be found in appendix D of Parker and Connor.) By multiple regression techniques, the authors fitted an equation relating manufacturer brand price premiums to market structure variables measuring the degree of monopoly in product classes. The price difference values predicted by the structural variables in the equation are monopoly overcharge percentages. Random variation and that portion of the price difference variation attributable to the nonstructural variables does not enter into the overcharge estimate. A very similar model was developed and tested using United Kingdom data by Nickell and Metcalf.

In constructing the price differential model, the private label-national brand price difference (*DIFF*) was hypothesized to be greater: the greater the advertising-to-sales ratio of the four leading firms (*ADS*4) in the product class, the more important TV advertising was to total advertising (*TVADV*) and the greater the proportion of advertising done by big firms (200*ADV*). In this case, big firms were the 200 largest food and tobacco manufacturing companies in 1975 (Connor and Mather). Concentration (*CR*4) was hypothesized to increase the price differential; however, it was introduced as a nonlinear term to reflect the general findings of structural-performance studies (Weiss). The Collins-Preston variable measuring geographic distribution of production relative to the distribution of the population (*GEOG*) was introduced to adjust the concentration ratio to market size (Collins and Preston, p. 120). A low value of the variable means similar distributions and a likelihood that national concentration ratios understate true concentration. A net import variable (*NETIMP*) also was introduced as a correction to concentration. Imports are the equivalent to adding additional domestic products to the denominator of a concentration ratio. Therefore, its sign in regression should be the opposite of that of the concentration ratio. Real growth (*GROW*), domestic consumer sales of the product class (*LNSIZE*), and number of manufacturers (*LNFIRMS*) were introduced to capture other differences affecting the price differential. Since private labels generally are considered "me too"-type brands, a rapidly growing product area should see manufacturer brand prices high, riding the tide of brisk demand, and facing little price competition from private labels. Large total sales of the product class, on the other hand, signal a mature product area and the likelihood of a well-established private labels supply. A large number of potential suppliers is also posited to signal a likelihood of well-established private labels and a large number of potential competitors for the national brand manufacturers. If the private label fringe collectively garners a significant portion of the market, price retaliation by the national brand manufacturers is likely (Scherer, p. 186). Thus, the expected signs of *LNSIZE* and *LNFIRMS* are negative.

The estimated price difference regression equation supported the hypothesized predictions for each of the variables (equation 3.1 of table 3). All the terms were statistically significant (except for *GEOG*), and the fitted equation explained nearly three-fourths the variation in the private label-national brand price differences. The good fit strongly supports our hypothesis that national brand price premiums are related to competitive conditions in food-manufacturing industries, and because of this we feel it provides a means for calculating reliable and disaggregated estimates of monopoly overcharges.

Table 3. Regression Results Explaining the Market Structure Determinants of National Brand-Private Label Price Differences and the Private Label Market Share in 1975

$$
\begin{array}{ll}
(3.1) & DIFF = \underset{(.252)}{3.362} + \underset{(2.443)^{***}}{.630\ CR4} - \underset{(-2.443)^{***}}{.0051\ (CR4)^2} \\
 & \quad - \underset{(-1.035)}{.0394\ GEOG} + \underset{(1.626)^{*}}{.909\ ADS4} \\

 & \quad - \underset{(-2.238)^{**}}{2.038\ LNFIRMS} - \underset{(-2.156)^{**}}{17.362\ NETIMP}, \\
 & \qquad R^2 = 0.72,\ F = 7.73^{***} \\
(3.2) & SHARE = \underset{(9.605)^{***}}{36.003} - \underset{(-3.781)^{***}}{.2156\ CR4} - \underset{(-4.331)^{***}}{2.312\ ADS4}, \\
 & \qquad R^2 = 0.94,\ F = 94.88^{***}
\end{array}
$$

Note: Both equations were run using 41 5-digit product classes as observations. Numbers in parentheses are t-values. Asterisks indicate increasing order of statistical significance: * is 10% level; ** is 5% level, and *** is 1% level. The share equation was corrected for heteroskedasticity. The variable definitions (and data sources) are as follows:

DIFF, the percentage that average private label price is lower than average manufacturer brand price (SAMI); *SHARE*, average private label share of grocery store sales of product class (SAMI); *CR*4, four-firm concentration ratio of product class (BOC 1972); *GEOG*, index used to correct *CR*4—a low value means production is distributed according to population and markets are regional or local rather than national (BOC 1972); *ADS*4, advertising expenditures on eight measured media, supporting brands of four largest firms, divided by their estimated consumer sales, 1975 (Connor); *TVADV*, national network television advertising expenditures as a proportion of total measured media advertising (Connor); 200*ADV*, percentage of four-largest-firm advertising done by firms ranking among 200 largest food and tobacco manufacturing companies, 1975 (Connor); *GROW*, real growth in output 1967 to 1972 (BOC 1972); *LNSIZE*, natural log of 1975 domestic consumer sales of product class (BOC 1975); *LNFIRMS*, natural log of 1972 companies in industry (BOC 1972); *NETIMP*, net imports minus exports as a percentage of value of shipments (BOC 1971).

SAMI private label sales shares were regressed on advertising-to-sales ratios and concentration ratios. More complete share equations were fitted, with the coefficients of the independent variables generally showing the correct (opposite) predicted signs.[6] However, variables other than concentration and advertising were statistically insignificant. The simplest equation was therefore selected.[7] The share equation was then used to predict private label shares from which their complements, manufacturer brand shares, were calculated for those product classes where SAMI data were missing. The estimated manufacturer brand sales used in calculating monopoly overcharge are 1975 census values of shipments for the product classes, adjusted for exports and imports, reduced by estimated sales to nongrocery retailers, and reduced by private label sales.

Thus, the dollar overcharge for a product class is manufacturer-brand domestic sales times the percent overcharge. The estimate of the overcharge rectangle (P_mP_cRM in figure 1) for all food and kindred product industries is the sum of the overcharges for all 5-digit product classes. Using the predicted values of the percentage overcharge and manufacturer brand sales, estimates were made for all product classes except "not specified by kind" (see appendix table B.1 of Parker and Connor). The amount of consumer loss attributed to the deadweight loss triangle (*MRC* on figure 1) was calculated using the conservative assumption that demand curves had an average elasticity of −0.5.

The total consumer loss due to monopoly in food and kindred products industries, based on the private label-manufacturer brand price differential model, was $12,436 million. This including a $11,877 million estimate for the overcharge rectangle and $559 million deadweight loss. This estimate is conservative because it encompasses only domestically produced food products sold through grocery stores. It excludes the approximately 30% of food manufacturer sales through restaurants and other mass feeding institutions, animal feeds, and sales that become inputs in more highly processed foods. The overcharges in these transactions eventually get passed on to consumers, but are not captured by our analysis. We have not applied our regression coefficients to estimate overcharges in nonconsumer transactions because we feel that buyers in these markets are much better informed than ordinary consumers and often their monopsony power partly countervails the monopoly power of sellers. The use of those coefficients would have overstated the

---

[6] The authors considered the possibility that price differences (*DIFF*) and private label share (*SHR*) were mutually determined, but experiments with simultaneous equation models did not prove fruitful. Moreover, heteroskedasticity was found in one equation (the share equation), and the authors are not aware of any econometric methods that permit a weighting scheme to be applied to a system of simultaneous equations.

[7] From an examination of the residuals, e_i, of the ordinary least squares (OLS) regression of the private label share equation, we found that both *CR*4 and *ADS* were quite clearly related to increasing variance of the e_i. To correct this heteroskedasticity, let $e_i^2 = \alpha(CR4)^{\beta_1}(ADS)^{\beta_2}$, $e_i^2 = \alpha(CR4)^{\beta_1}$, or $e_i^2 = \alpha(ADS)^{\beta_2}$ and estimate by OLS its double log transform. The last model was found to perform best and $\hat{\beta}_2 = 1.812$ was significantly different from zero. Hence, the appropriate weight to impose homoskedasticity on the share equation is $(ADS)^{-\beta_2/2}$ or $ADS^{0.906}$. A reexamination of the pattern of the residuals of the weighted equation confirmed the validity of this scheme. It should be noted that, prior to weighting, the private label share equation explained 58% of the variation.

effect of concentration, advertising, and other variables on the overcharge. By leaving non-grocery store sales out altogether, we have admittedly erred in the other direction, understating the actual total consumer loss by significant amounts.

Another source of underestimation error involves our assumption that private label prices are proxies for competitive prices. Private label prices are probably higher than competitive levels, particularly when competing manufacturer brands are highly advertised. Not only is there a possibility that retailers may enjoy higher net profits from their private label sales, but a substantial likelihood that retailers' procurement prices may contain elements of monopoly overcharge (Parker 1976). In addition, private labels generally have higher retail gross margins to cover their greater allocation of shelf space and slower turnover rates. To counter the advertising support behind manufacturer brands, retailers generally merchandise private labels by assigning them larger quantities of scarce and expensive-to-maintain shelf space (Walzer).

Despite these caveats relating to the use of *DIFF* as a proxy for consumer overcharge, we believe the results are sufficiently reliable to warrant its consideration as a basis for formulating competition policy with respect to grocery products. Moreover, the method permits the computation of consumer overcharges of narrowly defined product lines, unlike most previous approaches.

Summary and Conclusions

A summary of the three estimates is shown in table 4. The authors believe the estimates are conservative. However, because of the data sets used and because of the estimating procedures employed, a considerable degree of error is likely for each of the estimates. Scherer, for the whole economy, thought that the maximum error would fall within the range of 50% less to 100% greater than his estimate. The present authors have used statistically fitted structure-performance relationships and data specific to food manufacturing to estimate Scherer categories comprising about 60% of the total consumer loss estimate. The estimated values of these components are believed to be more reliable than Scherers' original values and should tend to reduce the error range of the overall loss estimate. The authors have no method for estimating the likely error

Table 4. Summary of Monopoly Loss Estimates in U.S. Food Manufacturing, 1975

Type of Consumer Loss	Loss Components (Adjusted)	Price-Cost Margin	Private Label Differential
	($ millions)		
Monopoly profit	3,613	12,933	11,877
X-inefficiency	8,480		
Allocative	430	823	559
Total	12,523	13,756	12,436

range of their two additional methods. They feel, however, that a 25% error on the two estimates is the most that would reasonably be expected. The extent of convergence of all three essentially independent estimates gives strength to the conclusion that consumer loss due to monopoly in the U.S. food-manufacturing industries in 1975 was at least $10 billion, but possibly as high as $15 billion.

To put these estimates in perspective, recall that Scherer ventured that the monopoly loss to consumers in the whole economy was 9% of GNP; with U.S. GNP running at $1,500 billion in 1975 (Council of Economic Advisors 1977), this implies an overcharge of some $135 billion (or $120 billion if he meant to include only the private sector of the economy). For food manufacturing, our estimate is equal to one-fourth of the total GNP (value added) attributed to the sector. However, put another way, our monopoly loss estimate for processed foods represents 1.1% of U.S. personal disposable income and about 5.7% of average U.S. household food expenditures in 1975.

There are significant implications of our monopoly loss estimates for public policy. The annual loss to consumers in food manufacturing alone is 250 times the combined antitrust budgets of both U.S. antitrust agencies and several thousand times that part of federal antitrust expenditures.

Besides demonstrating that food processing ought to have a high priority for the antitrust agencies, the findings of our price-cost margin and national brand-private label price models suggested that advertising represents an important problem area for consumer products. Furthermore, the problem is most serious when TV is the primary medium and when the advertisers are large firms. This suggests that consideration be given to limiting advertising in industries where it is already intense and to formulating stricter policies that would dis-

courage product extension mergers where differentiated consumer products are involved. This latter suggestion is further supported by evidence that food-manufacturing mergers on average exhibit a subsequent doubling of advertising outlays (NCFM 1966a), often accompanied by a shift toward greater use of TV. An antitrust policy or a new law that reduces food company mergers, especially takeovers by leading grocery product firms and other conglomerates, would be expected to moderate the market power of sellers by its effect on both concentration and advertising.

However, we recognize that neither advertising restrictions nor merger prohibitions may erode this existing market power at sufficient speed to achieve workable competition in all food-manufacturing industries. Under these circumstances, therefore, more direct restructuring may be necessary. Such restructuring could take the form of divestiture of portions of the physical assets of leading firms, compulsory licensing of major trademarks, or other affirmative programs to encourage the entry of firms into the affected markets.

Sharecropping, Production Externalities, and the Theory of Contracts

James Roumasset

Abstracting from transactions costs, the equilibrium bargaining solution with sufficient traders is equivalent to the Walrasian equilibrium. For a sharecropping economy, this proposition establishes the validity of the competitive theory of share tenancy. For an economy with production externalities, the same proposition serves as a nontrivial version of the Coase theorem.

Key words: core of an economy, Lindahl pollution solution, universal markets.

In his most celebrated article, Coase showed that inefficiency is not a necessary consequence of externalities; under well-defined property rights, voluntary arrangements are possible which can internalize externalities. In a similar spirit, Cheung (1969) has shown that share tenancy does not necessarily cause allocative inefficiency; the terms of a sharing arrangement may in fact pay factors their marginal products.

Both contributions can be viewed as different applications of the same point; namely, that under certain conditions, contracts are perfect substitutes for competitive markets. The purpose of the present paper is to illustrate what those conditions are and to show that a related theorem which has been developed and proven by Debreu and Scarf (1963) in another context serves as a solid cornerstone of the theories of sharecropping, production externalities, and contracts in general.

A modified version of the Coase/Cheung proposition is stated in the first section as a corollary of the Debreu-Scarf theorem. Because proofs of the theorem generally rely on advanced mathematics,[1] section two presents a demonstration of the proposition using an example of a simple sharecropping economy. The third section extends the proposition to production externalities. In the concluding section, the main results are summarized and suggestions are made for applying and extending the theory to explain patterns in agricultural contracts.

A First-Best Theory of Contracts

Perhaps the most fundamental concept in the theory of resource allocation is the Walrasian "competitive" equilibrium.[2] The relevance of the Walrasian equilibrium has been much assailed on the grounds that real economic agents do not act as price takers, and, even if they did, there is no strong reason for believing that an equilibrium would be attained. Indeed, the relevance of the Walrasian equilibrium seems to rest on the ad hoc defense of a mythical Walrasian auctioneer (Weintraub).

Roughly a century ago, Edgeworth defended the relevance of the Walrasian equilibrium using the concept of the core of an economy. The Walrasian equilibrium is a noncooperative solution concept based on the notion that agents respond to parametric prices without interagent negotiation. In contrast, the core is a solution concept for cooperative games wherein interagent bargaining is costless. Specifically, the core is the set of unblocked allocations. (An allocation is said to be blocked if some subset of agents can form a

[1] Debreu and Scarf (1963) and Hildenbrand. Recently, however, Johansen has provided an exposition which relies only on calculus.

[2] As Hildenbrand has noted, "Walrasian equilibrium" is at once more descriptive and more specific than the more conventional "competitive equilibrium."

new coalition whereby it can guarantee that all of its members will be better off.) Edgeworth showed that as the number of consumers in a two-commodity exchange economy is increased, the core "shrinks" until, in the limit, it contains only the Walrasian equilibrium (Debreu and Scarf 1972).

Edgeworth's "limit theorem" was resurrected by Shubik and extended to many commodities and production by Debreu and Scarf (1963). It is now commonly referred to as the Debreu-Scarf theorem. The entire literature on the relationship of Walrasian equilibria and the core, including further extensions, has been reviewed by Hildenbrand. Hildenbrand also credits Aumann for making precise the notion that agents will take prices as given if they have no influence on them. That is, Aumann's "equivalence theorem" shows that given reasonable restrictions on preferences, the set of Walrasian equilibria and the core are identical for an atomless exchange economy.

While the primary interest in the limit theorem has been to establish the relevance of the Walrasian equilibrium, it also serves as the basis for a theory of contracts. Just as the Walrasian equilibrium is a market solution, the core, with its assumption of unrestricted bargaining, can be regarded as a contract solution. Thus, the limit theorem implies that, with many traders, the contract solution is the same as the market solution.

More precisely, we can now state the following proposition:

> If property rights are well-defined and contracting costs are zero, then as the number of agents of each type becomes large, all viable contractual arrangements approximate the Walrasian equilibrium with universal markets, regardless of whether markets exist or not.

This is a corollary of the Debreu-Scarf theorem. How close the approximation is depends on how large is the number of agents. "Universal markets" is used, following Arrow, to mean that markets exist for all commodities and activities which enter into either utility or production functions.[3] The above proposition is a "first-best" theory of contracts in the sense that "second-best" considerations, i.e., transactions costs and other constraints, are ignored.[4]

When the corollary is applied to share contracts, we get Cheung's (1969) proposition that share tenancy allocates resources as if a profit-maximizing farmer hired land and labor from competitive factor markets. When it is applied to production externalities, we get a precise and nontrivial version of the Coase theorem.

The Core of a Sharecropping Economy

Cheung (1969) conjectured that aside from the allocative effects of uncertainty and contracting costs, the equilibrium terms of share contracts will be such that factors are allocated and compensated as if they were hired on competitive factor markets. His reasoning was that if the terms of the share contract were such as to induce inefficiency, then recontracting would occur to exploit that inefficiency. Furthermore, if a landowner or tenant were receiving less than his marginal product, he would take advantage of competition and recontract so as to receive his marginal product.

Cheung's attempt to provide a mathematical proof of this conjecture was not successful, but Reid later proved that if landowners and tenants regard the terms of the contract (labor intensity and the sharing rate) as fixed, then the equilibrium contract terms are those which pay factors their marginal products. Given such terms, the allocation of land and labor will be identical to the competitive market solution. The assumption of contract-term-taking behavior, however, appears to be inappropriate in a one-to-one contractual arrangement such as share contracting, where the contracting parties are frequently in contact. Because the costs of negotiation are relatively low, a bargaining model seems more appropriate.[5]

---

[3] Producers may be classified by "types" according to the commodity produced and their production functions. Consumers may be classified according to their demand functions.

[4] This distinction between first-best and second-best has become common only recently (see e.g., Layard and Walters, sections 6-1 and 6-2). The "theory of the second-best" of the 1950s is "If one of the standard efficiency conditions cannot be satisfied, the other efficiency conditions are no longer desirable" (Layard and Walters, p. 181). In modern technology, a second-best problem involves solving for efficiency conditions with one or more additional constraints to the basic restrictions on technology, resources, and preferences. One such additional constraint has captured the attention of economists recently and has led to a sizeable body of literature known as the theory of optimal taxation. The constraint is that government must generate a fixed amount of tax revenue, but it cannot tax leisure. Second-best efficiency is also referred to as "constrained Pareto optimality." The relationship to the "theory of the second-best" is straightforward because the reason we cannot satisfy one of the first-best efficiency conditions is that there must be at least one additional constraint.

[5] Bell and Zusman also have argued for a bargaining approach, but they have chosen the Nash solution as the appropriate solution concept, assumed that contracts stipulating the amount of labor

Applying the corollary from part one, we see immediately that in a bargaining context, sufficient competition guarantees that the Walrasian equilibrium or Cheung solution is attained even if the landowner and tenant regard the terms of the contract as negotiable. We now turn to a demonstration of this proposition. At the same time we investigate how "fast" the core shrinks to the Walrasian allocation.

Consider a simple one-good (rice) economy consisting of one landowner with land, H, and one tenant with labor, L. Production technology for rice is given by $Q = H^{1/2}L^{1/2}$. Utility of each is assumed to be an increasing function of his own share of the rice production. Because there are no other uses for land and labor, the core solution requires that all land and labor be employed in rice production. The only remaining variable to be established is the landowner's percentage share, r, of the gross harvest. But, because neither the landowner or tenant can guarantee himself any output whatsoever—land or labor must be jointly employed—there is no value of r which can be "blocked" by either tenant or landowner. That is, the core consists of all values from 0 to 1. We denote the core for one landowner and one tenant, C_{11}, as

$$C_{11} = \{r | 0 \leq r \leq 1\},$$

i.e., all values of r such that r is not less than 0 nor greater than 1.

Now consider an economy with two (identical) landowners and two (identical) tenants. Without loss of generality, we further assume that each landowner has one unit of land and each tenant has one unit of labor. A landowner with one tenant working his land therefore receives income equal to r. The extent to which landowners can "exploit" labor, i.e., r_{max}, is limited by the potential of one landowner breaking the coalition with the other and forming a new coalition with the two tenants. r_{max} is that rental share such that if r were to rise any higher, then a coalition of one of the landowners and the two tenants could guarantee themselves a higher payment than in the two-landowners two-tenants coalition. After paying the tenants what they were receiving in the old coalition, the landowner's share in the present coalition is $1^{1/2}2^{1/2} - (1 - r)2^{1/2}2^{1/2} = 2r + 2^{1/2} - 2$. To compute r_{max}, set this residual equal to the income received by each landowner assuming that landowners received equal share in the old coalition, i.e., r. (If they received different shares, then the landowner with the lower share could unite with the tenants and block the old coalition at some level less than r_{max}.) Therefore, r_{max} is the solution of the equation,

$$2r + 2^{1/2} - 2 = r, \text{ i.e.,}$$
$$r_{max} = 2 - 2^{1/2} = .586.$$

To solve for r_{min}, the lowest undominated landowner share, simply reverse the roles of land and labor and investigate how much the tenants can "exploit" their landowners, i.e., how much income they can extract before it becomes possible for two landowners and one laborer to form a blocking coalition. Thus, $r_{min} = 2^{1/2} - 1 = .414$.

The limits of the core for the general case can be derived by induction. For n landowners and n tenants, the relevant blocking coalition (*RBC*) is simply the coalition of all agents excluding one agent with the highest share.[6] In order to prevent the *RBC* from becoming effective, the group with the higher share (landowners or tenants) will divide their joint income equally. If landowners have the advantage, the *RBC* will exclude one of the landowners with an equal share of total landowners' income.

Thus, the *RBC* which limits landowner exploitation is the coalition of n tenants and $n - 1$ landowners, i.e., $RBC_{(n-1),n}$. Therefore, r_{max} is the solution of the equation

$$(n - 1)^{1/2}n^{1/2} - n(1 - r) = (n - 1)r, \text{ or}$$
$$r_{max} = n - (n - 1)^{1/2}n^{1/2}.$$

Similarly, r_{min} is computed with reference to $RBC_{n,(n-1)}$, i.e., r_{min} is the solution of

$$n^{1/2}(n - 1)^{1/2} - nr = (n - 1)(1 - r), \text{ or}$$
$$r_{min} = n^{1/2}(n - 1)^{1/2} - (n - 1) = 1 - r_{max}.$$

This formula was used to simulate the effects of increasing the number of agents on the core. Table 1 shows the limits of the core, r_{max} and r_{min}, for economies with increasing number of agents. It is readily seen that the core

to be applied have no effect on the amount of labor actually contributed, and also assumed that landowners strike independent bargains with each of their tenants (i.e., that a subgroup of tenants cannot bargain as a unit).

[6] For example, in the 6-person game, r_{max} is similarly determined with reference to the 2-landowner, 3-laborer coalition, i.e., the landowner is blocked if r is above the break-even level given by

$$2^{1/2}3^{1/2} - 3(1 - r) = 2r$$
$$r_{max} = 3 - 2^{1/2}3^{1/2} = .551, \text{ and}$$
$$r_{min} = .449.$$

Table 1. Core Shrinking for Equal Number of Landowners and Tenants

n (number of landowners)	r_{max}		r_{min}
1	$1 - 0\sqrt{1}$	$= 1.000$	0.000
2	$2 - \sqrt{1}\sqrt{2}$	$= .586$	.414
3	$3 - \sqrt{2}\sqrt{3}$	$= .551$	.449
4	$4 - \sqrt{3}\sqrt{4}$	$= .536$	.464
5	$5 - \sqrt{4}\sqrt{5}$	$= .528$	.472
10	$10 - \sqrt{9}\sqrt{10}$	$= .513$	.487
25	$25 - \sqrt{24}\sqrt{25}$	$= .506$	.494
100	$100 - \sqrt{99}\sqrt{100}$	$= .502$	.498
500	$500 - \sqrt{499}\sqrt{500}$	$= .500$	.500

shrinks to the competitive equilibrium solution, i.e., $r = .5$. Moreover, the shrinking is "fast." With only three pairs of landowners and tenants, the core consists of those solutions which are within approximately 10% of $r = .5$. More generally, for a production function of the form

$$Q = H^{\alpha}L^{(1-\alpha)},$$
$$r_{max} = n - (n - 1)^{\alpha}n^{(1-\alpha)},$$
$$r_{min} = 1 - r_{max},$$

and r_{max} and r_{min} converge to α as n becomes large.[7]

Behavior of the Core with More Tenants Than Landowners

Assume now that there are always twice as many tenants as landowners. In order to focus on the effect of this assumption on the bargaining solution, we assume that each tenant is endowed with $\frac{1}{2}$ of a unit of labor. This suffices to keep the land-labor ratio equal to 1 for all core solutions, just as it was for the economy investigated above.

Beginning with an economy with one landowner and two tenants, $r_{max} = 1$ because $RBC_{0,2}$ has no land. Then r_{min} is determined relative to $RBC_{1,1}$ and satisfies

$$1^{\frac{1}{2}}(\tfrac{1}{2})^{\frac{1}{2}} - r = \frac{(1 - r)}{2},$$

$$\text{i.e., } r_{min} = \frac{2}{\sqrt{2}} - 1 = .415.$$

Again proceeding by induction, the limits of the core for the general case of n landowners and $2n$ tenants are

Table 2. Core Shrinking with Twice as Many Tenants as Landowners

n (number of landowners)	r_{max}	r_{min}
1	1.000	.414
2	.586	.464
5	.528	.486
10	.513	.492
50	.503	.497
500	.500	.500

$$r_{max} = n - (n - 1)^{\frac{1}{2}}n^{\frac{1}{2}} \text{ and}$$
$$r_{min} = 2n^{\frac{1}{2}}(n - \tfrac{1}{2})^{\frac{1}{2}} - 2n + 1.^{8}$$

The limits of the core for various values of n are given in table 2. Notice that the r_{max} column in table 2 is identical to that in table 1. This is because the RBC with $n - 1$ landowners and $2n$ tenants, each with $\frac{1}{2}$ unit of labor, is indistinguishable from the RBC (from case one) of $n - 1$ landowners and n tenants, each with 1 unit of labor. On the other hand, r_{min} is no longer symmetrical to r_{max}. With twice as many tenants as landowners, it is now more difficult for tenants to "exploit" landowners. Landowners can minimize exploitation by forming a blocking coalition with all but one tenant. This involves sacrificing the marginal product of only $\frac{1}{2}$ of a labor unit as compared to 1 unit in the "symmetric" case.

Limiting our attention to economies where the number of landowners does not exceed the number of tenants, we can now draw the following conclusions from these and similar exercises. First, the core shrinks rapidly to the Walrasian equilibrium regardless of the ratio of tenants to landowners. Second, for a production function of the form $Q = H^{\alpha}L^{(1-\alpha)}$, r_{max} converges to α, the rate of convergence being independent of the tenant-landowner ratio.[9] Third, $r_{max} \geq r_{min} \geq 1 - r_{max}$, i.e., r_{min} converges to α (from below) at least as fast as r_{max} approaches α (from above).

[7] This convergence is readily checked by substituting any number between 0 and 1 for α.

[8] For an economy with 2 landowners and 4 tenants, r_{max} is determined by (from $RBC_{1,4}$),

$$1^{\frac{1}{2}}\left(\frac{4}{2}\right)^{\frac{1}{2}} - \frac{4(1 - r)}{2} = r, \text{ i.e.,}$$

$$r_{max} = 2 - \sqrt{2} = .586.$$

r_{min} is determined relative to $RBC_{2,3}$ and is given by

$$2^{\frac{1}{2}}\left(\frac{3}{2}\right)^{\frac{1}{2}} - \frac{3(1 - r)}{2} = 2r, \text{ i.e.,}$$

$$r_{min} = .464.$$

[9] This is readily confirmed by substituting other values for α, besides $\alpha = \frac{1}{2}$ or by substituting α and $1 - \alpha$ in the general expression for r_{max} taking the limit as $n \to \infty$.

These results provide a justification for the assumption of contract-term-taking behavior on the part of the landowners and tenants. Despite the assumption that landowners and tenants are free to bargain with one another about possible deviations from the equilibrium set of contracts, no such changes are viable in the sense of making all of the recontracting parties better-off. Thus, Cheung's (1969) intuition, that the power of individual landowners to establish inefficient exploitative contracts is limited by competition among landowners, can be shown to be formally correct. Furthermore, it has been established that for the competition to be effective, the minimum number of landowners (with at least as many tenants) is relatively small.

Specific Production Externalities and the Coase Theorem

Coase has been credited with the insight that externalities, i.e., nonmarket interdependencies among agents, are not a sufficient condition for inefficiency. Private negotiation may suffice to "internalize" the externality. More specifically, Coase asserted that if transactions costs are zero, private negotiation will remove the externality. This simple idea has been extracted from his article—a profound and pioneering treatise on law and economics—and labeled "the Coase theorem."

There has been an extensive debate in the economics literature regarding the proper statement of the Coase theorem and whether or not various versions are correct. The following is a fairly accurate synthesis of the many versions of the theorem:

If costless negotiation is possible, rights are well-specified, and redistribution does not affect marginal values, then

a. *The allocation* [*sic*] *of resources will be identical, whatever the allocation of legal rights.*
b. *The allocation will be efficient so there is no problem of externality.* (Layard and Walters, p. 192).

As Arrow notes, the second part of the theorem can only be proven by assuming that the only admissible solution concepts for cooperative games are those which are Pareto optimal by definition. That is, since the conclusion must be stated in the premise, the proposition is trivial.

The corollary stated above, however, provides a nontrivial version of Coase's proposition. If contracts serve as perfect substitutes for markets, it is irrelevant for resource allocation and income distribution if some markets do not exist, i.e., that certain interagent effects are external to markets. An allocation identical to that of the Walrasian equilibrium with universal markets will obtain regardless. In the pollution case, for example, the universal market solution includes a market in "polluter's rights" with a corresponding parametric price (Dales). Such a market is unnecessary, however, since private contracting among polluters and pollutees will achieve the same result.

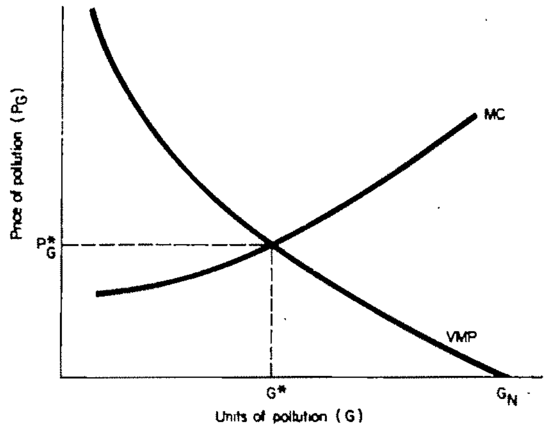

Figure 1. The Lindahl pollution solution

For purposes of illustration, consider the case of Upton's paper mill which dumps waste into a river which is used by Downley Baths (Starrett and Zeckhauser). The universal market solution for this example is depicted in figure 1. The graph shows the value of the marginal product, *VMP*, (to Upton) of the right to dump *G* units of "garbage" in the river and the minimum marginal cost, *MC*, to Downley of successive units dumped. In the case of pollutee rights, the universal market solution involves Upton buying G^* "pollution rights" (Dales) from Downley at the equilibrium price, P^*_G. This is equivalent to imposing a Pigouvian tax, $t = P^*_G$, on Upton per unit of G discharged and giving the proceeds to Downley on the basis of the minimum marginal cost (i.e., Downley is compensated according to the marginal cost he would incur if he invested optimally in pollution avoidance activities such as water filters).[10] Both the

[10] Since the compensation is not tied to Downley's actual behavior, it does not cause Downley to underinvest in avoidance activities as Baumol claims.

market and tax solutions are also equivalent to the competitive contract solution wherein Upton pays Downley $P^*_G G^*$ for the right to dump G^*.

There is a different set of equivalent solutions under polluter rights. For the universal market solution, polluter rights may be represented by initially endowing Upton with G_N pollution rights. In market equilibrium, Upton sells $G_N - G^*$ rights to Downley at price P^*_G. This is equivalent to Downley paying Upton a Pigouvian subsidy, $s = P^*_G$, for each unit that Upton reduces G below the profit-maximizing level, G_N. It is also equivalent to the contracting solution wherein Downley pays Upton $P^*_G(G_N - G^*)$ to reduce pollution to G^*.

In general, the core shrinks to a different universal market solution for each specification of property rights.[11] If we assume that changing property rights "does not affect marginal values" (the Layard and Walters version of the Coase theorem) then the production of the externality is independent of property rights. We have implicitly followed this assumption, to simplify the exposition, in our discussion of figure 1. Typically, however, marginal values will be affected, via both income effects and changes in relative factor prices. In the long run, we normally would expect a shift to polluter rights to be associated with an increase in pollution, although the amount of the change may be small.

As usually presented, the Coase solution holds the equilibrium quantity to be uniquely determined but the division of surplus between contracting parties to be indeterminate. Thus, the unaffected-marginal-values assumption is necessary to prevent an inconsistency. This assumption becomes unnecessary in the revised Coase theorem, because both quantities and income distribution are determined.

It is natural to question the applicability of the competitive contracting solution to most of Coase's examples which involve only two parties. For example, we envision one rancher's cattle affecting one farmer's crops. Similarly, in the case of *Sturges* v. *Bridgman* there was one confectioner bothering one (neighboring) doctor. But, our corollary requires a sufficient number of agents to make bargaining power small on both sides. As Coase has noted in verbal discussions of his paper, however, it is competition prior to the contract that counts. That is, even for one-to-one externalities there is *ex ante* competition in the sense that the parties involved can choose among various locations, and several parties may be competing for a particular location (Demsetz, in a personal communication).

One advantage in appealing to the Debreu-Scarf theorem as a cornerstone of the theory of contracts is that we have a list of sufficient postulates under which the theorem is valid. This gives us clues about when competitive contract theory is and is not applicable. In particular, it has been shown that the core of an economy with a public good does not shrink as the number of consumers is increased (Bergstrom 1970, and Muench). As the number of consumers increase, "agreers' surplus" (Pauly) increases because each successive consumer adds to total benefits of the public good without increasing its costs. As the surplus per member increases so does the range of viable solutions, i.e., the core "grows." In other words, because all members of the community are needed as members of the coalition which consumes the public good in order to minimize its average cost, there are no viable competing coalitions which can provide the competition required to make the core "shrink." Thus, the core of an economy with a public good contains a large number of solutions, each with its own prescription for sharing the surplus generated by group provision of the public good. Thus, in an economy with public goods we cannot say contracts necessarily tend to act as perfect substitutes for universal markets.

Similarly, the core does not shrink in the case of joint externalities. For example, if one agent contributes to a "pool" of pollution which negatively affects several recipients, then the pollution is a public bad for that community of recipients. Thus, the limit theorem can only be applied to specific, i.e., one-to-one, externalities. A classic example of a specific production externality is the case where a particular bee (or unit of bees) provides pollinating services during a particular unit of time to a particular apple orchard. As Cheung (1973) has shown, a contracting solution does in fact exist between beekeepers and apple orchard owners in the state of Washington which approximates a competitive market solution. Coase's examples were also specific production externalities. Even in the case of

[11] This result appears to be inconsistent with an example provided by Starrett wherein the core does not contain the Lindahl equilibrium (universal market solution). The paradox is resolved by noting that Starrett implicitly compares the core under polluter rights with the Lindahl equilibrium under pollutee rights.

the railroad whose sparks caused fires on adjacent farmers' fields, one unit of spark affects only one farmer. Thus, for the examples Coase had in mind the competitive theory of contracts serves as a correct and nontrivial version of Coase's proposition.

Another limitation of the theory regards restrictions on production. The Debreu-Scarf theorem requires that the production possibility correspondence is additive (Hildenbrand, p. 212). Additivity is satisfied by constant returns-to-scale. If economies of scale prevail, then it is possible that the Walrasian equilibrium does not exist and that the core is empty (Arrow). If decreasing returns prevail, then the core may contain allocations besides the Walrasian equilibria, regardless of the number of agents (Böhm).

Because a Walrasian equilibrium with universal markets is also called a Lindahl equilibrium (Bergstrom, 1975, 1976), we can now summarize as follows:

> The core of an economy with additivity in production, but no joint externalities, shrinks to the Lindahl equilibrium as the bargaining power of all agents is reduced by increasing numbers of agents.

Conclusions and Applications

Abstracting from transactions costs and bargaining power, the equilibrium contracting solution is just the Walrasian equilibrium with universal markets. This cornerstone of contract theory helps to clear up some controversies about sharecropping and production externalities.

Applying the proposition to sharecropping, we get Cheung's (1969) competitive theory of share tenancy. But instead of relying on the assumption that agents are "contract-term-takers" (e.g., as in Reid), the proof involves showing that the core shrinks to the Walrasian equilibrium. In the process of this demonstration, we learn that the core shrinks "fast," i.e., that even for a few landowners, solutions which deviate substantially from the Walrasian equilibrium are not viable.

Applying the proposition to production externalities, we see that the competitive theory of contracts serves as a revised version of, or a substitute for, the Coase theorem. That is, under zero transaction costs and where the production externality situation is characterized by precontract competition, the contracting solution is identical to the market solution where a market exists for the externality good. Furthermore, for any given specification of property rights, the contracting solution is identical to the universal market solution (Lindahl equilibrium) and is also equivalent to a Pigouvian solution. Thus, the efficiency of the contracting solution, the Pigouvian solution, and the market solution cannot be compared on "first-best" grounds as several authors (e.g., Baumol) tried to do. As Coase has said, in a personal communication, "the real choice in economic policy is a choice of institutional forms," and a complete evaluation inevitably requires considerations of transactions costs and excess burdens of alternative arrangements.

For positive analysis, however, even the simple theory of competitive contracts may be sufficient to explain some of the stylized facts of economic organization. For example, by combining the theory with reasonable specifications about land quality and production technology, we are able to explain the observation for share contracts that the landowner's percentage share tends to be positively related to land quality and physiological population density.[12] On the other hand, many of the rich variations of real world contracts will require a theory which incorporates transactions costs and bargaining power into the explanatory framework (see Roumasset 1978).

Long-Term Marketing Contracts: Intra-Firm Optima and Inter-Firm Agreement

S. T. Buccola and B. C. French

Long-term marketing contracts may be used to control risks associated with sales or purchase quantities, prices, or other trade terms. A model is here specified through which a firm may select portfolios of contract price clauses that maximize its expected utility. Offer curves are defined relating optimal portfolios to contract price parameter levels, and an equilibrium trade solution is developed among three vertically related agribusiness concerns. Price clauses considered for analysis—market price, cost-plus, and sales-minus—may be optimally utilized together, but only in restricted price parameter and utility function ranges.

Key words: cooperative, cost-plus, expected utility, marketing contracts, utility analysis.

The pervasive demand for opportunities to reduce risk, together with recent accentuation of market risks caused by declining firm numbers, product specialization, and capital intensification, have led to increasing use of marketing contracts in U.S. agribusiness. Contract clauses generally are distinguished according to sources of risk that can be controlled. Some of these are necessary elements of an act of trade: price and method of payment, shipment volume and timing, place of title transfer, and product specification and quality. Others serve to clarify trade terms or promote the contract's implementation: dockages and premiums, finance arrangements, technical services, clause flexibilities, and redress for noncompliance (Jesse and Johnson).

There is a bewildering variety of ways in which each contract clause can be formulated. Price formulas include fixed price, market price, and cost-plus, to name a few. Quantities can be fixed or follow time- or inventory-related formulas. Both price and quantity can be related to product quality (Harris and Massey). Past contract literature generally has employed an efficiency framework in which mean-variance trade-offs are calculated for alternative contract formulas or portfolios. Most models focus on fixed prices versus cash or futures market prices. Market contract terms are usually a single year and assume the firm has no influence over specification of the alternative formulas (Eidman, Dean and Carter; Barry and Willmann).

The goal of the present paper is to expand the portfolio analysis of contracting to encompass long-term contract decisions, additional pricing possibilities, and optimal marketing plans. Most important, it addresses a problem in which neither seller nor buyer is a price taker, and in which both the proportions of trade allocated to alternative formulas and the formulas themselves are decided through negotiation. A method for determining these equilibrium trade terms is proposed which may assist firms and government advisors in understanding and influencing the contract negotiation process.

The study considers a U.S. fruit- and vegetable-processing cooperative, a contracting customer for its bulk-packed tomato paste, and contracting nonmember suppliers of raw tomatoes. Following sections define the research problems in more exact terms, prescribe individual firm and joint market solu-

tions, then report model construction and results based on these prescriptions.

The Contract Portfolio Problem

In a stochastic universe and over a defined time horizon, a firm designing its marketing mix may be thought to prefer the set of contract formulas and open market opportunities that maximize the expected utility of present value profit. In a specific application of this problem addressed here, each firm holds a fixed quantity Q^o of one kind of output, and q^o of a principal input, and allocates these amounts among fixed-quantity sales and/or fixed-quantity purchase contracts that differ in pricing provisions. Defining P_a, Q_a as price and quantity of output sold under contract provisions a, $a = 1, \ldots, A$; P_b, q_b, price and quantity of input purchased under contract provisions b, $b = 1, \ldots, B$; $V_a = Q_a/Q^o$, sales portfolio proportions, $a = 1, 2, \ldots, A$; $R_b = q_b/q^0$, purchase portfolio proportions, $b = 1, 2, \ldots, B$; OR_t, OC_t, revenues and costs, respectively, associated with noncontracted items; t, a time period indicator, $t = 1, 2, \ldots T$; i, an average interest rate; and δ_1, δ_2, constants ($0 \leq \delta_1, \delta_2 \leq 1$), the expected-utility maximization problem becomes

$$\max_{V,R} E\left[U\left(\sum_a \sum_t \frac{1}{(1+i)^t} P_{at} V_a Q^o - \sum_b \sum_t \frac{1}{(1+i)^t} P_{bt} R_b q^o + \sum_t \frac{1}{(1+i)^t} (OR_t - OC_t)\right)\right]$$

$$\text{(1)} \qquad \text{s.t.} \sum_a V_a = \delta_1$$

$$\sum_b R_b = \delta_2$$

$$V_a, R_b \geq 0, \quad \text{all} \quad a, b.$$

This form becomes more determinate once traded commodities, market conditions, and alternative contract price formulas are specified. The authors are concerned with a multicommodity processing/marketing cooperative that contemplates contract paste sales to one buyer only. The buyer in turn reprocesses the paste into a line of tomato sauces and distributes it to retail markets. Some coop tomato requirements are purchased on a nonmembership contract basis from growers who also supply tomatoes on a membership basis. Firms at all three levels buy and sell additional goods in noncontractual markets, where they are price takers. The cooperative has agreed with the distributor/reprocessor on the total paste tonnage it will sell to it for the next ten years, and with growers on the number of nonmembership and membership acres whose yield it will purchase for the same period.

Price mechanisms considered suitable for either tomato paste sales or nonmember raw tomato purchases are (a) a specifically defined market price, (b) the seller's variable costs times a markup ("cost-plus"), and (c) the buyer's revenue from product resale times a markdown ("sales-minus"). Under market price contracts, both traders may avoid terms less advantageous in a short-run sense than those offered on the open market. Cost-plus prices provide sellers a guaranteed rate of gross margin, and sales-minus prices guarantee buyers a rate of return over the contracted input.

Profit Functions

In order to incorporate these specifications into a set of operational profit functions, we define the following symbols: (a) W_a, V_a, R_b, S_b ($a,b = 1, 2, 3$) are portfolio proportions of trade assigned, respectively, to the distributor's alternative paste purchase price formulas, cooperative's paste sales price formulas, cooperative's tomato purchase price formulas, and growers' nonmember tomato sales price formulas. (In each case, 1 is market price, 2 is cost-plus, 3 is sales-minus.)

(b) Q_d, Q_c, A_c, A_g are fixed total trade levels representing, respectively, the distributor's total contractual paste purchase from the cooperative (in tons raw equivalent); the cooperative's total contractual paste sales to the distributor (in tons raw equivalent); the cooperative's total contractual nonmember tomato purchases from growers (in acres); and growers' total contractual nonmember tomato sales to the cooperative (in acres). ($Q_d = Q_c = \alpha\beta A_c = \alpha\beta A_g$, where α is expected per acre tomato yields, and β is the proportion of total

cooperative tomato acres contracted on a nonmembership basis.)[1]

(*c*) m, k, n, l are contract price parameters, where $m, k > 1$ are cost-plus markups and n, l ($0 \leq n, l \leq 1$) are sales-minus markdowns.

(*d*) $MP_{sce}{}^{tr}$, $MP_{pst}{}^{tr}$, $MP_{tom}{}^{tr}$ are market prices of sauce, paste, and tomatoes per ton raw product equivalent; and $Y_{tom}{}^{a}$ is per acre tomato yield.

(*e*) $NPVC_{sce}{}^{tr}$ is nonpaste variable cost of sauce production per ton raw equivalent, $NTVC_{pst}{}^{tr}$ is nontomato variable cost of paste production per ton raw equivalent, and $VCG_{tom}{}^{a}$ is variable cost of tomato production per acre.

(*f*) $REVC$ is cooperative revenue from contract paste sales divided by A_c.

(*g*) ORD, ORC, ORG are other revenues; FCD, FCC, FCG are fixed costs; and $OVCD$, $OVCC$, $OVCG$ are other variable costs of the three firms.

Variables in (*d*) through (*g*) are, with the exception of fixed costs, considered random. Those which serve as coefficients of portfolio proportions W, V, R, S will be termed contract price bases. The definitions permit us to define profit or net margin functions for distributor/reprocessor, cooperative, and growers which reflect the trade arrangements and alternative price mechanisms discussed above:

Distributor

$$(2) \quad \pi_d = ORD + Q_d(MP_{sce}{}^{tr} - NPVC_{sce}{}^{tr}) - Q_d[W_1 MP_{pst}{}^{tr} + W_2 m(MP_{tom}{}^{tr} + NTVC_{pst}{}^{tr}) + W_3 n MP_{sce}{}^{tr}] - OVCD - FCD;$$

Cooperative

$$(3) \quad NM_c = ORC + Q_c[V_1 MP_{pst}{}^{tr} + V_2 m(MP_{tom}{}^{tr} + NTVC_{pst}{}^{tr}) + V_3 n \cdot MP_{sce}{}^{tr}] - A_c[R_1 MP_{tom}{}^{tr} Y_{tom}{}^{a} + R_2 k VCG_{tom}{}^{a} + R_3 l REVC] - Q_c[NTVC_{pst}{}^{tr}] - OVCC - FCC;$$

Grower (Nonmember Basis)

$$(4) \quad \pi_g = ORG + A_g[S_1 MP_{tom}{}^{tr} Y_{tom}{}^{a} + S_2 k VCG_{tom}{}^{a} + S_3 l REVC] - A_g[VCG_{tom}{}^{a}] - OVCG - FCG.$$

Following the approach taken by Helmberger and Hoos (p. 604), and adapted to multiproduct situations by Hardie (pp. 820–21), cooperative net margin (3) does not value member raw product as a cost. Members instead have a claim on total net margin in proportion to the tonnage, or market value, of all raw products delivered to the coop on a membership basis (Ladd, p. 511, eq. 5, adopts the same approach in his analysis of bargaining cooperatives, except that in his case the coop is also assumed to provide members with a set of input services, his S_1 and S_2.)

In addition to noncontractual revenue sources (ORC), cooperative revenue, of (3), consists of paste tonnage sold to the distributor times: a proportion V_1 of the market value per ton of paste (market price); a proportion V_2 of paste production variable costs per ton, times a coop rate of return m (cost-plus); and a proportion V_3 of distributor sales revenue from sauce produced with the coop's tomato paste, times the coop's revenue share n (sales-minus). Cooperative nonmember tomato acquisition cost, lines 3, 4 in (3), consists of nonmember tomato acreage times: a proportion R_1 of the market value of an acre's tomato yield (market price); a proportion R_2 of tomato production variable costs per acre, times a grower rate of return k (cost-plus); and a proportion R_3 of cooperative per acre sales revenue from paste produced with nonmember tomatoes, times the grower's per acre revenue share l (sales-minus). Elements in lines 5, 6 of (3) are nontomato paste production costs, and other cooperative variable and fixed costs.

Profit functions for distributor and grower are interpreted similarly. Note that market price, cost-plus and sales-minus paste purchase formulas in the third expression of (2) are, with due allowance for differences in proportion terms, identical to the paste sales formulas in the second expression of (3). In addition market price, cost-plus, and sales-minus nonmembership tomato purchase formulas in the third expression of (3) are, except for proportion terms, identical to the nonmembership tomato sales formulas in the second expression of (4). Random variables in (2) through (4) are present values of ten-year sums as required by the time summation in (1).

Model Construction: Contract Offer Curves

Price parameters m, n, k, l and portfolio proportions W, V, R, S in (2)–(4) may be consid-

[1] Presence of random yields implies tomato purchases may not exactly meet the coop's commitments to sell a fixed tonnage of paste. Although such discrepancies are in reality handled through inventory adjustments or changes in extracontractual arrangements, neither of these adjustments are included in the present model. In this sense, the model may understate risk exposure. However yield uncertainties themselves are included in profit probability distributions of each contractual arrangement.

ered constants in formulas defining the respective moments μ_π, σ_π^2, . . . , $E(\pi - \mu_\pi)^n$ of profit or net margin for each firm. Substituting these moment expressions into expectations of the Taylor expansion of each firm's utility-for-profit generates expected utility expressions as functions of the price parameters and portfolio proportions (Anderson, Dillon, Hardaker, p. 97). In general notation,

$$
\begin{aligned}
(5)\quad E[U_d(\pi_d)] &= g_1(W_1, W_2, W_3; m, n)\\
E[U_c(NM_c)] &= g_2(V_1, V_2, V_3, R_1, R_2, R_3;\\
&\qquad m, n, k, l)\\
E[U_g(\pi_g)] &= g_3(S_1, S_2, S_3; k, l),
\end{aligned}
$$

where E is an expectation operator; U_d, U_c, U_g are utilities; and g_1, g_2, g_3 are function indicators. For any set of mean, variance, covariance and higher moment estimates for the price bases, and for any set of price parameters m, n, k, l, portfolio proportions W, V, R, S may be found which maximize private expected utilities (5). By computing the first partial derivatives of (5) with respect to each portfolio proportion, setting these equal to zero, and simultaneously solving the equations for the unknown proportions, an expected-utility-optimal surface is produced in which each portfolio proportion is a function of all parameters present:

(6) Distributor:

$$W_a = W_a(m, n) \qquad a = 1, 2, 3$$

Cooperative:

$$V_a = V_a(m, n, k, l) \quad a = 1, 2, 3$$
$$R_b = R_b(m, n, k, l) \quad b = 1, 2, 3$$

Grower:

$$S_b = S_b(k, l) \qquad b = 1, 2, 3.$$

In this derivation the constraint that portfolio proportions sum to a constant—δ_1 or δ_2 in (1)—may be incorporated by expressing, in the distributor problem for example, $W_3 = \delta_1 - W_1 - W_2$. "Border solutions" are special cases of (6) that occur when one of these portfolio proportions is at zero level.

Equations (6) represent the firms' offer curves for market price, cost-plus, and sales-minus contract formulas. W and V functions are demand and supply, respectively, in the paste market. R and S functions are demand and supply, respectively, in the raw tomato market. An equilibrium solution for all price parameters and portfolios in both markets is suggested by combining (6) with market clearing equalities $W_2 = V_2$, $W_3 = V_3$, $R_2 = S_2$, $R_3 = S_3$. Solutions for $W_1 = V_1$, $R_1 = S_1$ are subsequently derived from proportionality constraints $\sum_a W_a = \sum_a V_a = \delta_1$, $\sum_b R_b = \sum_b S_b = \delta_2$, as in (1). An unrestricted equilibrium solution exists for the sixteen unknowns in (6) if the equations are independent and if offer curves for each contract option intersect in the nonnegative price-quantity quadrant. The independence requirement is met because each offer curve represents a different trade or contract option. Intersection in the nonnegative quadrant is not guaranteed; in the event a negative portfolio proportion W, V, R, S is indicated for any pair of traders, true equilibrium occurs where the proportion allocated to one option is 100% and the rest zero.

The contract problem in this framework may be envisaged as a sequential process. Each negotiator first assigns personally suitable values to cost-plus markups m, k and sales-minus markdowns n, l, then decides which proportions of the several price formulas maximize expected utility, given these constants. If buyer's and seller's resultant quantity offers under each formula are inconsistent, markups and markdowns are adjusted and the process repeated with the hope that consistency will be achieved.

Supply and demand curves (6) are, like those in neoclassical theory, nonstochastic. In the tradition of neoclassical analysis, two contract formulas are defined as substitutes when the portfolio proportion occupied by one rises as the other falls, and as complements when they rise and fall together. Own-price effects are partial derivatives relating the influence of a price parameter on its associated portfolio proportion, and cross-price affects the influence of a price parameter on an unassociated portfolio proportion. In the distributor's case, for example, own effects are $\partial W_2/\partial m$, $\partial W_3/\partial n$. Cross-effects are $\partial W_1/\partial m$, $\partial W_1/\partial n$, $\partial W_2/\partial n$, $\partial W_3/\partial m$. Market price options only have cross-effects since they employ no price parameters (premium or discount factors) in this model.

Parameters Employed

Complete specification of expected utility functions (5) requires selection of a functional form for each firm's utility of profit. If the firms' utility functions are quadratic in profit and if profit functions (2)–(4) are linear in portfolio proportions W, V, R, S, expected utility functions (5) are quadratic in these port-

folio proportions (Anderson, Dillon, Hardaker, pp. 97–98). In the cooperative's case, for example,

$$(7)\quad E[U_c(NM_c)] = a\mu_\pi - b(\mu_\pi^2 + \sigma_\pi^2),$$

where

$$(8)\quad \begin{aligned} \mu_\pi &= \mu_\pi(V, R; m, n, k, l) \\ \sigma_\pi^2 &= \sigma_\pi^2(V, R; m, n, k, l), \end{aligned}$$

and constants a, $b > 0$ are the linear and quadratic terms, respectively, of the utility-of-profit function. Results reported here assume quadratic utilities and linear profit functions for all firms.[2]

Profit-utility responses were elicited by the Von Neumann-Morgenstern (pp. 15–31) technique for eight tomato growers and for spokesmen from cooperative management and board. Utilities of the board spokesman and one grower were linear; all others were slightly to strongly risk-averse. Because no cooperation was obtained from an important customer of the cooperative's tomato paste, a hypothetical utility had to be used in conjunction with the distributor model.

[Quadratic functions employed are $U = 3.098\pi - .0469\pi^2$ (grower); $U = .031\pi - .000006\pi^2$ (cooperative); $U = .01\pi - .0000015\pi^2$ (distributor), where profit π is expressed in \$10,000 units.]

Once functions (8) were derived for each firm from profit functions (2)–(4), it was necessary to (*a*) develop mean and variance estimates for each revenue and cost variable and covariance estimates for each pair of these variables; (*b*) specify fixed total trade levels Q_d, Q_c, A_c, A_g; and (*c*) substitute into (8) provisional contract-price parameter values m, n, k, and l.

Mean and variance estimates for each revenue, price, cost, and yield term, defined over a ten-year planning horizon, were developed through a simulation program described in Buccola and French. This program incorporated historical data with subjective probability distributions elicited from decision makers. Where appropriate, revenue and cost moments were calculated from price and yield moments by use of standard formulas for product moments (Kmenta, pp. 57–66). Correlation coefficients were computed from historical series.

The distributor was assumed to contract with the cooperative for purchase of 75,800 tons of 32% tomato paste [in (2) and (3), raw product equivalents $Q_d = Q_c = 473{,}219$]. The cooperative, in turn, contracted to purchase the tomato output of 18,860 acres, of which 25% or 4,715 acres were allocated to nonmembers ($A_c = 4{,}715$). A representative grower raised 1,210 acres of tomatoes and an additional 1,940 acres of corn, wheat, and beans in a 5:3:2 proportion. Twenty-five percent, or 302, of the grower's tomato acres were sold to the coop on a nonmember basis [in (4), $A_g = 302$] and the remainder on a member basis. In this context the equilibration task was to discover values of price parameters m, n, k, l which would allocate the 75,800 tons of paste to a set of sales methods mutually acceptable to cooperative and distributor, and simultaneously allocate the 4,715 acres of tomatoes among sales methods mutually acceptable to the cooperative and a representative grower.

Model Results

Table 1 presents purchase and sale contract portfolios that maximize the cooperative's expected utility, given a particular set of contract price-basis probability moments, one cooperative executive's utility function, and selected values of the contract price parameters. (Similar tables for distributor and representative grower are omitted due to space considerations.) Offer curves for each contract option were estimated by regressing the portfolio proportions occupied by that option against all relevant price parameters. It was important that each firm's optimal portfolios be segregated into "interior" and "boundary" solution groups before such estimation. Due to the portfolio proportion nonnegativity conditions, offer curves develop a kink when any proportion reaches zero level. Hence linear fits to unsegregated data represent misleading averages of truly piecewise offer functions. In the cooperative paste sale model, for example, an interior solution occurs where $0 < V_1, V_2, V_3 < 1$. Six types of boundary solutions occur where $V_1 = 0, 0 < V_2, V_3 < 1$; $V_2 = 0, 0 < V_1, V_3 < 1$; $V_3 = 0, 0 < V_1, V_2 < 1$; $V_1 = 1$; $V_2 = 1$;

[2] Profit linearity restricts the accuracy with which some price options can be modeled. For example the cooperative sales-minus purchase option theoretically requires substituting the entire cooperative revenue expression into *REVC* in (3). Because the result is a quadratic expression, it is assumed that all paste is sold at market prices for the purpose of this option. Thus $REVC = MP_{pst}{}^{tr}Y_{tom}{}^{c}$.

Table 1. Optimal Contract Portfolios for Cooperative Tomato Paste Sales under Selected Price Parameters

Sales Contract Price Parameters		Sales Contract Proportions		
Cost-Plus Markup (m)	Sales-Minus Markdown (n)	Market Price (V_1)	Cost-Plus (V_2)	Sales-Minus (V_3)
1.39	.248	.268	.697	.035
1.39	.250	.173	.582	.245
1.39	.252	.064	.468	.468
1.38	.248	.375	.511	.113
1.38	.250	.270	.387	.344
1.38	.252	.150	.278	.572
1.38	.254	.034	.203	.763
1.37	.248	.473	.309	.218
1.37	.250	.356	.188	.456
1.37	.252	.226	.098	.676
1.36	.246	.655	.242	.103
1.36	.248	.552	.111	.338

Note: Purchase-side parameters $k = 1.35$ and $l = .38$; all tomato purchases are at sales-minus. $U = .031\pi - .000006\pi^2$ (π in \$10,000 units). Total paste volume sold is 75,800 tons.

and $V_3 = 1$. Only interior solutions are shown in table 1.

Linear offer curve sets for each firm, estimated from interior solution data in table 1 and the omitted tables, are shown in table 2. Cooperative tomato purchase portfolios were so sensitive to price parameter changes that interior solutions for them were not obtainable. A brief discussion follows of each offer curve set in table 2.

Table 2. Interior-Solution Offer Curves for Distributor Paste Purchases, Cooperative Paste Sales, and Grower Nonmember Tomato Sales

			Independent Variables					
Equation	Portfolio Proportion	Constant	Sales Side Cost-Plus Markup (m)	Sales Side Sales-Minus Markdown (n)	Purchase Side Cost-Plus Markup (k)	Purchase Side Sales-Minus Markdown (l)	R^2	Observations
Distributor								
1	W_1	−83.2702	25.9340	187.50000			.999	6
			(1.0826)	(1.4134)				
2	W_2	31.5080	−49.9991	145.9990			.997	6
			(6.6380)	(8.6664)				
3	W_3	52.7622	24.0651	−333.4990			—	6
Cooperative								
4	V_1	26.5474	−8.9486	−55.7513			.998	12
			(.2775)	(1.2786)				
5	V_2	−12.4668	19.0460	−53.6908			.996	12
			(.3893)	(1.7937)				
6	V_3	−13.0806	−10.0974	109.4421			—	12
Grower								
7	S_1	3.5167			−.3087	−7.7811	.987	6
					(.0147)			
8	S_2	−2.3644			1.7706	.2576	.894	6
					(.3616)	(1.2980)		
9	S_3	−.9023			−1.4619	7.5235	—	6

Note: Each regression coefficient indicates the change in a portfolio proportion (base = 100) when the appropriate price parameter rises by .01. Standard errors in parentheses, and R-squares, are shown to give some idea of closeness of fit; they have no statistical content because the data are generated deterministically. Note that equations for W_3, V_3, and S_3 are developed by identities $W_3 = 1 - W_1 - W_2$, $V_3 = 1 - V_1 - V_2$, and $S_3 = .25 - S_1 - S_2$.

Distributor

The distributor's input demand curves (representing own effects) for cost-plus and sales-minus options are negatively sloped in table 2, a result unambiguously predicted for risk-averse firms. Increases in m or n lower profit mean and increase profit variance; the firm loses satisfaction on both counts and reacts by lowering the associated portfolio proportion W_2 or W_3. All cross-effects between price parameters m, n, and unassociated portfolio proportions, including the market price purchase proportion, are positive, as required for substitutes when own effects are negative.

The narrow price parameter domain (1.36 to 1.38 for cost-plus, .255 to .257 for sales-minus) compatible with generally nonzero levels for all portfolio proportions is explained partly by the moderately positive covariances encountered among price bases and partly by the distributor's weak risk aversion. Sensitivity of portfolio proportions to changes in own-price parameters is highest for weak risk averters because the variance-reducing possibilities of portfolio combinations are least noticed by these decision makers.

Given the contract price-basis means used in this study, the expected values of all distributor contract options are equal at $m = 1.40$, $n = .25$. In the limiting case, therefore, in which the decision maker is risk-neutral, he would wish to sign all purchase contracts at market price if $m > 1.4$ and $n > .25$. At $m < 1.4$ or $n < .25$, all contracts would be desired at cost-plus or all at sales-minus. Thus, the normally imposed assumption of risk neutrality represents the most extreme sensitivity of portfolio proportions to price parameter changes, and introduction of even weak risk aversion serves to stabilize portfolios to some degree. One might argue that sensitivity is so great in the distributor's case that risk-neutral behavior is approximated; under that approximation, the distributor may take $m = 1.40$, $n = .25$ as its focus for decision making.

Cooperative

A priori expectations of the cooperative's supply-curve own effects are not as unambiguous as they are for the distributor's demand-curve own effects. For sales portfolios, increases in price parameters (here m or n) raise both profit expectation and variance; the risk-averting decision maker gains satisfaction on the first count and loses it on the second. Because in the expectation of the Taylor expansion on a utility function the variance effect is halved, only a highly risk-averse decision maker would value the variance effect greater than the mean effect. In the present case the cooperative chooses the more usual path and exhibits positively sloped own-price supply functions.

In the face of moderate positive covariances among contract price bases, contract options are substitutes, and cross-price effects are negative as required for substitutes when own effects are positive. Portfolio sensitivity to price parameter changes is lower here than for the distributor. A much wider range of price parameter levels would be involved if attention were extended to portfolio domains over which only two contracts are held at nonzero levels. Owing to covariances between contractual and noncontractual revenues and costs, portfolio sensitivity was also strongly affected by the presence of these noncontractual terms.

The 75,800 tons of tomato paste sold annually by the cooperative represents an expected net margin that is considerably higher than the midpoint net margin on its utility function. Offer curves subsequently generated for paste volumes approximating the utility midpoint were so price-parameter sensitive that even paste sale behavior approached risk neutrality. Even at the midpoint, results may have been considerably less price-parameter sensitive had contract price bases been negatively correlated.

Grower

As with the coop supply curves, all grower-curve own effects are positive. All cross-effects are negative except that increases in sales-minus parameter l appear to have a negligible effect on the quantity of tomatoes supplied on a cost-plus basis. This is consistent with the nearly zero correlation between the sales-minus and cost-plus price bases ($MP_{pst}^{tr} Y_{tom}^{a}$ and VCG_{tom}^{a}, respectively). In the presence of low correlation, the degree of substitutability or complementarity between these options depends upon the aggregate effect of all other covariances in the model.

As with the cooperative model, grower-expected profit at all price parameter levels is higher than the profit midpoint on the grower's

utility-of-profit function. Solutions near the profit midpoint approximated risk neutrality, so that expected utility was maximized by simply selecting the maximum expected profit contract option.

Contract Equilibrium

Specific optimal portfolios for the three firms that are consistent with mutual trade are found by satisfying the market clearing conditions. If it had been possible to develop interior-solution, tomato-contract demand curves for the cooperative, market clearing would have been established by setting $V_1 = W_1$, $V_2 = W_2$, $R_1 = S_1$, and $R_2 = S_2$, and solving the equations simultaneously. Under the circumstances, we develop separate equilibrium solutions for paste and tomato markets. For the paste market, we set $V_1 = W_1$ and $V_2 = W_2$ in table 2, and solve the equation pairs to obtain market-clearing-price parameter levels $m = 1.37311$, $n = .25455$. The corresponding equilibrium paste portfolio shares are $W_2 = V_2 = .018$, $W_3 = V_3 = .914$.

For the tomato market, we appeal to boundary offer curves where $R_3 = 0$, $0 < R_1, R_2 < .25$, and where $S_3 = 0$, $0 < S_1, S_2 < .25$. The associated linear offer-curve estimates are $R_1 = -177.4560 + 132.8530\,k$; $R_2 = .25 - R_1$; $S_1 = 2.5204 - 1.7920\,k$; $S_2 = .25 - S_1$. Setting $R_1 = S_1$, we obtain the market clearing cost-plus markup level $k = 1.3367$. This value is consistent with equilibrium tomato portfolio proportions $R_1 = S_1 = .125$, $R_2 = S_2 = .125$.

As a result, the 75,800 tons of paste sold by cooperative to distributor are divided 6.8% or 5,154 tons on a market price basis, 1.8% or 1,365 tons by cost-plus, and 91.4% or 69,281 tons by sales-minus. The 18,860 tomato acres contracted for purchase with growers are divided 75% or 14,145 acres to members, 12.5% or 2,357.5 acres at market price, 12.5% or 2,357.5 acres at cost-plus, and nothing at sales-minus. This may be interpreted as a competitive bargaining solution since no firm was assumed to have a negotiating advantage. When interior and boundary values were used together in offer curve estimates, the simultaneous paste market and tomato market equilibrium trade solution was $W_1 = V_1 = .123$, $W_2 = V_2 = .087$, $W_3 = V_3 = .790$, $R_1 = S_1 = .038$, $R_2 = S_2 = .091$, $R_3 = S_3 = .121$. This more elegant result was abandoned due to the bias problem discussed earlier. Clearly the bias is more prominent in the tomato market solution, a fact traceable to high sensitivity of cooperative purchase portfolios to price parameter changes.

Summary and Conclusions

The model developed here provides an expected-utility framework for analyzing intra-firm selection of marketing contract portfolios and inter-firm agreement on contract provisions. Under restricted cost-plus and sales-minus parameter ranges, and for a restricted range of the utility-of-profit function, risk-averse firms benefit by employing two or three price options simultaneously, even though most price bases are positively correlated. Offer curves for contract options exhibit own- and cross-effects with signs similar to neoclassical analysis. Contract portfolio sensitivity to price parameter changes is strongly affected by the presence of noncontractual trade terms.

Although the utility functions representing cooperative and grower appear from their concavity to reflect moderate to strong risk aversion, contract offer curves generated near the midpoints of these functions were so price-parameter sensitive as to approximate risk-neutral behavior. Sensitivity would have decreased with less positive or more negative price basis covariances, but there is at least room for skepticism that farmers and processors with concave utility invariably select risk-averse portfolios.

The contracting issues raised here form only a part of the firm's general marketing problem. Subsequent applied investigations might profitably consider contract quantity clauses; risks of inadequate inventory; contract allocations across alternative buyers, sellers, or types of goods; and the impact of generalized adoption of long-term marketing contracts.

Food Price and Supply Stabilization: National Buffer Stocks and Trade Policies

David Bigman and Shlomo Reutlinger

Trade policies are likely to have a greater impact on the stability of a country's food grain supply than any reasonable size buffer stock. At the margin, countries need to trade off the cost of additional stocks against the cost of unstable foreign exchange balances associated with free trade. A stochastic simulation model is specified to assess the impact of trade and buffer stock policies on the stability of consumption and prices and the expected values and standard deviations of costs and gains to consumers, producers, and the government, and the balance of payments.

Key words: buffer stocks, food grains, stabilization, trade policies.

The stability of food grain supply and price is of continuous concern to many governments. In the past decade, fluctuations of grain prices and the threat of widespread famine in times of major crop failures have become a major preoccupation of the international community. In most discussions, both at the theoretical and at the policy-making level, attention is on national and international stock policies as the main instrument of stabilization (Turnovsky). In practice, however, most governments are engaged in a wide variety of policies that have direct or indirect effects on food grain supply and price. They include subsidies to low income families, support prices to farmers, and various trade policies relating to agricultural products (Sarris, Abbot, Taylor).

The effects of international trade, in general, and of trade policies, in particular, on domestic food grain supply and prices have not always been appreciated adequately; and as a result, free trade in these products is unpopular in many quarters. It often has been accused of depressing agricultural production in importing countries, increasing their dependence on the exporters of these products, and thereby exposing them to a higher risk of shortages in supply. At times of poor domestic harvests and/or high prices for imported grain, it is not uncommon for governments to pronounce themselves in favor of large buffer stocks while protectionist sentiments grow stronger. Free trade is presumed to "import" instability because of the growing dependence on surpluses that may be temporary. Isolation from the world market combined with national stock policy would thus not only encourage domestic food production but also reduce instability in the domestic market.

This paper has three principal objectives: first, to analyze the effects of international trade on the domestic market of food grains, particularly on the stability of domestic supply and price; second, to examine the contribution of internal policies—notably subsidy and stock policies—and of external policies—notably free trade versus restricted trade—on the stability of grain prices and supplies; third, to provide estimates for the direct financial costs, the overall economic costs, and the distributional consequences of the various policies and programs.

We commence the analysis by discussing the limitations of some of the strong assumptions which are necessary in the more stylized models generally used in the theoretical litera-

---

David Bigman is an economist with the International Monetary Fund, and Shlomo Reutlinger is a senior economist at the World Bank.

This paper is part of an extensive study undertaken by the World Bank (RPO 671-24) on various aspects of food market stabilization policies. Some results have been already reported by Reutlinger; Reutlinger, Eaton, Bigman; and Bigman and Reutlinger.

The authors wish to thank the numerous persons who provided comments and advice. In particular, they express their gratitude to David Eaton, Bruce Arntzen, David Blum, and Keith Knapp, who participated at various stages of the study. The views expressed in this paper are those of the authors and are not to be attributed to the International Monetary Fund or the World Bank.

ture. To overcome these limitations, we develop a simulation model which provides a framework for analyzing (*a*) the extent to which annual instability in a country's food grain production and the world market price of food grains translate into instability in the country's food grain consumption and price under alternative trade policies and market structures, and (*b*) the extent to which a buffer stock of varying sizes contributes stabilization, at what social and financial costs or gains, to producers, consumers, and the government. While our method of analysis lends itself to consideration of a wide range of domestic and external trade policies, we have opted to emphasize the effect of protectionist trade policies. Our analysis leads to the conclusion that for most countries, especially the developing countries, free trade and avoidance of protectionist policies would be a far more powerful instrument for stabilizing domestic grain prices and ensuring the continuity of supplies than any reasonably sized buffer stock.

The Analytical Framework

The merits of stabilization policies from a theoretical point of view have been discussed quite extensively by economists. Most have taken the approach initially advanced by Waugh, Oi, and Massel (1969, 1970) and have examined the welfare implications of price stabilization as measured by changes in consumer and producer surplus. The early literature on the subject dealt with a single market in a close economy. In recent years, however, increasing attention has been paid to price stabilization in international trade. Hueth and Schmitz have extended the basic framework of Waugh, Oi, and Massel to examine the welfare gains from stabilizing the price of internationally traded goods. Just et al. (1977) examined the distribution of welfare gains from international price stabilization under distortions.

It has been recognized, however, that the scope of this analytical framework is quite limited because a number of common assumptions underlying the Waugh-Oi-Massel analysis and most of the subsequent literature are highly restrictive (see Just et al. 1976, 1977; Turnovsky). First, a key assumption in most of these works is that of linear demand and supply schedules. Recently it has been demonstrated that certain important propositions of this analysis do not generalize to the nonlinear case. Second, a typical assumption in this model is that of complete price stabilization, achieved by means of a sufficiently large buffer stock; that is, a buffer stock of the commodity is set up which is large enough to ensure a fixed price for any random disturbance. It is quite apparent that the cost of a "sufficiently large" stock required for complete stabilization invariably would exceed the gains. In practice, the authorities are more likely to set an upper limit on storage capacity and to engage in only partial stabilization. Practical interest, therefore, focuses on gains and costs from partial stabilization and on the degree of stability achievable with a given storage capacity. Third, the costs of operating the buffer stocks and maintaining the storage facilities generally are ignored. Our analysis shows that taking these costs into account drastically changes and often reverses the conclusions about the benefits of stabilization. Fourth, the Waugh-Oi-Massel analysis assumes supply and demand to be determined by the actual market price. On the supply side, especially with regard to agricultural commodities, this assumption is unrealistic because most, if not all, production decisions are made before the actual price is known (on the basis of expected price). Fifth, in the context of the two-country model, the analysis of Hueth and Schmitz assumes away trade barriers such as transportation costs and tariffs. For a country which is normally self-sufficient, these barriers may prohibit trade even when there is a price differential between the domestic and the international market. Trade will be permitted only at times of a severe shortfall or large excesses in domestic production. From an analytical point of view, taking these barriers into account may make the analysis almost unmanageable.

These restrictive assumptions, which are rather technical in nature, raise serious doubts about the validity of the propositions emerging from the Waugh-Oi-Massel type analysis. We find, however, more fundamental difficulties with this approach. Most important, this analysis evaluates the desirability of price stabilization on the basis of welfare gains only. Stabilization is presumed to be desirable only to the extent that it increases the combined consumer and producer surplus. We argue that while economic efficiency is an important consideration, it is only one among several objectives of stabilization policy. In most countries the primary objective of buffer stocks and other stabilization policies is to

ensure a regular flow of supplies to consumers and to meet the needs of vulnerable sections of the population. A recent study undertaken by the United Nations Food and Agriculture Organization (FAO) shows that most countries rate the insurance of a continuous flow of supply as the main objective of their cereal stock policies. The promise of welfare gains "over the long run" from price instability provides only little comfort to consumers who may find themselves unable to buy food at times of very high prices. In our view, the expected economic and financial losses to consumers, and possibly also to the economy at large, due to price stabilization should be regarded as an insurance premium paid by the market participants in order to avoid scarcity and famine. In addition, stabilization of food prices may have significant macroeconomic effects which a complete cost-benefit analysis must take into account.

Another weakness of this analytical work is its vagueness regarding the mechanism and the specific policy instruments engaged in stabilization. Typically, in this literature the desirability of price stabilization is assessed by comparing two extreme cases: one in which prices are permitted to fluctuate freely, and the other in which the price is fixed. In practice, governments implement a variety of policies affecting the level of stability of commodity prices, such as price supports for farmers, subsidized rations to low income consumers, and various controls on imports and exports. In assessing the desirability of buffer stocks, for example, the relevant question is what are the incremental effects of stocks on prices and on welfare, given the price policies which already are practiced. In a more general context, the inquiry should be extended to analyze the effectiveness of different combinations of policies in achieving prespecified stabilization goals.

Finally, little attention has been paid in the literature to the stabilizing (but potentially also destabilizing) effects of international trade per se. An open economy can offset potential price instability caused by fluctuations in domestic supply through exports and imports. On the other hand, trade can transmit fluctuations in supply in other countries to the domestic market. Consequently, the possible gains from stabilization measures in a given country will differ substantially in the presence or absence of trade.

The stochastic simulation model presented was developed to demonstrate that economists can do better in providing analytical underpinnings to policy than to espouse general propositions whose validity depends on a large number of unrealistically restrictive assumptions about the nature of the problem and the objectives of stabilization policy. We have no reservations in recommending the stochastic simulation-modeling approach for the purpose of analyzing the consequences of policy in a specified environment. However, we are aware, and the reader should be aware, that this approach cannot and does not yield readily definable generalizations because the results will depend on the specific parameters applied in the analysis. By means of sensitivity analysis we are able, however, to determine the range of applicability of our conclusions.

The Model

The model is of an open economy principally concerned with stabilization policies for food grains. It examines the effects of random fluctuations in the country's production and in the international price of grain on the various parameters of the domestic market, such as prices, quantities available for consumption for individual consumer groups, welfare gains and losses, the fiscal budget, and the balance of payments—given a set of policies implemented by the government. The country is assumed to be "self-sufficient" in the sense that in a "normal" year, when both the country's production and the world price are at their median level, there would be no differential between the price in the world and in the country to provide an incentive for trade. Yet random fluctuations in the supply of either the country or the world may create at times price differentials to an extent that despite transportation costs and tariffs, imports or exports could occur. Thus, even countries which embark on the objective of self-sufficiency in food supply can realize substantial gains from trade as a consequence of (uncorrelated) random fluctuations between food grain production in the country and in the rest of the world.

For any given level of grain production in the world and in the country, the model estimates (*a*) world price; (*b*) price and quantity of grain consumed, stored, and traded by the country; and (*c*) gains and losses to consumers, producers, government, and society. The structure of the model is described briefly below.

World Price

Examination of the effect of trade policies on the stability of a country's grain market requires an estimate of the distribution of the world price. Because there is little direct historical evidence for estimating future variability of the world price, a simple (much too simple a model for other purposes) world price model is postulated which transforms any production level into a world price on the basis of a prespecified world demand function. World production is a random variable with a specified probability distribution.

Country's Production

Production of grain in the country is a random variable with a specified probability distribution. In the present version of the model, planned production remains constant, i.e., the model is stationary. The implicit assumption permitting extrapolation of the results from the model over time is that the growth rates of food production and consumption are equal, so that the country remains self-sufficient. Allowances are made for the possibility of year-to-year serial correlation in production and for correlation between the country's production and world production (and, therefore, the world price).

Country's Demand

The country's demand for grain is assumed to consist of the combined demand of two consumer groups defined by income levels, a low income group and all other consumers. The government is assumed to have an explicit food policy by which the low income group's consumption is assured not to fall below a desired level by means of an adequate subsidy program. The demand function for the economy at large is piecewise linear with a kink at the mean, reflecting the inelastic demand induced by the government's intervention on behalf of the low income group when supplies are scarce.

International Trade

Trade activities between the country and the world are carried out by the free market within limits of a specific trade policy implemented by the government. Thus, grain is imported when the domestic price exceeds the import price and exported when the export price exceeds the domestic price. Import and export prices are determined by the world price, transportation costs, and tariffs. The instruments for enforcing government goals with respect to trade are tariffs. Those goals need not be restricted to the balance of payments and we also have considered policies deliberately designed to prevent wide fluctuations in supply or price beyond certain critical levels caused by trade. Thus, exports are not permitted when the quantity available for domestic consumption is below a prespecified lower level, and import is restricted never to let the domestic price fall below a specified lower limit.

Storage Policies

Storage policies consist of rules which determine the desired amount of grain to be stored or released in any year and a storage capacity constraining the actual level of storage activity. In the present paper, storage rules are defined by a quantity band. Within the boundaries of the band, supply is allowed to fluctuate freely with no storage activity. When domestic production (Q) exceeds the upper limit of the band (Q_H), the amount of grain stored is the excess of production above Q_H—up to the capacity limit of the facility. When production is less than the lower limit of the band (Q_L), the amount of grain taken out of storage is the amount by which production falls short of Q_L—up to the quantity limit of grain available in storage.

It should be noted that trade and storage activities can substitute for each other on occasion to achieve stabilization objectives. When production is short, the world price is low and stored up grain is available, grain can be imported or withdrawn from storage. Likewise, when production is plentiful, export prices are high and there is vacant storage capacity, grain can be exported or stored. We assume that the authorities emphasize the food security aspect of the storage operations; and thus grain is imported prior to releasing from storage in times of scarcity, and excess supply is put first into storage and only the remaining quantity is released for exports in times of good domestic harvest.

One point is worth emphasizing with respect to these storage rules: the domestic price in any given year depends on the quantity produced domestically, the world price, and the

quantity of grain in storage—or the vacant storage capacity—at that year. The latter, in turn, depends on the quantities of grain produced domestically, on world prices in previous years, and on the initial stock and the storage capacity. Consequently, some degree of serial correlation is introduced into the time series of domestic prices due to the storage operations, even when production events are not correlated.

Gains and Losses from Stock Operation

The gains and losses from buffer stocks to society and their distribution among consumers, producers, and the government depend largely on the difference between the price of grain with and without stock operations. When grain is withdrawn from the market into storage, the price is raised; consumers lose and producers gain. Vice versa, when grain is withdrawn from storage to augment current supply, the price is reduced; consumers gain and producers lose.

These gains and losses, as well as the costs and revenues to the government when grain is put into or withdrawn from storage, are illustrated in figures 1(a) and 1(b) and are summarized in table 1 in terms of the designated areas on the graph. The quantity available for current consumption without storage is Q and with storage Q'. P and P' are the corresponding prices without and with storage.

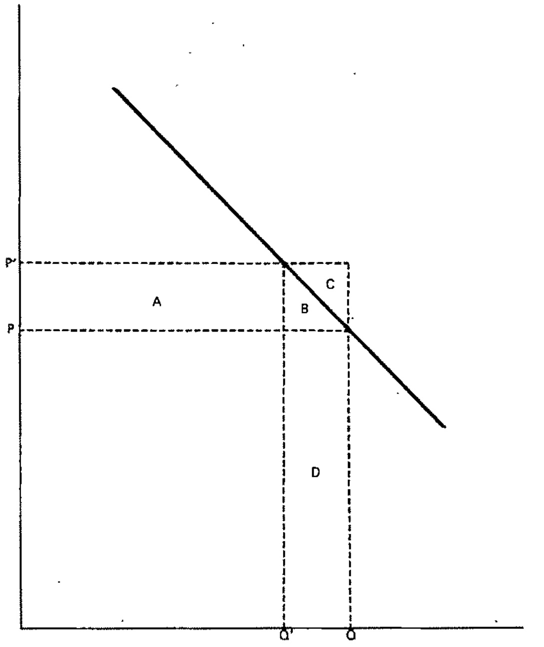

Figure 1(a). Gains and losses from storage operation: grain into storage

Total market demand is assumed to be the sum of the separate demand of "low" and "high" income consumers. Consumption of

Data and Parameters

The specific parameters selected for the simulation experiments are not representative of any particular country; they are, however, deliberately chosen to approximate orders of magnitude of a country like India. This section describes briefly the data and parameters underlying illustrative results presented in the next section.

The results reported in this paper were obtained by simulating 300 runs of thirty-year sequences of random production "events." The total sample size consists, therefore, of 9,000 observations drawn at random from the specified probability distributions.

The country is assumed to produce an average of 110 million tons of food grains. Specifically, production is assumed to be distributed normally, with a mean of 110 million tons and a standard deviation of 7 million tons.

Table 1. Types of Gains and Losses When Grain Is Stored and When Grain Is Withdrawn from Storage by Reference to Areas Shown in Figure 1a–1b

Types of Gains and Losses	Designated Area of Gain or Loss
Grain into storage [Fig. 1(a)]	
Consumers	− A − B
Producers	A + B + C
Government (financial)	− B − C − D
Overall (economic)	− B − D
Grain withdrawn from storage [Fig. 1(b)]	
Consumers	F + G
Producers	− F
Government (financial)	H
Overall (economic)	G + H

the "low" income population is maintained through government intervention at a minimum level. This level is assumed to correspond with the "low" income population's consumption at the median price of $125 per ton. The consumption maintenance policy is implemented through a price subsidy scheme for the low income population. The specific parameters of the demand schedules adopted for the numerical analysis are listed in table 2. Equal food grain consumption by the low and the high income group at the median price of $125 subsumes that the low income group consists of more than half of the total population and per capita consumption is less in the low income group.

World wheat production is assumed to be distributed normally, with a mean of 350 million tons and a standard deviation of 14 million tons. This distribution is transformed to a distribution of the world price on the basis of a kinked demand function. At the mean level of world production, the price is $125 per ton, and the price elasticities of the two segments of the demand function at that point are as follows:

$$\eta = 0.1 \text{ for } P > \$125$$
$$\eta = 0.3 \text{ for } P > \$125.$$

Notice that while production is assumed to be distributed normally, the transformed distribution of price is skewed, with its mean being larger than the median.

Shipping costs are assumed to be $25 per ton. Trade policies are implemented by the level of tariff. In any event, imports are not permitted to reduce the domestic price below .95 of the median price (i.e., increase total supply above 112 million tons). Exports are not permitted to reduce the quantity available for domestic consumption below 108 million tons. In addition, the following general three trade policies are examined in the base case: Free Trade, no tax is imposed on exports or imports; Restricted Trade, the government imposes a tax of $25 per ton on all imports and exports; No Trade, the government imposes a tax high enough to rule out all trade.

Grain production in excess of 112 million tons is put into storage to the extent that there is vacant storage capacity. Grain is taken out of storage when domestic production is less than 108 million tons to the extent of the deficit or to the extent of available stocks in storage, provided the world price is so high as to prevent any imports. A handling charge of $2 per ton is assumed at the time grain is loaded into storage. The rate of interest is 8%; construction costs are assumed to be $100 per ton of capacity and storage facilities are assumed to be amortized within a period of thirty years.

Simulation Results

Tables 3 and 4 summarize the stabilization effects of buffer stocks and of the three trade policies. Our attention is given to the stability of food grain supply, and specifically, on the lower tail of its probability distribution;

namely, the events of extreme shortfalls in the quantity available for consumption.

A noteworthy characteristic of our results is the strong stabilizing effect of international trade which far exceeds the effect of a sizeable buffer stock. The standard deviation of the quantity available for consumption is 6.9 million tons (6.3% of mean consumption) in the closed economy compared with 3.9 million tons (3.5% of mean consumption) under free trade. The probability of a shortage in excess of 5 million tons is 23.5% in the closed economy compared with 6.2% under free trade. In contrast, a buffer stock of 6 million tons in the closed economy reduces the standard deviation of the quantity available for consumption from 6.9 million to 6.3 million tons and the probability of a shortage in excess of 5 million tons from 23.5% to 14.1%. Equally noteworthy is the fact that as the country becomes more open to trade, the additional stabilizing effect of buffer stocks is progressively reduced. Thus, for instance, a buffer stock of 6 million tons reduces the standard deviation of the quantity available for consumption by 25%—from 6.9 million tons to 5.3 million tons—in the closed economy but by only 15%—from 3.9 million to 3.3 million tons—in the open economy.

The extent to which trade and stocks stabilize grain consumption and prices will depend, of course, on the relative variability of the world price and the country's price in the absence of trade. The country's price in the absence of trade will depend on its production variability and the shape of its demand function. To investigate the sensitivity of our conclusions, we simulated the effects of trade and stocks under two alternative assumptions about the variability of production in the country: "more stable" production (a coefficient of variation half that assumed in the base case) and "less stable" production (a coefficient of variation twice that assumed in the base case). The standard deviation of price ($/ton) with free trade or, alternatively, with a 6 million ton buffer stock under different scenarios is as follows:

	No Trade No Stock	Free Trade	6 Million Ton Stock
Base case	54	27	43
"More stable" production	27	19	21
"Less stable" production	108	33	94

Our results also indicate that a moderate degree of correlation between the country's grain production and that in the world does not change our basic conclusions. With a correlation coefficient of $R^2 = 0.3$, for instance, the standard deviation of the quantity available for consumption would still be reduced by 35%—from 6.9 to 4.6 million tons—with free trade (compared, however, with 45% when there is no such correlation).

Figure 2 illustrates the extent of supply stabilization attained by the three trade policies and by increasing sizes of buffer stocks (storage capacities). Here attention is given the availability of food grain for consumption measured by the probability of a serious shortfall in grain consumption. The graph illustrates that even as large a buffer stock as 12 million tons (11% of annual average consumption) would not provide the same degree of protection against extreme shortfalls as would free trade. The slope of the curves manifests the marginal stabilizing effect of each additional unit of storage capacity. Clearly, the marginal effect becomes smaller as trade restrictions are relaxed, and in all cases it declines sharply with increases in storage capacity. For instance, an increase in storage capacity from 6 million to 9 million tons would reduce the probability of a shortage in excess of 5 million tons from 14% to 11% if no trade is permitted, but from 3% to only 2.5%, if trade is free. Without trade, increasing the storage capacity from 0 to 6 million tons would reduce the probability of a shortage in excess of 5 million tons from 24% to 14% but a further increase from 6 million to 12 million tons would reduce this probability only from 14% to 11%.

One conclusion of these results is that the stabilization benefit from a buffer stock is generally much higher in a closed economy than in an economy open to trade. The diminished effect of stocks in an open economy also is reflected in its economic and financial benefits and costs. In general, net gains from storage operation are larger, the larger is the number of transactions (acquisitions for and sales from storage) and the larger is the difference between the price at which grain is purchased and sold.

In the free market economy, trade activities can replace storage activities and the variability of grain prices is generally reduced. As a result, buffer stocks would be operated much less frequently and the differential between

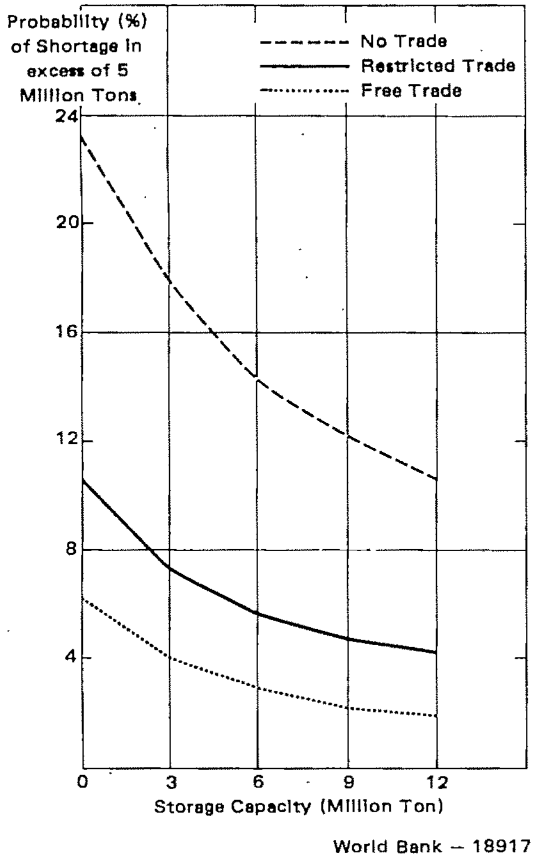

Figure 2. Relative frequency of serious supply shortfall with alternative storage capacities and trade policies

the purchase price and the sale price would be considerably lower in the open economy. The net result would be smaller gains, and even losses, from the operation of the storage facility to the extent that the amortization costs would far outweigh any possible gains.

Table 5 summarizes the gains and losses to society as a whole and their distribution among consumers, producers, and the government from a 6 million ton capacity storage operation. In a closed economy, net annual economic losses from a 6 million ton buffer stock would be relatively small ($12 million annually). However, in an open economy, the same size of buffer stock would not only contribute much less to stabilization but would also be much more costly ($70 million annually).

The distribution of losses and gains is, however, by far more important than the overall amounts. With the demand function specified in our model, price stabilization normally would yield gains to consumers and losses to producers. Our results show, however, that consumers would suffer losses rather than gain. The reason is that under the postulated subsidy program, low income consumers do not gain from the reduction in price when grain is removed from storage. They would pay the same subsidized price regardless of the actual market price when supplies are scarce. When

[b] "Quantity restrictions" on imports and exports are implemented by an appropriate tariff. Thus, the government will have some tax revenues even under a "free trade" policy.

the subsidy program is practiced, gains from stabilization accrue primarily to the government in the form of saving on subsidy payments.

The more restricted is international trade and the larger is the buffer stock, the larger are these fiscal benefits from stocks. This should not be interpreted, however, to mean that governments should favor protectionist policies and large buffer stocks. To the contrary, the "gains" by the government from stocks only partially compensate for the additional fiscal burden the government incurs in the first place, as a consequence of greater instability in grain prices introduced by the trade restrictions. Put differently, total subsidy payments in the open economy are considerably lower than in the closed economy with buffer stocks.

Figure 3 illustrates the rapidly declining cost effectiveness of increasing levels of buffer stocks under all trade scenarios. While the probability of a shortage in consumption in the excess of 5 million tons declines with increasing stock levels, this increased protection is bought at rapidly accelerating cost to the economy. Only in the closed economy and for a very small stock would there be some gains at the same time that the probability of a shortage would be reduced. Under restricted trade, an annual outlay of $45 million for buffer stocks would reduce the probability of a severe shortfall for approximately 8% to 5%. However, an additional outlay for buffer stocks of the same magnitude would reduce the probability of such a shortfall only an additional 1.1%.

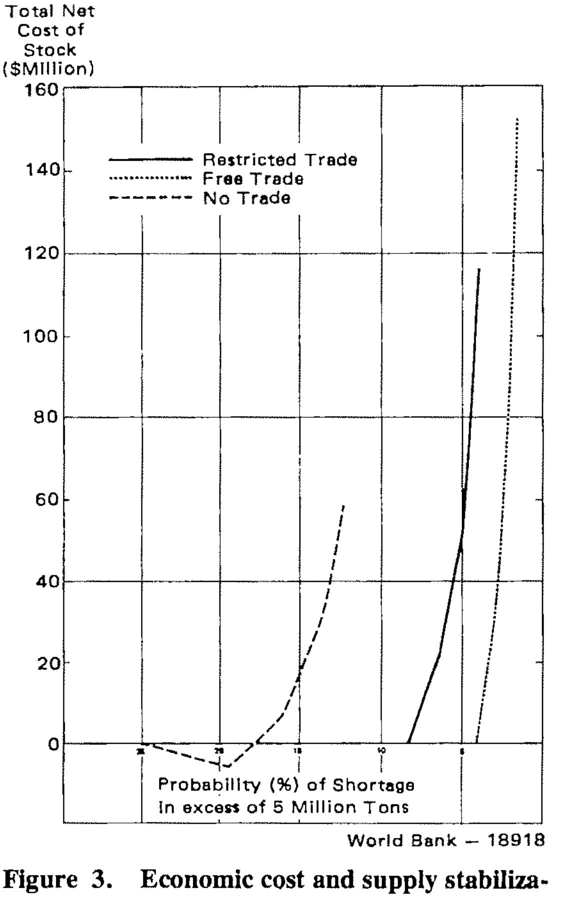

Figure 3. Economic cost and supply stabilization with alternate trade policies

Conclusions

The single most important observation based on our analysis is that for most countries international trade would be a good way of achieving greater stability in the domestic market. Although countries can choose between liberalizing their trade or maintaining buffer stocks as alternative ways of promoting stability, our analysis shows that buffer stocks sufficiently large to stabilize supplies can be very costly. Obviously, the trade option has its own costs as well, in the form of larger fluctuations in foreign exchange balances and the need to draw on large reserves in times of shortfall in domestic production or high world price. In this context and in recognition of the potentially strong stabilizing effects of trade, the international community also should reevaluate the directions of its efforts aimed at ensuring a stable food supply in developing countries.

The Net Social Benefits from a Research-Induced Cost-Reduction of an Energy Backstop Technology

Frank A. Ward

Substantial effort has been devoted to the development of measures of benefit attributable to agricultural research that lowers commodity costs. With increasing scarcity of energy inputs, many research resources are being devoted to overcome this scarcity by reducing the costs of "backstop" technologies, i.e., nonexhaustible sources of energy output. This paper draws from (*a*) the theory of exhaustible resources and (*b*) the literature of traditional surplus measures of benefit and cost, to develop a conceptual framework for quantifying the net social benefit for successful backstop cost-reducing energy research.

Key words: backstop technology, exhaustible resources, research benefits, social cost-benefit.

In recent years, several researchers have developed measures of the benefits from agricultural research. Griliches, Arndt and Ruttan, and Evenson and Kislev all have attempted to estimate the social rate of return on such research. More recently, Lindner and Jarrett developed a generalized measure of research benefits as dependent on the manner in which research affects commodity supply curves. Thus, there would seem to be an emerging consensus for evaluating the social benefits of agricultural research.

This paper attempts to develop a conceptual framework for measuring the net social benefits for energy-related research. The need for a distinct measure of energy research benefits rests on the fact that for much of the world's present-day energy output, exhaustible mineral resources make up a substantial portion of the required factor inputs, and a conceptually acceptable measure of energy research benefits would need to take into account the inherently dynamic nature of exhaustible energy minerals extraction. The development of an acceptable measure requires that this paper bridge two distinct bodies of literature.

On one hand, the concept of net social benefits is heavily dependent on the cost-benefit literature, such as Mishan; Currie, Murphy, and Schmitz; and Lindner and Jarrett. Second, however, an analysis of net benefits as applied to exhaustible energy resources logically should draw from the exhaustible resources literature, such as that of Goldsmith, Hotelling, Herfindahl, Nordhaus, Solow, and Weinstein and Zeckhauser. The present article draws from both sources of literature.

The basic approach of this paper is as follows: Assume that a given form of energy can be supplied by two sources, (*a*) an exhaustible mineral of which there is an absolutely fixed supply, but for which the extraction costs are constant and relatively low, and (*b*) a "backstop technology" (see Nordhaus), a technology of high capital costs, which although not presently economical, nonetheless will not require the use of exhaustible energy resources when the transition is made to this technology. We consider the question: Suppose research effort is directed at reducing the cost of this backstop technology (the B-cost), then what are the net social benefits attributable to that cost reduction?

Journal Article No. 699, Agricultural Experiment Station, New Mexico State University, Las Cruces.

Assumptions, Definitions, and a Brief Review of the Basic Economics of Exhaustible Resources

Following Hotelling, Herfindahl, and Solow, it is assumed that the exhaustible resource (the E-source) market is made up of price takers who face constant costs and a parametrically invariant demand schedule. That is, the marginal cost schedule of resource extraction is horizontal and does not shift up with the cumulative quantity mined. All deposits of a specific homogeneous exhaustible resource are fully known and individually appropriated. Each producer is a price taker, but economic profits do not draw in additional producers, because the mineral supply is fixed. Furthermore, each mine owner discounts future profits at the same discount rate, assumed equal to the marginal social rate of time preference. Under these assumptions, at any point in time, equilibrium market price exceeds extraction costs where the residual (a scarcity rent referred to as a "royalty" in this paper) rises over time as the mineral stock becomes depleted.

The E-source is assumed substitutable by a backstop technology (B-technology) which, although immediately available, has a higher cost than is presently economical (Nordhaus). It is further assumed that there exists a complete set of futures and contingency markets.

Solow analyzes the comparative dynamics and stability conditions as to how a change in the B-cost affects the E-source's capitalized value and price-output paths over time. "One imagines that resource companies keep a careful eye on the prospective costs associated with the backstop technology. Any laboratory success or failure that changes those prospective costs has instantaneous effects on the capital value of existing resource deposits, and on the current rate of production" (p. 5). For example, given a reduction in the B-cost, perfectly functioning forward and contingency markets would signal a reduction in the future and present price of the E-source, which would immediately have the dual effect of reducing the capitalized value of a unit of the E-source (i.e., the unit royalty, or scarcity rent) and speeding up the present and expected future output flow of the E-source as industry output flows moved down along the industry demand schedule. Solow writes that "if futures markets actually existed, we could probably accept the notion that their equilibrium configuration is stable . . ." (p. 6).

Net benefits are defined to consist of consumer surplus plus producer royalties, where royalties are explicitly taken to mean the flow of scarcity rent accruing to owners of the fixed mineral stock. For example, in figure 1, suppose that q_o represents the initial period output flow of uranium ore, the E-source which is used to produce electricity, and C_e is the unit cost of uranium extraction. Electricity also can be produced by a high-cost solar technology (the B-technology). Under the assumptions of this paper, q_o, and hence initial period price, p_o, and initial period unit royalties, $p_o - C_e$, are simultaneously determined by (a) the cost of solar-produced electricity, (b) the rate at which mineowners discount future unit royalties, (c) the total stock of uranium, and (d) the unit extraction cost of uranium, C_e. Total initial-period royalty flow is equal to the lower shaded area $p_o p'_o C'_e C_e$, while the total net initial-period benefit flow for output level q_o is equal to the shaded area, $C_e D p'_o C'_e$. The present value of the sum of such shaded areas over the life of the uranium industry is that industry's contribution to net benefits derived from energy production-consumption. The period-by-period flow of shaded net benefits, of course, would be substantially less after society switched its dependence to the relatively high-cost B-technology (not shown in figure 1).

A Basic Model of Net Benefits Measurement

Given the above assumptions and definitions, it has been shown (see Hotelling, Herfindahl, Peterson, Solow) that the mineral market's competitive equilibrium is characterized by marginal profits (unit royalties) which grow at

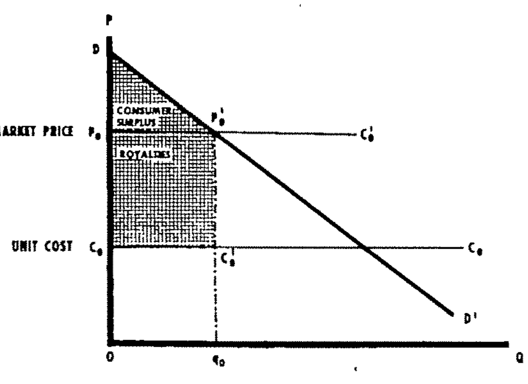

Figure 1. Total net benefit, consumer surplus, and royalties

the rate of discount. This result is based on the notion that mineowners are indifferent between marginal profits now, R_o, and marginal profits $R_o e^{rt}$ at some point, t, in the future.

The effect of a research-induced B-cost reduction on net social benefits can be explored via a system of four equations in four endogenous variables. Equation (1) is obtained in five steps.

First, note that market price is made up of unit extraction costs and unit royalties,

$$P(t) - C_e - R(t) = 0, \tag{1a}$$

where price, P, of the E-source (the E-price) at any point in time, t, equals unit extraction costs (the E-cost), C_e, plus unit royalties, R, at that time. Royalty payments are considered distinct from extraction costs because royalties are not an opportunity cost, and hence can be viewed as a net social benefit of production, whereas this is not the case with extraction costs.

Step two is simply the mathematical statement of the exhaustion constraint. Assuming absolute fixity of the total E-source stock, then

$$\int_0^T q(t)dt = K, \tag{1b}$$

where (1b) states that the flow of production, $q(t)$, summed over the period of production, 0 to T, is equal to the mineral stock, K. The implication is that the resource is exhausted at the switch point, time T. Clearly, one can think of many exhaustible resources which are no longer used but which have not been exhausted. Presumably, this is due to the rising costs of cumulative extraction. However, given this paper's assumptions, known deposits of the exhaustible resource with constant costs would be mined out before the switch was made to the backstop technology. For a similar description, see Solow (p. 5).

Next, the flow of production, $q(t)$, equal to the quantity demanded, is related to the market price via the (partial equilibrium) demand schedule, i.e.,

$$q(t) = q[p(t)], \quad q'(p) < 0, \tag{1c}$$

where $q[p(.)]$ is notation for the specific functional form of the demand curve for the E-source–B-technology energy commodity. Note that the term "supply curve" has not been mentioned. Recall that when a resource is exhaustible, the supply curve for the industry (and the firm) is not that of the traditional price taker. This, for two reasons. First, producer output at each point in time depends on the entire expected intertemporal price path. Thus, one cannot determine unambiguously how today's producer output flow will change given a change in today's price, for today's price does not change without future prices changing also. Second, analogously to a pure monopoly producer, a distinct price path over time is traced out by the industry depending on the manner in which the demand curve shifts. Clearly, the notion of a traditional industry supply curve does not describe the market for exhausible resources under this paper's assumptions.

Because unit royalties grow at the rate of compound interest in the competitive energy-mineral market under constant cost conditions,

$$R(t) - R_o e^{rt} = 0, \tag{1d}$$

where $R(t)$, the generalized functional notation for equilibrium unit royalties at a point in time, t, is initial-period royalties compounded to that period, i.e., $R_o e^{rt}$.

Equations (1a), (1b), (1c), and (1d) can be combined into a single equation, which in implicit form is

$$\int_0^T q(R_o e^{rt} + C_e)dt - K = 0. \tag{1}$$

Equation (1) shows that the total quantity of the resource used over its life is equal to its given supply, K. The expression $(R_o e^{rt} + C_e)$ is the E-source's price as an explicit function of time, t; $q(.)$ is the functional notation for quantity demanded as a function of the E-source's price.

A second equation states that at the time when production of the E-source ceases, i.e., at T (Nordhaus' "switch point"), its price will be equal to the unit B-cost,

$$R_o e^{rT} + C_e - C_b = 0, \tag{2}$$

where C_b is the unit B-cost. The formulation of this equation assumes that (a) the E-source has unit costs less than the B-technology; and (b) that any change in unit B-costs instantly results in a new equilibrium time path of extraction.

Next, the notion of net benefits is developed. Define the flow of net benefits at a given point in time as the flow of consumer-plus-producer surplus,[1] where producer surplus

[1] There is not universal agreement among economists that the constant money-income consumer surplus is an appropriate measure of efficiency benefits. Some feel that the Hicksian consumer

equals royalties as defined in this paper.[2] Total surplus for output flow q_o is equal to the shaded area in figure 1, because consumer surplus and royalties each are a social payoff in excess of the opportunity costs of extraction.

The total time-discounted value of net social benefits arising from the E-source, hereafter referred to as U_1 benefits, can be obtained by integrating net benefits over the life of the E-source, 0 to T, while continuously discounting at the real rate of time preference (assumed equal to the market rate of interest), r, i.e.,

$$(3) \quad \int_0^T ns[q(R_o e^{rt} + C_e)]e^{-rt}dt - U_1 = 0,$$

where $ns(.)$, compact functional notation for net surplus flow, equals the shaded area in figure 1, which is total willingness-to-pay less extraction costs for output flow, $q(.)$; and e^{-rt} is the discount factor applied to the flow of net benefits at ^{T} to make them commensurate at time zero. It should be emphasized that U_1 benefits are defined as the present value of total net benefits attributed solely to the use of the E-source. Benefits arising from the B-technology will be distinguished from those arising from the E-source, if only for the sake of analytical convenience. (Presumably, to the final buyer of energy, for example, electricity generated from coal is not distinct from solar-generated electricity.)

The fourth and final equation defines the present value of time-discounted net social benefits arising after the introduction of the B-technology. These benefits (U_2 benefits) consist of consumer surplus discounted from the switch point, T, to perpetuity, ∞ (because no producer surplus can exist given a constant long-run supply price). Mathematically, U_2 benefits are defined as

$$(4) \quad \int_T^\infty \{ns[q(C_b)] - q(C_b)(C_b - C_e)\}e^{-rt}\,dt - U_2 = 0;\ C_b - C_e > 0,$$

where $ns(.)$, as in equation (3), is the flow of net surplus for output level $q(C_b)$, and $q(C_b)$ is the output flow demanded at a B-cost, C_b. From $ns(.)$, must be subtracted $q(C_b)$ $(C_b - C_e)$, the royalty flow no longer received by E-source owners once the switch is made to the B-technology.

Note that equation (4) is written in such a way as to emphasize that producer surplus no longer exists when the economy switches to the B-technology. However, the reader can see that since U_2 is simply the time-discounted area under the demand curve and above the B-cost (C_b) supply price, equation (4) could also be written as

$$(4a) \quad \int_T^\infty \int_{Cb}^{pm} q(p)e^{-rt}dpdt - U_2 = 0,$$

where $q(p)$ is the demand function and p_m is the demand price that chokes consumption to zero. In either case, equation (4) or (4a) defines U_2 benefits as the discounted value of consumer surplus for a B-cost, C_b from the switch point, T, to perpetuity.

Equations (1) through (4) have been constructed so that equilibrium values can be determined for each of the following four endogenous variables: (a) U_1, total time-discounted net benefits from the E-source; (b) U_2, total time-discounted net benefits from the B-technology; (c) R_o, initial period royalties (and hence royalties and price) at all points in time; and (d) T, the switch point. Each of the four endogenous variables is thus indirectly a function of the following parameters: r, the interest rate; C_e, the per unit cost of the E-source; C_b, the per unit B-cost; K, the stock of the E-source.

Within the context of equations (1) through (4), recall that the purpose of this paper is to focus on the specific sensitivities, $\frac{\partial U_1}{\partial C_b}$ and $\frac{\partial U_2}{\partial C_b}$, i.e., the sensitivities of (the endogenously determined) U_1- and U_2-benefits to parametric shifts in the B-cost. Of course, the four equations could be used, if desired, to determine the sensitivity of all four endogenous variables to other parameters including, for example, the net benefits attributable to (a)

surplus is the correct measure. For example, Herfindahl and Kneese (p. 190) state that the area beneath the Marshallian demand curve is correct only when the income effects of actual payments, if they were made, is zero. For an alternative viewpoint, see Ward (1979). In addition, it is not altogether clear that public investments in energy cost reduction technology should worry about the loss of rents to present natural monopoly holders. This is a political question rather than a scientific calculation.

[2] Market demand price is assumed equal to marginal willingness-to-pay, and the unit cost of mineral extraction is assumed equal to marginal opportunity cost. That is, it is assumed that the entire net social payoff of energy production-consumption is captured between the relevant market demand and unit cost curves. This assumption is not entirely consistent with much of the conceptual foundation of cost-benefit analysis. The cost-benefit approach quantifies the net social benefits of resource reallocations under conditions where marginal social value diverges from the demand function, and/or marginal opportunity cost is not equal to private marginal costs.

research that reduces the E-costs, C_e, and (b) changes in the stock of the E-source.

The Implicit Function Theorem of mathematics (Chiang, pp. 198–240) allows one to solve directly for the required partial sensitivities. It is straightforward to show that they are as follows (derivations are available from the author):

$$\text{(7a)}\quad \frac{\partial U_1}{\partial C_b} = \frac{1}{|J|}\{ns[q(C_b)]e^{-rT} \int_0^T q'(R_0e^{rt} + C_e)e^{rt}dt - q(C_b) \int_0^T ns'(q)q'(R_0e^{rt} + C_e)dt\},$$

$$\text{(7b)}\quad \frac{\partial U_2}{\partial C_b} = -q(C_b)\frac{e^{-rT}}{r} - \frac{\partial T}{\partial C_b}\{ns[q(C_b)] - q(C_b)(C_b - C_e)\}e^{-rT}$$

where $|J| = \begin{vmatrix} \int_0^T q'(R_0e^{rt} + C_e)e^{rt}dt & e^{rT} \\ q(C_b) & rR_0e^{rT} \end{vmatrix}$,

and primes indicate partial derivations.

Examining the two sources of benefits, attention is directed first to (7b), $\frac{\partial U_2}{\partial C_b}$. According to (7b), the reduced C_b (B-cost) has two effects on U_2 benefits. The first term in (7b) says that the extra benefits of a unit B-cost reduction equals that B-cost reduction times the flow of consumption, $q(C_b)$, to which the reduced cost applies, multiplied by $\frac{1}{r}e^{-rT}$. This first term is the present value of the infinite stream of cost-savings for which receipt commences at the switch point, T. This term is simply the dynamic analogue, in differential form, of Lindner and Jarrett's static net benefit measure of a research-induced reduction in supply price.

The second term in (7b) is one which is unique to the intertemporal nature of the competitive mineral extraction process. This component of $\frac{\partial U_2}{\partial C_b}$ is the reduced waiting time for the switch point to occur, $\frac{\partial T}{\partial C_b}$, times the consumer surplus flow which energy consumers receive at the existing B-cost, where e^{-rT} discounts that increment of nearer-to-the-present surplus back to time zero from the switch point. This second component is a quantification of the notion that because the switch point itself is brought closer to the present resulting from the decreased B-cost, energy buyers receive their discounted B-technology consumer surplus at an earlier point in time would have been the case had the B-costs not fallen.

For example, suppose that under conditions of a relatively high B-cost, energy consumers could expect a potential undiscounted annual flow of \$100 in consumer surplus benefits after the switch to the B-technology. However, under conditions of a lower B-cost, consumers could expect to receive that annual flow of benefits "t" years earlier, due to the speeding up of the E-source's exhaustion. The second component of (7b) would then be (\$100t)e^{-rT}, which measures the discounted value of B-technology consumption benefits being brought "t" years closer to the present.

Thus, in summary, equation (7b), $\frac{\partial U_2}{\partial C_b}$, sums the two subcomponents of the gain in U_2 benefits attributable to a B-cost reduction. First, consumers receive the benefit of a future cost savings arising from the lower B-cost. This cost savings must be summed and discounted from the switch point to infinity. In addition, the decreased B-cost reduces the period of dependence on the E-source. The undiscounted consumer surplus which would have been received at the "initial" switch point, say thirty years from now, instead will be received at a point earlier in time, say twenty years from now, when the B-costs fall.

Equation (7b) has summarized two subcomponents of the net benefits attributable to a B-cost reduction. However, there is another more subtle term which should be included in the measure of net benefits. This term is summarized by $\frac{\partial U_1}{\partial C_b}$.

Examining equation (7a), observe the conditions which are sufficient to force $\frac{\partial U_1}{\partial C_b}$ to take on a value of zero, i.e., for U_1 to reach an extremum relative to changes in C_b. That condition is zero (E-source–B-technology) energy

consumption, $q[.] = 0$, at the switch point, T. This, of course, would only come about if the B-technology were uneconomical, in which case T would represent the terminal period of consumption. For a sufficiently uneconomical (high) B-cost, consumers would be forced back to the level of zero consumption on their demand curve, where both (*a*) the output flow, $q(C_b)$, and (*b*) net surplus flow, $ns(C_b)$ are necessarily zero. In this situation, both halves of (7a) take on a zero value which, given a nonzero denominator, is sufficient to yield a value of zero for $\frac{\partial U_1}{\partial C_b}$. (In all practicality, the point of zero consumption may never be reached.) What are the economic implications of equation (7a) taking on a zero value?

Recall that under this paper's assumptions, the competitive market allocates the exhaustible mineral over time in such a way that (*a*) unit royalties grow at the rate of compound interest, and (*b*) output flow at the switch point, T, is restricted just sufficiently for the E-source market price at T to equal the B-cost. Since the price of the E-source at T must equal the B-cost, (7a) says that if the B-cost is so high that consumption shrinks to zero at T, then $\frac{\partial U_1}{\partial C_b} = 0$, and the present value of net benefits from the E-source (U_1 benefits) reach an extremum. Is this extremum a maximum?

The following geometrical presentation shows that (*a*) U_1 benefits do reach a maximum when exponentially growing unit royalties are coupled with an output flow of zero at T, and (*b*) $\frac{\partial U_1}{\partial C_b}$ is greater than zero (i.e., falling B-costs reduce U_1 benefits) when the existing B-cost is low enough to be economical. (See the appendix for more rigorous proof using optimal control theory.)

Suppose that the expected time path of energy mineral output follows a pattern such that unit royalties, equal to marginal net benefits, i.e., price less marginal cost, grow at less than the rate of compound interest. If this is the case then clearly U_1 benefits can be increased by allocating less output flow to later periods and more to earlier periods. However, recalling that the magnitude of the B-cost directly affects which specific dynamic exponential growth path of unit royalties is actually tracked by the competitive market, the relevant question becomes: Do all output

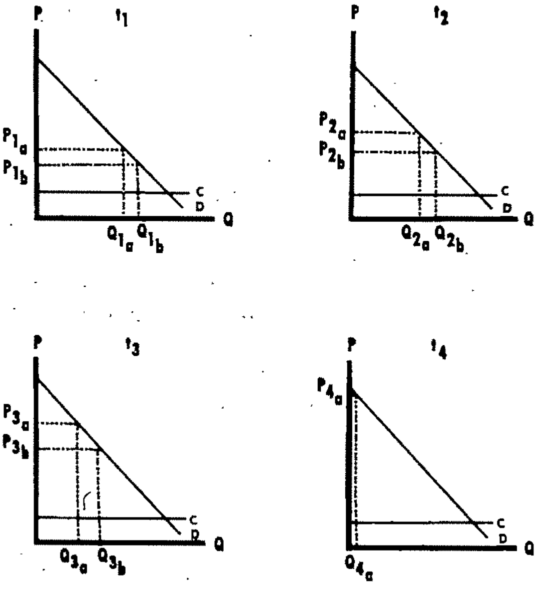

Figure 2. Two possible time paths of extraction which exactly exhaust a given supply of an energy mineral

paths where marginal net benefits grow exponentially bring about equal U_1 benefits?

In figure 2, panels $t_1 - t_4$, there are two time paths of mineral output shown, each of which yields exponentially rising unit royalties. In each panel, the demand curve is D and unit E-cost is C. The path with "*a*" subscripts shows output flow following the four-period time path of Q_{1_a} through Q_{4_a}, with unit royalties taking on the successive values of P_{1_a} (minus C) through P_{4_a} (minus C). Suppose that when path "*a*" is followed, the fixed supply of the mineral is exhausted in four periods and the B-cost (C_b) is sufficiently high so that the final period price of the E-source, P_{4_a}, is high enough whereby one unit, the last remaining unit in the ground, is demanded.

Next, consider an alternative time path of extraction with "*b*" subscripts. Call this path "*b*". Assume that path "*b*" would be the equilibrium path followed when the B-cost, C_b is equal to P_{3_b}. Unit royalties still grow at an exponential rate, but because of the lower B-cost, royalties are lower in each period and the output flow of the E-source is higher, corresponding to a lower price in each production period. Assume that this "*b*" path leads to exhaustion in three periods.

Focusing attention on panel t_3, if the marginal unit of output represented by Q_{3_b} were shifted out of period three into period four,

then period three's social cost of the output in foregone net benefits is P_{3_b} (minus C). The gain of that output increment measured in period four's net benefits, when discounted by one period, equals P_{3_d} (minus C), [P_{4_a} (C), discounted by one period] which is larger than P_{3_b} (minus C). Clearly, that incremental shift increases discounted net benefits, which means that a path such as "b" does not yield maximum U_1 benefits. Thus, for U_1 benefits to be at a maximum, the marginal unit of output in the last period must be such that (a) when discounted, it yields marginal net benefits in the last period equal to those of previous periods, and (b) price minus unit cost is at a maximum. (More generally, marginal benefits equals average benefits. See the appendix for a proof.)

From the results of the geometrical presentation in figure 2, it can be seen that if the B-cost is less than the choke price, P_{4_a}, then under competitive conditions, U_1 benefits fail to reach a maximum. Extending the above reasoning, it can be seen that further reductions in the B-cost actually reduce U_1 benefits. Therefore, $\frac{\partial U_1}{\partial C_b}$, as defined by (7a) is positive; reductions in the B-cost actually reduce U_1 benefits, when the existing B-technology is sufficiently cheap to allow positive consumptions of B-source-produced energy.

What, then, are the economic implications of the net benefit measurements of (7a) and (7b)? First, when the cost of the backstop technology declines, society stands to benefit substantially due to lower energy prices from that day (time zero) onward. Second, however, this reduced B-cost will have the effect of speeding up the extraction rate of the E-source, which speedup tends to lessen the present value of U_1 benefits that will be obtained from that source. Thus, the benefits lost on the E-source resulting from the B-cost reduction, $\frac{\partial U_1}{\partial C_b}$, must be deducted from the otherwise positive benefits of the falling B-cost, $\frac{\partial U_2}{\partial C_b}$, to obtain total net social benefits attributable to research which lowers the B-cost.

Summary and Conclusions

This paper has developed a conceptual measure of net social benefits attributable to increased energy research, a measure developed by establishing an analytical linkage between the literature of (a) social cost-benefit analysis, and (b) the economics of exhaustible resources. There are three major such sources of welfare change identified in this paper. First, society receives a cost savings brought about by the backstop cost reduction which should be discounted from the point at which society switches to backstop technology into perpetuity. Second, because the switch point itself is reduced by the falling backstop cost, energy consumers receive a consumer surplus benefit from the backstop technology at an earlier point in time. That consumer surplus must be summed and discounted across the extra increment of time by which the switch point is reduced. Third, the extraction rate of the exhaustible mineral is sped up due to the reduced backstop cost, which reduces the present value of the net social payoff receivable from the exhaustible resource when considered in isolation. Although it is clear that a research-induced reduction in the backstop cost confers immense positive net benefits on an energy-dependent society, it is necessary to evaluate all three sources of net benefits. Particularly if the third source is ignored, the net benefits of energy research can be overstated.

Limitations and Needs for Further Research

This paper's net benefit measure of energy research has been based on several simplifying assumptions. Clearly, it would be desirable if a similar measure could be developed under a more realistic set of assumptions, and hence this study points to the need for further research. One wonders about the limitations of the assumptions, particularly as they affect the third source of net benefits, i.e., the loss in net social payoff of the exhaustible resource due to the cost reduction in the backstop technology. This third source is shown to bring about a negative contribution to benefits because of the assumption that a fixed stock of homogeneous resource with constant costs will be extracted over time, regardless of the cost of energy provision via the backstop technology. It is the speeding up of the extraction from this given stock which reduces the present value of benefits derivable from that stock. Perhaps under a more general set of assumptions, further work may show that the sign of this third component of net benefits is reversed. In spite of simplifying assumptions, this paper constructs a net benefits measure of energy re-

search that establishes a linkage between the cost-benefit literature and a received theory of exhaustible resources. Therefore, the present paper provides a point of departure for quantifying the net social value of energy research.

Appendix

Necessary Conditions for U_1 *To Be a Maximum*

As an alternative way of seeing that zero terminal-period consumption is required for the net U_1 benefits to be maximized, let us recast the net U_1 benefits measure in terms of a control-theoretic formulation, where, according to the assumptions of this paper, it is desired to choose the time path of mineral extraction which makes U_1 a maximum, subject to the constraint of a fixed total mineral stock. The terminal period of production, T, is a decision variable. The problem then becomes

$$(A_1) \qquad \text{Max } U_1 = \int_0^T \{ns[q(t)]e^{-rt} - \lambda[q(t)]\}dt,$$

where all variables are defined as before, with the exception of the added undetermined Lagrangian multiplier, λ, reflecting the constraint of the fixed total stock of the mineral, K.

Note that the solution to the control theoretic problem picks the time path of mineral flow which maximized U_1 benefits (subject to the mineral stock constraint), whereas the comparative statics approach taken in the body of this paper is that of determining the marginal effect on U_1 benefits of several alternative parametric shifts, based on an output path explicitly defined by a set of competitive assumptions. Thus, the control approach treats $q(t)$ and T, respectively, as (a) an unknown function of time, and (b) an unknown terminal time period, to be determined by the optimal control solution, whereas the comparative static approach defines $q(t)$ and T as known functions which are explicitly determined by the structural competitive equations (1) through (4).

The solution of the control problem comes from the Euler equation and transversality (end-point) condition (Hadley and Kemp). They are, respectively, given by (A-2) and (A-3).

$$(A_2) \qquad ns'(q)e^{-rt} = \lambda,$$

$$(A_3) \qquad \frac{ns[q(T)]}{q(T)} = \lambda.$$

Equations (9) and (10), respectively, say that in order for the time path of extraction to yield maximum U_1 benefits, (a) the discounted marginal net benefit flow, $ns'(q)$ should be equal in all periods; and (b) in the terminal production period, the marginal net benefits flow should equal the flow of average net benefits, $ns[q(T)]/q(T)$. Given the assumptions of this paper, this means that unit royalties should grow at the rate of compound interest and terminal-period output flow should be zero, as marginal and average net benefits are equal only at a zero output.

Notes

Canadian Farm and Nonfarm Family Incomes

R. Paul Shaw

Analysis of the level and distribution of economic well-being in North American agriculture is, without doubt, underdeveloped and fraught with ambiguity. Bawden refers to this situation as "the neglected human factor" (p. 879). It stems from censuses of agriculture that are typically enterprise-oriented, problems of monitoring self-employment incomes, incomplete income measurement, and inadequate information on the increasing importance of off-farm work in the farm family income equation.

In Canada, the paucity of quantitative studies on the subject is highly visible. Examples of the few and far between include Fitzpatrick's regional analysis of farm family income based on a 1958 farm survey; a Federal Task Force on Agriculture evaluation of the low income problem using limited data on farm sales and capital value; Gellner and Davey's study of incomes using aggregate tax data; McClutchy and Campbell's estimates of "farm family real income," using the questionable 1972 Agriculture Enumerative Survey; and Kulshreshtha's 1967 measurement of farm:nonfarm incomes in historical perspective. Most of these studies are comparable in neither methodology nor empirical coverage. Absence of information on returns to off-farm work is particularly conspicuous. With the exception of Kulshreshtha's work, little attempt has been made to evaluate alternative farm:nonfarm income measures, or the extent to which their viability depends on the context in which they are being used.

These shortcomings prompted a complete linkage of Canada's 1971 Censuses of Agriculture and Population, resulting in a unique data base with a wealth of income data. Some 365,000 farm enterprise questionnaires (with 199 questions) have been computer matched with independently enumerated Census of Population questionnaires for the respective farm households. One-third of the latter have been enumerated on a detailed sample basis. They contain approximately sixteen detailed income and employment-related questions and cover all members of the census farm household. The linkage was designed and performed under the direction of the author. For details see Shaw (1971, 1979a) and Freeman. Income questions on the 1971 Census of Population pertain to 1970. Total family cash income is the sum of all income earned by family members from wages and salaries, net farm self-employment, nonfarm self-employment, transfer payments, interest, rent, and other.

This linkage commences a new decennial series with the advantage that income coverage for farm and nonfarm families will stem from the same census methodology and will pertain to the same time period. We draw on this improved source (*a*) to place disparities in farm:urban incomes in Canada in clearer perspective, and (*b*) to single out the incredible impact that off-farm work is having on reducing disparities.

R. Paul Shaw has been affiliated with the University of British Columbia and International Labour Organization.

Measuring Proximity to Parity

Needless to say, comparison of incomes from largely self-employment contexts with those of wage and salary contexts faces many hazards. For example, the flow of income in self-employment farming is more susceptible to wide fluctuations (e.g., depending on weather, international trade), farm and nonfarm incomes should be measured in cash as well as "in kind," reported incomes may be biased downwards due to delayed consumption of current income (i.e., toward building up capital stock), psychic or nonpecuniary returns may be higher in rural-farm contexts, etc. In other terms, the 1971 agriculture-population linkage data represent a sound point of departure to which various refinements must be made.

In table 1, column 3, various farm-urban income ratios are summarized for Canada; table 2 gives a corresponding set of ratios for provinces. Rows 1–3 relate to individuals. In many respects, these ratios represent the standard approach to measuring disparities in economic well-being. At the Canada level, comparison of mean farm:urban per capita incomes (from all sources) implies a ratio of only .50 (table 1, row 1). The farm per capita gini coefficient is more than 1.5 times that of the urban sector. The proportion of the population in rural farm areas falling below Canada's "low level income cut-offs" or poverty lines, is more than double that of the population in urban areas. The "low level income cut-offs," based on expenditure data from Statistics Canada's family expenditure survey (1973a) specific to place of residence are (*a*) approximately $4,650 for an "average" urban family of 3–3.5 persons, for 1970, and (*b*) approximately $4,150 for an "average" rural farm family of 4–4.5 persons in 1970.

According to table 2, col. 1, the provincial per

[a] The numerator of this ratio is "total family income of those farm families reporting farm self-employment as their major or largest source of income."
[b] The numerator of this ratio is "total family income of those farm families reporting wages and salaries as their major or largest source of income."

employment agriculture lag far behind those of the urban sector.

The first set of refinements acknowledges that (*a*) families, not individuals, are the major consumptive units in Canadian society, (*b*) "income in kind" is likely to be a more important source of nonpecuniary return in rural farm than urban contexts, and (*c*) stock must be taken of unusual fluctuations in farm productivity, sales, etc. With respect to the latter point, wheat is by far Canada's leading crop; and it is of some importance that declining exports between 1965–68 resulted in (*a*) an accumulation of unsold stocks, (*b*) voluntary reduction of wheat plantings by about 15% in 1969–70, and (*c*) a one-year federal scheme to remove up to 22 million acres of prairie land from wheat production in 1970. While producer incomes were compensated somewhat by government aids promoting shifts into production of barley, forage, oilseeds, and livestock, the fact remains that total 1970 net farm income in Canada's farm sector was about 14% less than the 1961–71 average (Shaw 1977).

Significance of the considerations above is reflected in table 1, rows 4–6. The farm:urban family ratio is .67, or .17 points higher than the per capita ratio. The difference is attributable to larger family size in farm areas of about 4.5 persons, on average, compared with 3.5 for urban areas. Adjustments for "income in kind" favors farm families with $1,563, on average, compared with $769 for urban families. In farm areas, "income in kind" constitutes the value of consumption of home-grown food, wool, and woodlot products, plus an imputed rental value of owner-occupied farm dwellings; in urban areas it constitutes an imputed rental value of owner-occupied urban dwellings.[1] Finally, the adjustment for the "wheat problem" raises the ratio another .02 points to .79. The "wheat adjustment" for the average Canada ratio was made by increasing the share of the farm family income from farming per se by 14%. At the provincial level, the adjustment was made solely among Canada's major wheat producers where returns to farming were augmented to offset respective provincial losses. In defense of these adjustments, see Shaw (1977).

The importance of these adjustments is particularly apparent among provinces. For example, in table 2, column 5, the intersectoral status of Canada's principal wheat producers, Manitoba, Saskatchewan, and Alberta has improved by a factor of 1.5 over the per capita ratios in column 1. Incomes of farm families are now close to par in Ontario and actually exceed urban levels in British Columbia.

The second set of refinements addresses the tendency to delay consumption of current income for purposes of building up equity. It is well-known that capital deepening is particularly prevalent among self-employed farmers, and that the nature of tax reporting and allowances in agriculture is particularly conducive to such behavior (Shaw 1977). As a result, reported pecuniary returns to farm labor and capital may be biased downwards disproportionately.

A crude way of incorporating this consideration is to estimate a combined stock and flow of average yearly income for both farm and urban families. The stock consists of a yearly annuity (A) on net wealth (NW). In the case of farm families, then, the combined stock and flow (FY^*) can be estimated as follows:

$$FY^* = Y_{nf}^{o} + Y_{nf}^{m} + A, \tag{1.1}$$

$$A = NW\{r/[1 - (1 - r)^{-n}]\},\ n = e_x^{o} - a, \tag{1.2}$$

$$NW = K - D, \tag{1.3}$$

where Y_{nf} is nonfarm income, o is operator, m is family members, K is total value of farm capital, e_x^{o} is age-specific life expectancy of the family head. K includes land, buildings, machinery, and livestock. Average rates of return on capital in agriculture and manufacturing (r) were derived from Jenkins. Life expectancy and age data were obtained from Statistics Canada (1974). Net wealth (NW) was derived using average farm debt specific to province, obtained in Bank of Canada and Rust and elaborated in Shaw (1977).

To avoid double counting returns to farm capital value, income from farming is not included in equation (1.1) (Weisbrod and Hansen, Carlin and Reinsel). For urban families, NW corresponds to the total asset holdings of the family (K) minus average family debt (D)—asset and debt profiles for urban families were obtained from Statistics Canada (1973b). The flow of family income corresponds to average non-self-employment income of all family members.

Assuming that household welfare can be represented as a function of expected total lifetime resources, the annuity on lifetime resources in FY^* and UY^* represents a behavioral definition of current economic welfare. As long as expected income in all future periods equals current income, then the value of FY^* and UY^* will serve as an accurate estimator of this annuity. Admittedly, these measures may understate (*a*) the current welfare of households whose incomes are expected to rise, and (*b*) the relative welfare of households employed in sectors with higher levels of on-the-job training and greater experience premiums. Further, FY^* and UY^* might understate the welfare of younger

[1] Gross estimates of "income in kind" to farmers are provided for Canada and the provinces in Statistics Canada (1973c, p. 6). These figures have been divided by the respective number of farm households to estimate average figures on a family basis. As for urban families, Statistics Canada (1976, p. 278) estimates a value for "gross imputed rent" of owner-occupied dwellings, but this is published for all families at the national level only. Statistics Canada has supplied me with their estimation procedure towards deriving figures specific to urban areas at the provincial level. Essentially, Statistics Canada multiplies the average yearly rent of urban rented dwellings by the number of urban owner-occupied dwellings (adjusted for space) and divides the product by the total number of urban dwellings. Data for this exercise were obtained from Statistics Canada (1975).

households relative to that of older households to the extent that age-earnings profiles would tend toward convexivity. Herein lies the crudeness of our measures. At best, we can assume that these problems will tend to cancel one another out as we are interested primarily in ratios of average FY^*/UY^*.

Our adjustment for equity holdings among farm and urban families results in a FY^*/UY^* ratio near parity (table 1, row 7). Table 2, column 6, reveals that Ontario and British Columbia are considerably in excess of parity. Only in Quebec is the relative income situation discernably in favor of Quebec's urban sector. Two of the ratios in table 2, column 6 are grouped, as asset and debt data for the calculation of UY^* were limited to four regions only (Ontario, British Columbia, Atlantic provinces, and the prairies).

If we also acknowledge that both farm and nonfarm incomes vary considerably between Canadian provinces, then disparities in provincial FY^* are more evident. Table 2, column 7 suggests that Newfoundland, Prince Edward Island, and New Brunswick are on the low end of the "standardized scale" whereas Ontario, British Columbia, and Alberta are in excess of parity.

Our final set of refinements concerns the rising trend of off-farm work in North American agriculture. In many respects this trend is a blessing in North America's rural/urban adjustment process, as it serves to relax the dilemma of "forced" occupational and residential relocation in instances where returns to farming per se are inadequate (Shaw 1979c). As such, we propose that it is working to boost systematically the relative income situation of an increasingly large share of Canadian farm families (more on this later).

Major or largest source of income during the year is used to gauge the influence of off-farm work on the relative income situation of farm versus urban families. Census-classified farm families are disaggregated into two principal subgroups. Those with "farm self-employment income" as their major source constitute 43.9% of Canadian census farm families. Those with "wage and salary income" as their major source constitute 41.2%. While this split may seem to imply that bonafide farm families fall into the former group, it is important to note that such a conclusion does not emerge when farm enterprise characteristics of the two groups are compared (Shaw 1979a chap. 4).

Clearly, table 1, rows 8–9, reveals that farm families in the wage and salary group are considerably better off than those in the farm self-employment group. In fact, the provincial comparisions in table 2, column 9 reveal that farm families with wages and salaries as their major source of income are better off than their urban counterparts in Ontario and British Columbia. A similar impression emerges when our stock and flow measure (FY^*) is derived specific to each subgroup. This calculation is made at the national level only (table 1, rows 10–11). In deriving these measures, we found that the annuity on net wealth of the "farm" group was about 1.5 times that of the "wage and salary group." However, the off-farm income differential between the two groups, $Y_{nf}^{o} + Y_{nf}^{m}$ in equation (1.1), is such that FY^* of the wage and salary group outshines that of the farm group by almost $4,000. It is a full 11% larger than for urban families (UY^*).

Summing up, the various comparisons above stand in sharp contrast to the popular belief that problems of low or inadequate incomes go hand in hand with rural farm living. In many respects, they give credence to the old suspicion that "farmers seem to live poor, die rich" by showing that the average relative income and equity situation of Canadian farm families appears to be close to parity, especially among those with access to off-farm employment opportunities. While these findings are clearly relevant to equity goals in Canada, let us focus specifically on the outstanding contribution of off-farm work in view of its relevance to the two most recurrent policy concerns in Canadian agriculture—"to help low income farm families make a better living" and "to protect farmers against income instability."

Focus on Off-Farm Work

From a historical perspective, there can be little doubt that the improvement in the relative income situation of North American farm families is, in part, attributable to the increased prevalence of off-farm work (Bollman, Gunn, Schuh, Schultz). Between 1940–70, the author found that the contribution of off-farm wages and salaries to total farm family incomes in Canada increased from approximately 12% to 59%. During the same period, the ratio of total farm family income to urban family income (adjusted for income in kind) increased from approximately .57–.76. Corresponding figures for the United States between 1949–69 are 29–52% and .60–.77, respectively (Shaw 1979c).

The impact of off-farm earnings on the distribution of total employment income in Canada has been such that without it, the proportion of "self-employed farm operators" in the "poverty" category would be about 1.5 times its present size (Shaw 1979a, p. 129). Almost identical results were reported for the United States by Larson.

We already have shown that families reporting wages and salaries as their major source of income have considerably higher average incomes than those largely reliant on self-employment farming. In most cases, heads of families in the former category are part-time farmers and multiple jobholders. These farm operators tend to work a large part of their work-year off the farm at occupations requiring nonfarm skills. In Canada, they accounted for almost 30% of Canada's 365,000 farm operators in 1970. They worked, on average, 150 days off their farms as construction workers (24%), in transport (17%), in machine product fabrication (17%), sales

(10%), processing (9%), clerical (6%), as managers, administrators, and teachers (8%), and in other primary jobs (9%).

While part-time farmers and multiple jobholders often own relatively small-scale farms, it is not always appropriate to assume that these farms go hand in hand with marginal farming or that multiple job holding represents an initial stage of farm abandonment. Rather, off-farm work, and especially multiple job holding, represents an important source of revenue for capital deepening and reduces vulnerability of farm families to wide swings in farm prices and net farm income. It is also an important means by which returns to education, and, therefore, total employment income, can be augmented (Shaw 1979b).

Toward evaluating the relationship between off-farm work and income disparities more rigorously, we regress "% of part-time farmers" (*P*) in each of 252 census divisions (*CD*'s) on three income measures. These are (*a*) the ratio of average cash income of farm families to urban families in each *CD* (*FFY/UFY*), (*b*) the proportion of farm families below Canada's "low level income cut-offs" (*% POOR*), and (*c*) gini coefficients of concentration (*G*) for farm families per se. As a check on our representation of part-time farmers and multiple job holding, we also have regressed the three income measures against "average number of days worked off-farm" (*D*) by census farm operators/family heads in the *CD*.

In each regression, value of farm capital (*K*) has been included as a control variable. Farm capital value (*K*) is known to be positively correlated with almost all farm magnitude variables, net farm income, etc. Its place in explaining variations in each of the three income measures is relatively straightforward; an increase in *K* will result in an increase in *FFY/UFY*, a decline in *%POOR*, and an increase in the gini coefficient of concentration (*G*). That is, higher *K* will positively influence net farm income and, therefore, *FFY*. The higher the value of *K*, net farm income, and *FFY*, the smaller the proportion of farm families with incomes below the poverty lines. In contrast, as capital continues to be distributed unequally among Canadian farm families and as this inequality perpetuates income inequality, *K* is hypothesized to be positively related to *G*.

We also include a dummy variable (*DUM*) to represent proximity to large urban labor markets. *DUM* has been represented as 2 if the census division includes, or is adjacent to, a census division with an urban center of 25,000+ inhabitants (1, otherwise). Unfortunately, this variable does not have an unambiguous interpretation. For example, it tends to represent greater opportunities for off-farm work per se, and thus tends to be multicollinear with the effect of *P* on *FFY*. Our principal interest in *DUM* is to control for the possibility that jobs located in closer proximity to urban centers offer higher rates of remuneration. Thus, while multiple jobholding may have a positive effect on *FFY* via days worked off-farm, location of the job in close proximity to an urban area may add an additional wage effect.

Results, summarized in table 3, convey the following: (*a*) According to equations (1)–(3), prevalence of part-time farming or multiple job holding (*P*) boosts the ratio of farm family to urban family income, reduces the proportion of farm families below Canada's poverty line (*% POOR*), and reduces inequalities in the distribution of income

			(.0200)	(.0018)	(1.22)		
			(13.30)	(7.86)	(5.13)		
6.	*G*	.4668	−.00084 *D*	+.000047 *K*	−.00954 *DUM*	.210	23.33
			(.00012)	(.000011)	(.00673)		
			(7.00)	(4.26)	(1.42)		

[a] *FFY/UFY* is average farm family total income per census division divided by the average urban family income of the same census division; *% POOR* is percentage of families in the census division with per capita family income less than the provincial "low level income cut-offs"; *G* is gini coefficient of concentration.

among farm families. Similar results are found in equations (4)–(6), where (P) is replaced by days of off-farm work (D).

(b) Higher levels of farm capital value also contribute to a higher ratio of farm family to urban family incomes, and is related negatively to the incidence of poverty. However, in contrast to the distributional benefits of part-time farming or multiple job holding, higher values of farm capital (K) contribute to inequalities.

(c) In equations (1) and (2), proximity to urban areas (DUM) has a significant positive effect on the farm to urban family income ratio, and is negatively associated with the incidence of "poverty." While this variable does not have an unambiguous interpretation, as noted above, it suggests that off-farm work is not equally available across geographical units, and/or that the off-farm opportunity wage differs between regions also.

(d) Of the three variables considered, part-time farming (P) or days of off-farm work (D) are most significantly related to improvements in the various income measures. While neither R^2 values, nor point elasticities are large, i.e., elasticities of about .4 to .6 for P in equations (1)–(3), they are extremely significant in view of (i) the slow pace of improvement in measures of farm family income over the last few decades (especially income inequalities), (ii) the fact that point elasticities for P exceed those of farm capital value, and (iii) the fact that part-time farming or multiple jobholding, which represents an important structural adjustment to changing conditions in Canadian agriculture, has gone largely unaided policywise.

Conclusion

Previous to the 1971 agriculture-population linkage, farm families just about everywhere appeared to be in need of some kind of income assistance. This impression certainly hampered effectiveness of Canada's Small Farm Development Program because the extent and whereabouts of poverty among family units was virtually impossible to measure (Shaw 1979a). In view of the findings here, however, farm families in some provinces are better off, on average, than their urban counterparts. This is certainly relevant to rethinking geographical targets for Canadian income policy, particularly as it applies to transfer payments and income supplements to farm families in Ontario and British Columbia versus, say, Manitoba and Quebec.

The fact that a large and growing share of farm families have access to off-farm employment which works to boost family incomes and accumulated wealth also is clearly relevant to rethinking population targets for income policy. Our estimates suggest that those in the "part-time" farm subgroup are considerably better off, on average, than their "full-time" counterparts. While both groups may be bonafide farmers, presence of off-farm income earning opportunities among the former group certainly will cushion inadequate farm incomes during difficult times and could be used to screen recipients of grants-in-aid.

With respect to boosting incomes of full-time farmers or reducing disparities in the distribution of income, policies designed to increase access to off-farm employment are clearly relevant. Indeed, our findings marry well with those of numerous surveys that have revealed that off-farm work is an important and growing contributor to farm family income at various stages of development. For example, off-farm work is prevalent among 47% of U.S. farm families, 72% in Japan, 59% in Poland, 40% in Taiwan, 25% in Korea, 30% in Lebanon, 30% in Algeria, and 50% in Kenya (Benachenon, Huffman, Kenya Central Bureau of Statistics, Larsen and Hu, Szenberg). The concentration of off-farm work and multiple jobholding among small-scale farms in the United States, Algeria, Malawi, and Central Java is particularly important as it has been shown to have an important bearing on equalizing the distribution of employment earnings (Benachenon, Chipeta, Soejono).

Finally, off-farm work is clearly relevant to problems of income instability. It tends to reduce vulnerability of farmers to wide swings in farm prices and net farm income, and aids beginners or small-scale farmers by providing a more even income flow for capital deepening or debt servicing. While rural development policy in Canada has sought to encourage alternative employment opportunities in rural areas, it is also true that off-farm work and multiple job holding per se have gone largely neglected by Canadian policy makers.

Area and Yield Response to Price Policy: A Case Study in Guatemala, C.A.

Carlos Pomareda and Otto Samayoa

The responsiveness of farmers to changes in the price of a particular product are dictated by many conditions, which include resource endowments—especially land and family labor—choice of crops and techniques, off-farm employment possibilities, relative product prices, and the presence of uncertainty in returns and the farmers' attitudes toward risk. In trying to measure the price responsiveness of farmers, alternative methods have been used. The advantages and disadvantages of such methods for estimating supply functions, i.e., linear programming (LP) models, production functions, and econometric analysis of time-series and cross-section data, have been widely discussed since the pioneering work of Nerlove and Bachman. More recently, Shumway and Chang highlighted the advantages of LP versus alternative methods. The limitations of LP models, however, related their capacity to reflect the actual situation because of misspecification of the farmers' goals, the stepped nature of the production possibilities, or resource constraints. The majority of cases have used fixed supply of inputs, hence implying the short run. If these problems are overcome, LP can be an effective tool for simulating the actual behavior of farmers.

Numerous studies of agriculture in developing countries have shown varied and contrasting evidence of the supply responsiveness of traditional farmers (see Askari and Cummings). Most of these studies, based either in positivistic analysis or in normative models, concentrate on measures of output elasticities, with limited discussion of the area and yield changes. The majority of econometric models use the adaptive expectations Nerlovian approach, in which only area planted is a function of expected prices. It is recognized that, under such specification, the analysis underestimates the actual responsiveness to price (Houck and Gallagher). A few of these studies, however, have explicitly included area and yield responsiveness to product prices (Tweeten and Quance, Herdt). However in programming models used to estimate supply responsiveness, no explicit reference is made to results which show the two components of output elasticity.

A regional linear programming model was implemented for the south Pacific region of Guatemala. The model incorporates the most important actual constraints and takes into account farmers attitudes as risk-averter individuals. Basic results for the model were comparable to the situation observed, as far as levels of resource use, areas planted, and production levels. A complete description of the model can be found in the work of Pomareda and Samayoa. The model builds on two types of substitution: (*a*) each crop can be produced in several ways, i.e., various points in the production function, and (*b*) crops compete for scarce resources. Therefore, any increase in price of a particular product will result in increases in production derived from increases in yield in area planted at the expense of other crops.

Economic Rationale and Model Overview

The basic model specifies that for the ith crop:

$$Q_i = f(Y_i, A_i), \tag{1}$$

$$Y_i = g(P_i/P, C, W, T_{is}), \tag{2}$$

$$A_i = h(P_i/P_j, C), \tag{3}$$

where, for the crop, Q_i is total production, Y_i is yield per unit of area, A_i is area planted, P_i is the expected price, P is an aggregate of expected prices for other products, W is a factor that takes into account weather and other elements that make yields stochastic, T_{is} is the technology s for production of crop i, and C is an aggregate of input prices.

For risk-averse farmers, the model can be formulated in linear programming form as

$$\text{Max} \sum_i P_i Q_i - \sum_i \sum_k \sum_s C_k b_{iks} - \Phi V^{1/2}, \tag{4}$$

$$\text{subject to, } b_{iks} \leq \mathbf{B}_k, \tag{5}$$

where, in addition to the terms already defined, C_k is the price of the kth resource; b_{iks} is the amount used of the kth resource by the ith crop; $\mathbf{B}_k$ is a vector of resource constraints; V is a variance-covariance matrix of gross returns, which accounts

Carlos Pomareda and Otto Samayoa are agricultural economists with the Center for Studies in Central American Integration and Development (ECID) of the General Secretariat of Central American Economic Integration (SIECA).

The views here expressed are those of the authors and they should not be ascribed to SIECA. The authors acknowledge comments by Jerry Carlson, Enrique Delgado, Roger Norton, James Seagraves, and two anonymous reviewers.

for the risk implicit in the uncertainty in yields and prices; and Φ is a subjective constant risk-aversion parameter, which reflects the attitudes of farmers towards risk.

The model incorporates two types of farms prevailing in the region, large commercial and small traditional. The first is dedicated to basic grains and to export crops, i.e., cotton, sugar cane, and coffee. The second group is dedicated to basic grains, i.e., maize, rice, and beans, sesame associated with maize, and beans associated with maize and cassava (yuca).

Techniques for production actually observed in the region were specified, implying that labor, machinery, and animal power are substitutes, and changes in their relative amounts imply movements along the same isoquant. Four possible combinations were chosen. The use of fertilizer, chemical inputs, and better cultural practices implies higher yields, hence shifts in the isoquants. Also, four possibilities of intensity of use in inputs were chosen. As a result, each crop could be produced in as many as sixteen possible ways on each type of farm. The choice of technique was made on the basis of the access to inputs; and the adoption of a particular technique by each type of farmer implies changes in yields because of differences in managerial capacity.

Requirements of land, labor, animal power, and machinery are specified on a monthly basis and their supply is assumed fixed. Requirements of fertilizers, chemicals, and other inputs are specified on an annual basis and their supply is assumed perfectly elastic. Credit is required for the purchase of hired labor, machinery, fertilizers, chemicals, and other inputs; and the supply of credit is assumed perfectly elastic at the given market interest rate.

In the labor market, small farmers depend only on family labor, but they can also work on commercial farms. The latter depend on permanent residents, and when these are exhausted, they can hire small farmers and landless peasants within the region and migrant workers from the neighboring regions, particularly from the Highlands.[1]

Accounting for risk measures has been recognized in linear programming models of the agricultural sector. The model incorporates risk measures and risk aversion parameters as suggested by Hazell. The constant risk-aversion coefficient, Φ, reflects the farmers attitudes toward risk, and larger absolute values reflect more conservative attitudes. The model was solved at alternative levels of Φ for both groups of producers. Values of $\Phi_1 = 0.5$ and $\Phi_2 = 1.5$ for large commercial and small traditional producers, respectively, provided cropping plans that most accurately reflected the actual situation. These values of Φ are consistent with studies of the attitudes of producers by Moscardi and de Janvry and Dillon and Scandizzo; Pomareda and Simmons; and Hazell, Norton, Parthasarathy, and Pomareda. The importance of risk in determining the characteristics of supply response is discussed and empirically illustrated in the work of Hazell, Norton, Parthasarathy, and Pomareda.

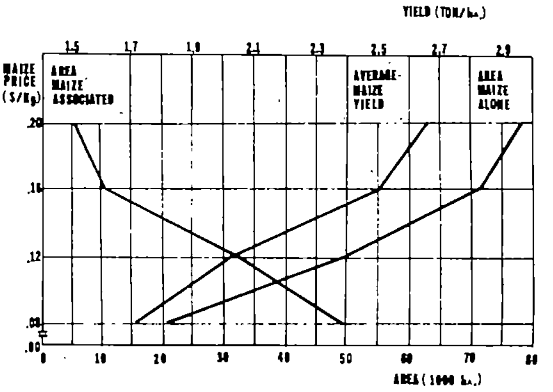

Figure 1. Maize area and yield response to prices in small farms

The Responsiveness to Price

At the given levels of resource use and risk parameters, the model reflected satisfactorily the behavior of farmers; areas planted, technology mix, crop yields, total production, resource use, and shadow prices fell close to the actually observed levels in the base period. The model was then used to measure the supply elasticity of maize and to evaluate the process of technique adoption and crop-to-crop substitution, in response to changes in maize price.[2] Prices of other crops, prices of inputs, and resource endowments were held at basic levels. Given the assumptions about the fixed supply of resources and the availability of technologies actually used by producers in the area, the situation analyzed reflects the short run.

Of particular interest was the nature of supply response in small farms. Table 1 shows the process of technique adoption by small farmers brought about by higher prices of maize. Higher prices motivate farmers to adopt more input-intensive higher-yielding techniques that are also riskier (see table 2) and farmers plant smaller areas of maize associated with other crops, which were initially chosen as a way to avoid risks. Incidentally, at prices higher than $0.12 per kilogram, the total area planted in maize (alone plus associated) remains constant, but there is substitution between maize associated with other crops, by maize alone, which

[1] Labor is particularly scarce in critical periods at planting, weeding, and harvesting during the crop season; yet there is significant unemployment during other periods of the year.

[2] In Central America, maize is the most important food crop. In Guatemala in 1970, maize provided 55% of the calories for the lower income, 85%, of the population; and maize used 734,700 hectares, representing 53% of the total area cultivated by annual and perennial crops excluding pastures (SIECA/FAO, 1974).

Table 1. Area, Production, and Yields, and the Process of Technique Adoption in Response to Maize Prices in Small Traditional Farms

Variables	Price of Maize ($/kg)[a] 0.08	0.12	0.16	0.20
Areas: (hectares)[b]				
*MAD*2	21,044	34,077	22,942	16,659

has a higher average yield. These facts are of particular interest in the measurement of direct and cross-price elasticities of supply, especially in developing an agriculture where many of the crops are grown associated, as a way to reduce risk.

Figure 1 illustrates the shape of the area and yield-response functions to price for small farms. Over the full price range simulated, the elasticities of supply measured at average price and quantity levels are +0.50, +1.336, and −1.89, for yield, area of maize alone, and area of maize associated, respectively. The resulting net output elasticity is +0.68. The elasticity of yield, not frequently measured in studies of supply response, is consistent with the results of Houck and Gallagher, who reported corn yield elasticities between 0.24 and 0.76, estimated with alternative econometric models. The region's aggregate maize output elasticity measured over the same range and at the average price and quantities, is 0.81. The large commercial farmers output elasticity is 0.96. The latter is only an area response, because yields remained constant at already high levels for the larger farmers.

The overall effect of price changes at the regional level is shown in table 3. Over the range simulated, expanded production of maize in small farms is at the expense of the production of sesame and beans. It must be recalled that sesame and beans are pro-

[d] Produced alone.

duced only in association with maize; but when the price of maize increases, these areas diminish and maize is grown alone, using more input-intensive techniques. In large farms, expanded maize production takes place at the expense of upland rice. Interestingly, the increase in maize production, using techniques more intensive in machinery and other purchased inputs, frees labor in small farms, and off-farm employment increases. Hence cotton, the most labor-intensive crop, grown only in large commercial farms, responds positively to the increases in the price of maize. Sugar cane and coffee do not show any definite positive or negative relationship. Coffee is grown on a different type of land and it is a permanent crop, and sugar cane is a five-year crop.

This paper has presented results of a linear programming model to determine the yield and area components of output elasticity. The approach was found to be of particular relevance in developing agriculture, where land and family labor are extremely scarce; hence, any increase in food production would have to take place through increases in yields, intensifying the use of inputs, such as fertilizers, improved seeds, and technology.

The Structure and Changes of Technology in Prewar Japanese Agriculture

Le Thanh Nghiep

The nature of technical progress of the Japanese agricultural sector has been discussed intensively; yet, the literature still does not give a satisfactory explanation consistent with important aspects of the experience. The purpose of this note is to develop an interpretation that is capable of explaining the technical progress of the Japanese agricultural sector and is consistent with present knowledge about Japanese economic history.

Regarding technical changes in the Japanese agricultural sector in the period 1900–40, the migration of labor from farming and the decrease in the prices of commercial fertilizers and other nonagricultural inputs are considered critical. The sustained high growth rate of labor productivity of the nonagricultural sector induced a continuous stream of off-farm migratory labor which was not totally offset by the growth in the labor force due to the natural increase of rural population. In addition, there was a tendency for the price of commercial fertilizers to decline as a result of the increase in fertilizer imports and of cost improvements in the domestic fertilizer industry. These changes in factor endowments and prices caused an intersectoral reallocation of resources resulting from factor substitution and technical changes.

It is hypothesized that the agricultural sector of Japan during the concerned period was locked into extremely narrow regions of factor substitution, and large parts of changes in the input levels of factors were due to biased technical changes. It also is hypothesized that biased technical changes were more or less induced by the changes in the relative prices of factors in directions that eased the restrictions imposed by resource endowments.[1] In what follows, an analytical framework will be set, based on which statistics then will be computed from Japan's 1903–38 data to test the above-stated hypotheses.

Le Thanh Nghiep is an agricultural economist at the International Development Center of Japan, Tokyo.

This paper is the result of research for the Rural Development Project undertaken at the International Development Center of Japan (IDCJ). The author is greatly indebted to Kazushi Ohkawa, Yujiro Hayami, and two anonymous reviewers for helpful comments.

[1] Hayami and Ruttan introduced this notion in agricultural analysis. However, the notion of technical progress, induced by relative prices of production factors, had been disputed previously by Hicks, Fellner, Ahmad, Kennedy, among others (see Ferguson).

Analytical Framework and Method of Estimation

The shapes of the isoquants at a given point of time and the over-time shifts of these curves present the essential aspects of the technology of an economy. The shapes of the isoquants, in turn, are characterized by the partial elasticities of substitution between factors. It is on this basis that the analytical framework to be employed was derived. Two categories of partial elasticities of substitution will be distinguished and estimated. One corresponds to the substitution possibilities for a given technology. The other one includes over-time changes of technology. In figure 1, a change in the input combination from A to B, corresponding to relative prices P_1 and P_2, can be analyzed in two ways. First, the

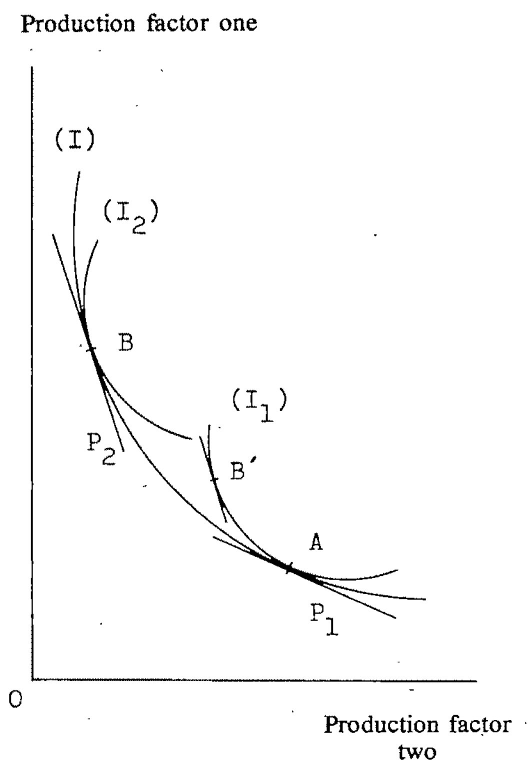

Figure 1. Resource allocation under the prevailing technology and through technical changes

change can be fragmented into a substitution effect presented by the movement from A to B' along isoquant I_1 and a biased effect of technical change from B' to B. By eliminating the effect of the technical change, one can obtain the partial elasticities of substitution for a given technology. Second, an isoquant like I can be interpreted as enveloping curves I_1 and I_2 from below and, thus, yielding the second concept of substitution elasticity.

Method of Estimation

A modified translog cost function approach was used in the analysis. The approach is a slight modification of that first applied by Binswanger. The modification is presented in some detail by Nghiep 1977. Corresponding to the two types of isoquant illustrated in figure 1, there exist the following two cost functions:

$$(1) \qquad C = F_1(P_1, P_2, \ldots, P_n, Y, T_e),$$

$$(2) \qquad C = F_2(P_1, P_2, \ldots, P_n, Y),$$

in which C is the minimizing cost; P_is, prices of n production factors; Y, output level; and T_e, a technical index.

The presence of the technical index in function (1) permits estimation of the partial elasticities of substitution of the first type and specification of the nature of technical bias. Equation (2) corresponds to the meta-production function (Hayami and Ruttan). As technical changes generally consist of price-induced and nonprice components, there should be three different effects associated with the prices and technical index in equations (1) and (2): a price-induced technical bias, a nonprice-induced technical bias, and a substitution effect. In equation (1) the price variables identify the substitution effect, and the technical index captures both price-induced and nonprice-induced technical biases. On the other hand, the price variables in equation (2) are expected to remove the substitution effect and price-induced technical biases.

A direct application of Shephard's lemma, equalizing the first derivative of the cost function with respect to the price of a factor to its input level, leads to a group of regression equations from which demand elasticities, partial elasticities of substitution, and their standard deviations can be calculated (Binswanger, Berndt and Wood, Halvorson). However, there is little assurance that this equilibrium condition holds in the short run. In the present paper, Shephard's lemma is assumed to hold at the long-run equilibrium level of input to which its observed level is related by a distributed lag scheme (Nerlove). As a result, the estimation is made rather complicated and the variances of the estimates of the required elasticities cannot be directly calculated.

The cost function is defined as

$$(3) \ \ln C = \nu_o + \nu_y \ln Y + \nu_t \ln T + \sum_{i=1}^{n} \nu_i \ln P_i + \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} \gamma_{ij} \ln P_i \ln P_j + \sum_{i=1}^{n} \gamma_{iy} \ln P_i \ln Y + \sum_{i=1}^{n} \gamma_{it} \ln P_i \ln T + \gamma_{yt} \ln Y \ln T,$$

where $\gamma_{ij} = \gamma_{ji}$ (the symmetry constraint), and $\sum_i \nu_i = 1$, $\sum_i \gamma_{ij} = 0$, $\sum_i \gamma_{iy} = 0$, and $\sum_i \gamma_{it} = 0$ (linear homogeneity in input prices). The time variable T is used as a proxy for the technical index.

By assuming that the corresponding production function is homothetic, so that $\gamma_{iy} = 0$, and using Shephard's lemma, the following equations are obtained:

$$(4) \ \frac{\partial \ln C}{\partial \ln P_i} = \frac{\partial C}{\partial P_i}\frac{P_i}{C} = X^*_i \frac{P_i}{C} = S^*_i = \nu_i + \sum_{j=1}^{n} \gamma_{ij} \ln P_j + \gamma_{it} \ln T,$$

for $i = 1, 2, \ldots, n$ and where X^*_i and S^*_i indicate the desired levels of input and cost share of factor i. The S^*_i's are defined by

$$(5) \qquad (S_{it} - S_{it-1}) = \alpha_i (S^*_{it} - S_{it-1}).$$

In the equations, S_{it} stands for the real share of factor i at time point t. Because the real or desired shares of all factors sum up to 1, equation (5) implies[2]

$$(6) \qquad \alpha_i = \alpha.$$

The following system of regression equations is thus obtained:

$$(7) \ S_{it} = \alpha\nu_i + \sum_j \alpha\gamma_{ij} \ln P_j + \alpha\gamma_{it} \ln T + (1 - \alpha) S_{it-1},$$

with constraints,

---

[2] Summing each term in (5) over n variables,

$$0 = \sum_{i=1}^{n} \alpha_i S^*_{it} - \sum_{i=1}^{n} \alpha_i S_{it-1}.$$

Since $\quad S^*_{nt} = 1 - \sum_{i=1}^{n-1} S^*_{it}$ and $S_{nt-1} = 1 - \sum_{i=1}^{n-1} S_{it-1},$

$$0 = \sum_{i=1}^{n-1} (\alpha_i - \alpha_n)(S^*_{it} - S_{it-1}).$$

This identity would always hold if

$$(\alpha_i - \alpha_n) = 0, \text{ or } \alpha_i = \alpha_n = \alpha.$$

$$(8)\ \gamma_{ij} = \gamma_{ji},\quad \sum_i \gamma_{ij} = 0,\quad \sum_i \nu_i = 1,\quad \sum_i \gamma_{it} = 0,$$

where $i, j = 1, 2, \ldots, 4$ are the indices for the factors of production and $t = 1, \ldots, 35$ denotes the time periods. The partial elasticities of substitution are computed as

$$(9)\qquad \sigma_{ij} = \frac{\gamma_{ij}}{S^*_i S^*_j} + 1, \text{ and}$$

$$(10)\qquad \sigma_{ii} = \frac{1}{S^*_i}(\gamma_{ii} + S^{*2}_i - S^*_i).$$

Technical biases will be factor i using, neutral, or saving, according to the sign—plus, zero, or minus—of the coefficient γ_{it}. The restricted generalized least squares method (GLS) of regression (Theil) was applied to compute $\alpha\nu_i$'s, $\alpha\gamma_{ij}$'s, $\alpha\gamma_{it}$'s, and α, and the associated var-covariance matrix. Then the elasticities of substitution σ_{ij}'s and their confidence limits were calculated from these estimates (Nghiep 1977).

Data

The estimation of the differential equations derived from the cost functions presented in the last section requires observations of prices and cost shares of factors. To obtain factor shares, in addition to prices, the quantities of inputs also are needed. The data about factor shares and prices used in the present paper are shown in table 1.

Production factors are classified into five categories: labor, land, fertilizer, machinery, and others. The other factors include nonfertilizer current capital and nonmachinery-fixed capital. The data for prices and quantities, except that for labor quantity, are based on long-term economic statistics (Ohkawa, Shinohara, Umemura). The figures used for labor input are from the revised series of Yamada and Hayami, constructed from Umemura's revised series of total gainful workers employed in agriculture and forestry. Rent is taken as the price of land, and the machinery expenditure is represented by the total depreciated value of power machinery, tools, and implements. Other fixed capital expenditures included in the category of other factors are represented by their depreciated values. The wage rate of yearly contract workers is used as the price of labor.

The price indices indicate that wage was the most rapidly rising price in the period 1903–38. After wage, prices of land, machinery, and "other" rose most dramatically. Fertilizer price increased least during the period. On the basis of induced technical changes, it is expected that technical biases would be of the inverse order. That is, if γ_{LAB}, γ_{LAN}, γ_{FER}, γ_{MAC}, and γ_{OTH} stand for the technical coefficients of labor, land, fertilizer, machinery, and other factor, respectively, the inequalities $\gamma_{LAB} < \gamma_{LAN} < \gamma_{OTH} < \gamma_{MAC} < \gamma_{FER}$ must hold.

Estimation Results

Because the items included under the "other" category are rather heterogenous from nonfertilizer current inputs to nonmachinery fixed capital, characteristics of the elasticities of substitution related to this factor will not be discussed. The estimated partial elasticities of substitution and technical biases of labor, land, fertilizer, and machinery will be examined.

Estimates are presented in table 2. The partial elasticities of substitution are shown in table 3. The GLS coefficients for the four share equations, including the time variable, are rather high: .79 for labor, .96 for land, .80 for fertilizer, and .93 for machinery. The coefficients for the equations not including the time variable are .58, .96, .40, and .96 for labor, land, fertilizer, and machinery, respectively.

Technical Biases

The figures in table 2 show, on an annual basis over the period 1903–38, a decrease of .48% in labor share, an increase of 1.3% in fertilizer share, an increase of .25% in machinery share, and an increase of .24% in the share of factors included in the other category. These technical biases correspond

Table 1. Factor Shares and Indices of Factor Prices

	Labor		Land		Fertilizer		Machinery		Other	
Year	Price	Share	Price	Share	Price	Share	Price	Share	Price	Share
		(%)		(%)		(%)		(%)		(%)
1905	100	48.5	100	28.9	100	4.0	100	4.1	100	14.5
1910	117	48.7	114	29.5	84	5.3	97	3.8	98	12.7
1915	133	46.0	120	28.7	93	6.6	129	5.4	103	13.3
1920	329	49.2	261	27.5	158	6.6	207	3.7	228	13.0
1925	376	51.7	238	25.3	127	6.7	141	3.4	209	12.9
1930	279	52.8	157	23.1	83	6.9	132	4.3	153	12.9
1935	240	45.0	177	27.4	82	8.2	149	4.9	155	14.5

Note: All figures are five-year averages centering on the years shown.

Table 2. Restricted Coefficients of Translog Cost Functions

	Price of Labor	Price of Land	Price of Fertilizer	Machinery Price	Price of Other	Year	Lagged Variable
Time variable included:							
Share of labor	.1746	−.1060	−.0194	−.0135	−.0356	−.0355	.1544
	(.0168)[a]	(.0088)	(.0068)	(.0024)	(.0137)[b]	(.0052)	(.0366)
Share of land		.1937	−.0144	−.0180	−.0552	.0001	.1544
		(.0109)	(.0060)	(.0023)	(.0129)	(.0026)	(.0366)
Share of fertility			.0295	−.0108	.0152	.0230	.1544
			(.0063)	(.0023)	(.0092)	(.0025)	(.0366)
Share of machinery				.0411	−.0096	.0032	.1544
				(.0022)	(.0036)	(.0007)	(.0366)
Share of other					.0852	.0092	.1544
					(.0196)[b]	(.0039)	(.0366)
Time variable not included:							
Share of labor	.0995	−.0991	.0254	−.0054	−.0204		.2195
	(.0115)	(.0074)	(.0067)	(.0022)	(.0103)		(.0383)
Share of land		.1874	−.0119	−.0185	−.0577		.2195
		(.0107)	(.0054)	(.0024)	(.0131)		(.0383)
Share of fertilizer			−.0006	−.0128	−.0001		.2195
			(.0056)	(.0021)	(.0103)		(.0383)
Share of machinery				.0382	−.0013		.2195
				(.0019)	(.0040)		(.0383)
Share of other					.0911		.2195
					(.0218)		(.0383)

[a] The figures in parentheses are standard errors.
[b] The standard errors in the column "price of other" and that of the time coefficient in the line "share of other" were computed from the var-covariance matrix of other coefficients and the imposed restrictions: $\sum_i \gamma_{ij} = 0$ and $\sum_i \gamma_{it} = 0$.

to expected changes in factor prices and, thus, support the hypothesis that technical changes in the period resulted from private and public efforts to ease resource constraints.

Partial Elasticities

All partial elasticities of substitution, except those of the fertilizer-machinery pair, corresponding to

Table 3. Estimates of Partial Elasticities of Substitution

	Land	Fertilizer	Machinery	Other
Time variable included:				
Labor	.061	.230	.215	.357
	(−.099, .222)	(−.336, .783)	(−.042, .483)	(−.158, .865)
Land		−.029	−.859	−.787
		(−.947, .845)	(−1.424, −.339)	(−1.711, .084)

	(−.115, .190)	(1.504, 2.647)	(.393, .943)	(.092, 1.116)
Land		.088	−1.083	−1.006
		(−.797, .938)	(−1.781, −.475)	(−1.969, −.066)
Fertilizer			−5.344	.990
			(−7.791, −3.208)	(−2.239, 4.238)
Machinery				.709
				(−1.192, 2.560)

Note: In parentheses are upper and lower limits of the 5% significance level.

the cost function including the time variable, have absolute values of less than 1. Moreover, at the 5% significance level most of these estimates appear not significantly nonzero. These figures, thus, support the hypothesis that prewar Japan's agricultural sector was characterized by an inflexible structure of technology.

Machinery appears to have been a substitute for labor and a complement to land. While the labor-machinery technical relationship is apparently plausible in every respect, the estimate for the land-machinery pair supports Hayami-Ruttan's view in favor of its complementarity and differs from Binswanger's result for the case of the United States. The negative elasticity of substitution computed for fertilizer-machinery pair indicates that these two factors are complements for each other.

The partial elasticities of substitution corresponding to the cost function not including the time variable incorporate both the substitution effect and the price-induced technical bias. Most relevant estimates are of similar signs and have larger absolute values when compared with those that include the time variable. The large absolute values for labor-fertilizer and labor-machinery pairs are especially noteworthy. They indicate that price-induced technical changes in the period 1903–38 did result in an enlargement of the substitutional regions, especially of those between the most scarce resource (labor) and the newly invented inputs that became cheap (fertilizer and machinery).

The positive elasticity of substitution for the labor-fertilizer pair requires careful consideration. Although fertilizer is commonly believed to be a complement to labor, the estimate appears quite consistent with the author's expectation. Self-supplied fertilizers which required farm labor for their production were extensively used in Japan until the 1900s. Consequently, as wages rose and labor became scarce, commercial fertilizers were substituted for self-supplied fertilizers, the price of which was increased by rising farm labor wages (Nghiep and Sakiura, Nghiep 1975). It is useful to notice that Hayami and Ruttan, although emphasizing the possible complementary relationship between labor and fertilizer, did find a similar result in their quantitative analysis of Japanese agriculture for the same period.

The direct price elasticities of demand, corresponding to the cost function that includes the time variables, are −.089 for labor, .114 for land, −.372 for fertilizer, .202 for machinery, and −.116 for the other factor. Because the elasticities for land and machinery are positive, it should be understood that the cost function is not well behaved and that the resulting elasticities of substitution must be viewed with caution. However, there are reasons to support these results. First, because the agricultural sector itself is treated as the production unit, the cost function is not necessarily well behaved. Second, farmers conceivably could utilize their labor force to develop new land and to produce farm implements in slack seasons when the prices of these items rose.

Substitution Effect and Technical Biases

From the results associated with equations (1) and (2), if for the cost share of factor i a_i, b_i, and c_i stand for the substitution effect, the price-induced technical bias, and the nonprice-induced technical bias, respectively, the following relationship holds:

$$a_i = \sum_j \gamma_{ij} d\ln P_j, \tag{11}$$

$$b_i + c_i = \gamma_{it} d\ln T, \text{ and} \tag{12}$$

$$a_i + b_i = \sum_j \gamma'_{ij} d\ln P_j, \tag{13}$$

where γ indicates coefficients of the cost function including the time variable, and γ' indicates coefficients of the cost function without the time variable.

Using equations (11) to (13) effects of substitution, price-induced technical changes, and nonprice-induced technical changes can be computed. In the above equations, the lagged variable has been omitted for simplification. To determine the long-run effects of these variables, two steps were required. First, separate short-run effects of price and time, and the lagged variable contribution were calculated. The sum of separate effects of the prices and time corresponds to the total short-run effect of these variables, while the sum of this total short-run effect and the contribution of the lagged variable can be regarded as their total long-run effect. The separate short-run effects of the prices and time were then weighted by the ratio of these two sums to calculate these variables' separate long-run effects.

The results of the computation of different effects on factor shares in the period 1903–38 are presented in table 4. The price-induced technical biases are especially prominent in the cost shares of labor and fertilizer and negligible in the cost shares of land and machinery. The signs and the absolute values of these biases support the hypothesis on price-induced technical changes. Effects of nonprice-induced technical changes are large in the labor, fertilizer, and machinery shares.

Labor-Saving versus Labor-Using

The common view is that Japanese agriculture has been characterized by a labor surplus well into the first decades of the twentieth century.[3] This belief served as the rationale for a labor-using bias of agricultural technology in the prewar period

[3] The date of the turning point is still disputed among supporters of the turning-point theory. For example, Ohkawa and Rosovsky, Ohkawa, and Minami have chosen somewhere around 1955, while Fei and Ranis suggested some year around 1917.

Table 4. Substitution Effects and Technical Biases in Factor Shares (1903–38)

	Predicted Changes in Factor Shares				Actual Changes in Factor Shares
		Technical Biases			
	Substitution Effects	Price-Induced	Nonprice-Induced	Total	
			(%)		
Labor	8.9	−7.8	−6.0	−4.9	−4.1
	(−217)	(190)	(146)	(119)	(100)
Land	−2.1	−0.1	0.1	−2.1	−2.3
	(91)	(4)	(−4)	(91)	(100)
Fertilizer	−3.4	5.6	3.8	6.0	6.0
	(−57)	(93)	(64)	(100)	(100)
Machinery	0.2	0.4	0.8	1.4	1.2
	(17)	(33)	(67)	(117)	(100)

Note: Inside the parentheses are percentages with actual changes in factor shares set equal to 100.

(Sawada and Shintani). Even among neoclassical economists there are some who—through comparison of resource endowments between Japan and such land-abundant countries like the United States, Canada, and Australia—conclude that technical changes in Japanese agriculture essentially were attempts to compensate for limited land (Hayami and Ruttan).

This paper hypothesizes and provides empirical evidence that technical changes in prewar Japanese agriculture were labor-saving. The hypothesis is based on an analysis of the dynamic aspects of Japanese resource endowments in the period studied. A static comparison between Japan's resource endowments and those of land-abundant countries might result in the conclusion that the technical structure of Japanese agriculture was relatively land-saving and/or labor-using. However, a dynamic comparison with focus on changes over time in factor prices should bring to light the fact that Japan's agricultural wage was increasing and, in this way, verify the labor-saving hypothesis.

Biochemical Technology and Mechanical Technology

The main conclusions related to fertilizer and machinery can be summarized by the following: (*a*) fertilizer was a substitute for labor in the long-run, (*b*) machinery was a substitute for labor and a complement to the land, (*c*) machinery and fertilizer were complements for each other.

The first point may be a result of the particular circumstances prevailing in prewar Japan. This outcome is a characteristic of an economy in which self-supplied fertilizer had been intensively employed in agricultural production before labor—the major input in producing self-supplied fertilizer—became scarce as the development process progressed.

The conclusions related to machinery-labor and machinery-land relationships are somewhat more general. The higher the wages compared to machinery prices, the more speedy the diffusion rate is a relationship that can be expected. One might also expect to find the same relationship between high machinery-labor ratio and large farm-size.

The terms biochemical technology and mechanical technology are often used as if they were technically exclusive of each other. The results in this paper do not support this clearcut division. The negative elasticity of substitution between these two factors is quite consistent with the fact that these two categories of technology exist side by side in most parts of the world.

Gross and Net Productivity: A Problem of Aggregation

Folke Dovring

Comprehensive productivity measures are sometimes regarded as superior to the more special ones such as labor productivity. In the words of Fabricant, "The best measure is one that compares output with the combined use of all resources" (p. 6). Rather than selecting one measure as "best" for all purposes, we should aim at understanding what the various measures mean and what analytical purposes they may serve.

The economic meaning of productivity measurement is a complex problem and will not be discussed here. Nor is it intended to repeat here the whole debate about index-number problems in productivity measurement. The focus is instead on a problem which has received relatively little attention; namely, how index numbers of productivity may be affected by the level of aggregation: a whole economy, major industry groups, individual industries, individual firms, or individual enterprises.

For this discussion, we will define gross and net productivity: gross productivity is the ratio of output over all inputs; net productivity is the ratio of value added over internal factors of production (land, labor, and capital internal to the industry or firm). The two concepts coincide when a whole national economy is analyzed. The two concepts generally differ more, the more disaggregated the analysis.

Net productivity has prevailed in most analyses to date. Gross productivity has begun to attract more attention in recent years (Christensen, Howe and Handy). The analytical purpose which gross productivity answers better than net productivity is that of assigning credit for productivity gains among the several factors which jointly generate these gains (Griliches, Pasinetti, Hulten).

A major problem with gross productivity is the fact that the apparent rate of productivity change is to some degree dependent on the level of aggregation chosen for analysis. The more disaggregated the treatment, the slower becomes the apparent rate of productivity change. This has been observed by Ruttan (1954, pp. 24–28; 1957, pp. 1570–74), Horring (pp. 46 ff.), and Dovring (p. 64). These previous observations will be restated in simple notation before an attempt is made to reconcile the results of gross and net productivity measurements.

For some schematic examples, let us first think of an industry (Industry 1) which for simplicity is treated as a closed system (no intermediate products are considered) and which may be disaggregated into two subindustries (Industry 1a and Industry 1b) which together comprise all the activity of Industry 1. Then, let gross productivity over some arbitrary time span increase by 10%. For Industry 1, we obtain

(1) $$110\ O_1/100\ I_1 = 110.$$

Suppose, further, that Industry 1a has half the outputs and inputs of Industry 1, maintaining the fictitious assumption of a closed system. For industry 1a the equation reads

(2) $$55\ O_{1a}/50\ I_{1a} = 110.$$

Industry 1b, which represents a later stage of production, absorbs the entire output of Industry 1a as input, along with its own internal factors of production, and turns out as its output the same final goods as Industry 1. We then obtain

(3) $$55\,O_{1a} + 55\,O_{1b}/55\,O_{1a} + 50\,I_{1b} = 110/105 = 104.76.$$

It now becomes obvious that rates of change in gross productivity are not comparable between units of analysis which represent different levels of aggregation (1b versus 1), or which absorb external inputs in their factor mixes in different proportion (1b versus 1a).

By contrast, net productivity changes are comparable irrespective of the level of aggregation. Netting out the factors absorbed from Industry 1a, we obtain for Industry 1b,

(4) $$55\ O_{1b}/50\ I_{1b} = 110.$$

How far gross productivity indexes differ from net indexes, and from each other, depends on several things, among which are the level of aggregation and the rate of productivity change. Level of aggregation may be represented by the ratio of value added to total output, or value-added ratio (*VAR*). The smaller this ratio, the lower the level of aggregation. The ratio is 100 at the highest level of aggregation; that is, the entire national economy, where all intermediate products are netted out and there are no "external" factors of production. The *VAR* is lower, the larger the "throughput" of external factors and can be quite low on highly specialized enterprises such as chicken farms and petroleum refineries. If Industry 1b had only 10% instead of 50% of value added in its gross output,

Folke Dovring is a professor of land economics at the University of Illinois-Urbana.

then its gross productivity index would be only 100.92.

Rate of change also affects the difference between gross and net productivity. If the index for Industry 1 were 200 instead of 110, then with 50% value added, Industry 1b would have an index of 133.33; with 10% value added, it would come to 105.26. Note that these cannot be aggregated even by exponential reckoning: 1.333 is less than the square root of 2, and 1.053 is less than the tenth root of 2. This will cause some minor difficulty with time series data, when the value-added ratio varies over time.

Different types of indices may not be directly comparable between themselves, yet they reflect in different ways the same reality. Work on aggregated-labor productivity in American agriculture (Dovring) showed that a long-run productivity trend from the early 1920s to the early 1960s reflected an acceleration factor of 3½% (of the rate of productivity change) per year, and that the same acceleration factor can be traced also in the otherwise widely differing indexes of both gross and net productivity.

This leads to the question how the differing rates of change in gross and net indexes may be reconciled. It appears that gross productivity indexes can be reduced to a comparable scale by translating them into net productivity indexes which are comparable in the sense that they can be aggregated into larger sectors, and into the whole economy, without difficulty. Provided the *VAR* is known, we can start from equations (3) and (4) above, where gross productivity (*GI*) was changed into net (*NI*) by removing the external factors from both sides of the expression. Consequently, external inputs can be computed as the difference between the gross index and the gross index multiplied by VAR, and the internal inputs as difference between all inputs and the external ones. We then write

$$\text{(5a)} \qquad \frac{GI \times VAR}{1-(GI - GI \times VAR)} = NI,$$

or in a simpler notation.

$$\text{(5b)} \qquad \frac{VAR}{\frac{1}{GI} - (1 - VAR)} = NI.$$

Applying this to the above treated case of Industry 1b with 50% *VAR*, we have

$$\text{(6)} \qquad \frac{.50}{\frac{1}{1.0476} - (1-.50)} = \frac{.50}{.45456} = 1.10,$$

which is the expected rate of net productivity change.

Such index differences sometimes have striking consequences. An extreme example is in the American poultry industries, where purchased feed dominates the inputs and value added is a small fraction of total turnover. In the 1950s and 1960s, these activities expanded vigorously and the relative prices of eggs and chicken meat fell sharply, yet gross productivity rose only slowly (Dovring, pp. 35 ff).

A large case in point is in gross productivity for American agriculture, as computed for the years 1940–57. According to Loomis and Barton (p. 1), in those years "agricultural productivity increased at an average annual rate of 1.6 percent, compared with 2.3 percent for the economy as a whole." In net productivity, agriculture comes out ahead of the national economy.

Use of gross productivity can thus lead to misjudgment of the performance of a sector. This points to the special roles the various productivity measurements can play. Gross productivity is necessary for analysis of the causation of productivity change but is misleading as to rate of change, unless the index is corrected in the way suggested above. Net productivity is comparable between sectors but leaves some uncertainty as to what it is we measure.

By the same criterion (of purpose of analysis), the single-factor productivity measures will have continuing roles to play in addressing distinct problems. They also have the advantage of being simpler and less beset with conceptual problems. Use of aggregated-labor productivity did elude most of the index-number problems and showed some economically meaningful relation to trends of relative output prices. Before 1973, the price of labor was the single most important issue for which productivity analysis could be undertaken. For the future, we have to count upon rising prices of energy—above all the capital costs of the energy industries—and so it will now be important to watch the energy-productivity performance of the food and fiber complex, which can be pursued by techniques similar to those of aggregated-labor productivity analysis.

A Spatial Model of Land Market Behavior

Leroy J. Hushak and Kazem Sadr

This paper presents results of an application of a transcendental function in the analysis of land market behavior. The assumption of featureless space in the Von Thunen model is dropped and characteristics of the space hypothesized to affect land prices are incorporated (Hushak 1977, Sadr). Results are presented for three different areas for which land transactions data have been collected. The availability of three separate data sets allows examination of alternative mathematical specifications across, as well as within, data sets. Based on pretest estimation criteria discussed by Wallace, the ability to cross-test alternative models on different data sets provides stronger criteria for model selection.

In log form, the transcendental relationship determining land prices over space is

$$(1)\ \text{Log}price = a_0 + a_1\ \text{Log}size + a_2\ Real\ Tax\ Rate + a_3 \frac{Taxable\ Building\ Value}{Total\ Taxable\ Value} \Sigma\, b_i x_i + e,$$

where price is price per acre, size is acres in the land parcel, real tax rate is the property tax rate multiplied by the ratio of taxable value to price, taxable building value/total taxable value is the control for buildings, the x_i's are other parcel characteristics, and e is the random disturbance. The coefficient a_1 is a price flexibility (the inverse of the price elasticity of demand) providing the estimated percentage of change in price per acre for a 1% change in parcel size. Its expected sign is negative and it must be less than one in absolute value (elastic) for total parcel price to increase with size.

The coefficients a_2, a_3, and b_i yield constant changes in the log of price per unit change in the variables, which approximate constant percentage changes for values of less than 10%.[1] These constant log changes result in greater arithmetic price changes as price increases. The coefficient a_2 is expected to be negative, while a_3 is expected to be positive and about 2%. Each one percentage point increase in taxable building value/total taxable value is accompanied by a one percentage point decline in taxable land value/total taxable value.

Factors x_i include measures of distances from urban centers, distances from transportation arteries, and land use activities.[2] The expected relationships for these variables are detailed elsewhere, in particular Hushak (1975), and are not repeated here.

The Transcendental Function

Most previous studies have used an arithmetic function, but with a number of modifications. Arithmetic functions tend to fit well in those studies using aggregate data, e.g., Hammill, Pasour (1973, 1975), and Schuh and Scharlach. However, several problems arise when arithmetic functions are fitted to microdata, e.g., Clonts, Downing, and Hushak (1975). First, the relationship between per unit price and parcel size is highly nonlinear. One reason is that the cost of subdividing land parcels is approximately constant, and this cost is spread over less area as parcel size declines. Hushak (1975) incorporated this nonlinear relationship by using the reciprocal of parcel size as a variable.

Second, an arithmetic function imposes an inconsistent relationship between property tax rates and per unit land prices. Conceptually, the expected impact of a unit change in the property tax rate is negative and proportional to land price. The arithmetic function imposes a constant change in per unit land price regardless of the price level. At best, an average impact for the sample can be estimated. The use of the log of the property tax rate by Pasour (1973) does not resolve this inconsistency. Lacanere used an exponential function, i.e., log price as the dependent variable, to obtain a consistent relationship, but retained the reciprocal of parcel size as an explanatory variable. Hepner, Lewis, and Muraco used a transcendental function, which sub-

[1] For larger changes, the constant change in log price using base e is converted to percentage of change by $(e^{b_i} - 1) \times 100$.

[2] Local government expenditures and topographical characteristics are two additional sets of variables which may affect land prices. For given property tax rates, local government expenditures are expected to be positively related to land prices (Tiebout). When included in two data sets, local government expenditure variables did not have expected signs or high t-ratios. Crude information on some topographical characteristics was obtained for part of one data set. When included, the coefficients of topographical variables had expected signs and significant t-ratios. These results are not presented here because they were available for only part of one data set and their inclusion had no effect on coefficients of included variables.

stitutes the log of parcel size for parcel size and its reciprocal in the exponential function.

The transcendental function also provides a consistent means of controlling for the contribution of buildings to land prices with taxable building value/total taxable value. The taxable values are the values applied to land and buildings for property tax purposes. Because most parcels in the data sets contain buildings, a means of controlling for the impact of these improvements on land prices is needed.

Theory does not provide a basis for preferring one function over the other with respect to the other factors, x_i. Downing found that reciprocals of distance variables yielded better fitting results than linear distance variables. In this study, the statistical consistency and significance of the estimated coefficients of the x_i in the transcendental function (1) are much greater than for either the arithmetic function or for an alternative transcendental function which used the logs of the distance variables.

Preliminary estimates of several alternative models were obtained. One alternative used price per acre times taxable land value/total taxable value as the dependent variable. This formulation, which provides an alternative specification to control for building values, gives similar results. In addition, estimates from subsamples of each data set were obtained. Under all alternative formulations, the estimated coefficients of the transcendental function are similar to the results presented. The results from alternative specifications are not similar within or across data sets.

Description of Study Areas and Data Sets

Two of the three Ohio study areas are metropolitan areas. Columbus had a metropolitan (SMSA) population of 916,228 in 1970, a 21% increase over 1960 population. The city of Columbus had a 1970 population of 540,025, an increase of 14.6% over 1960. Dayton had a metropolitan population of 850,266 in 1970, an increase of 17% from 1960, but the city of Dayton had a 7.4% population decrease from 1960 to 242,917 in 1970. The third area consists of five rural counties in southeast Ohio (SE Ohio): Athens, Gallia, Jackson, Meigs, and Vinton. The 1970 population of this area was 136,521, an increase of 0.7% over 1960. Population increased only in Athens County; the remaining four counties had declines. All counties have participated in the "population turnaround" since 1970 (Beale). The estimated five-county 1976 population was 141,400, a 3.6% increase over 1970 (Bureau of the Census).

Each data set is a stratified random sample of "arms-length," or open market, cash transactions. The Ohio Board of Tax Appeals separates all land transactions into usable and nonusable transactions. The usable group includes all transactions where the recorded price of the land parcel exchanged is expected to represent an unencumbered market price. Examples of nonusable transactions are exchanges between related individuals and sales to settle estates. All observations for this study came from the set of usable transactions, which are expected to be open market, cash transactions.

The Columbus and Dayton data sets were stratified on the basis of land area; the SE Ohio data set was selected by stratifying 50% of the sample on the basis of land area and 50% on the basis of population. The data sets were further stratified by use; nearly all transactions of agricultural and commercial property were obtained. The objective of these stratification procedures was to obtain a sufficient number of parcels by type and throughout the study areas for reliable statistical estimation. The samples are not representative of types of land transactions in the study areas.

Characteristics of the three data sets are presented in table 1. The Columbus and Dayton study areas included all townships with more than 50% of their land area within a 25-mile radius of the central business districts. For Columbus, all of Franklin County, in which Columbus is located, and parts of the six adjacent counties are included. Platted land parcels were excluded, but land parcels within the boundaries of Columbus and other incorporated cities and municipalities were included if unplatted.

For Dayton, all of Montgomery County, in which Dayton is located, and parts of the seven adjacent counties are included. Excluded were platted parcels and parcels within Dayton and other incorporated cities and municipalities (in contrast to Columbus). Also, special controls for the impact of Springfield were developed because Springfield is a relatively large urban center near Dayton. The SE Ohio data set includes parcels from all parts of the study area, platted and unplatted, within as well as outside of incorporated municipalities. There are an approximately equal number of observations for each of the five years.

The summary characteristics in table 1 are highly dependent on the structure of each data set. The high mean values of price per acre for commercial and residential transactions in the SE Ohio data set are due to the inclusion of central business district commercial transactions and platted residential transactions, both of which are improved and have relatively high building values. Taxable building value/total taxable value is highest for this data set. The real tax rate is similar (perhaps surprisingly) for the three data sets.

Results

In the estimation of equation (1) *log price* is the log of the total value of the transaction per acre; *log size* is the log of the acres in the land parcel; *use* is a set of two dummy variables with residential use as the control group—*commercial* = 1, land use is commercial, industrial, or multiple-unit dwelling, 0

otherwise; *agriculture* = 1, land use is agriculture, 0 otherwise. *Log size-comm* is log size multiplied by the qualitative variable, commercial; *log size-agr* is log size multiplied by the qualitative variable for agriculture; *real tax rate* is property tax rate multiplied by $\frac{\textit{total taxable value}}{\textit{total value of transaction}}$ (mills); *real tax-comm* is real tax rate multiplied by commercial; *real tax-agr* is real tax rate multiplied by agriculture; $\frac{\textit{taxable building value}}{\textit{total taxable value}}$ is the ratio of taxable building value to total taxable value; *distance urban center* is the direct line distance in miles from the nearest city hall or major shopping center (Columbus, Dayton); *location Springfield* = 1, land parcel located within fifteen road miles of Springfield, 0 otherwise (Dayton); *distance Springfield* is road distance from Springfield if location Springfield = 1, 0 otherwise (Dayton); *distance second city* is the direct line distance in miles from nearest city with population of more than 10,000 including urban center (Columbus, Dayton); *location* is a set of two dummy variables in the SE Ohio data set with land parcels located closer to the city of Gallipolis than to Athens or Jackson as the control group; *location Athens* = 1, land parcel is closer to Athens than to Gallipolis or Jackson, 0 otherwise; *location Jackson* = 1, land parcel is closer to Jackson than to Athens or Gallipolis, 0 otherwise; *distance Gallipolis* is the direct line distance in miles from Gallipolis if Gallipolis is nearest city, 0 otherwise (SE Ohio): *distance Athens* is the direct line distance in miles from Athens if location Athens is 1, 0 otherwise (SE Ohio); *distance Jackson* is the direct line distance in miles from Jackson if location Jackson is 1, 0 otherwise (SE Ohio); *distance municipality* is the direct line distance in miles from the nearest incorporated municipality of any size including cities; and *disturb-comm* is distance urban center multiplied by commercial (Columbus, Dayton). Continuing: *railroad* = 1, land located within 0.6 mile of a railroad for Columbus and Dayton or within one mile of a railroad for SE Ohio, 0 otherwise; *rail-comm* is railroad multiplied by commercial; *distance highway* is the road distance in miles from the nearest major highway (major city streets, state and U.S. highways, and interstate highways); *highway-comm* is distance highway multiplied by commercial (SE Ohio); *county* = 0, land parcel in central urban county, 1, land parcel not in central urban county (Columbus, Dayton). The variables *log size-comm, log size-agr, real tax-comm, real tax-agr, disturb-comm,* and *highway-comm* are introduced to allow differential responses of land prices by land use.

Estimates of equation (1) for each data set are presented in table 2. The *F*-ratio for each equation is highly significant. Each equation contains a large number of variables. In the present analysis, the potential increase in variance from the inclusion of extraneous variables appears less costly than the potential bias from false restrictions (Wallace, pp. 432–33).

The coefficients of log size are price flexibilities for changes in parcel size. For Columbus, the estimated price flexibilities are −0.638 for residential, −0.393 for commercial, and −0.176 for agricultural

parcels. All price flexibility coefficients are less than one in absolute value, implying price elasticities of demand for parcel size which are elastic. The relatively higher price flexibility coefficients for residential and commercial parcels in SE Ohio are partially explanable by the rough topography of the

region, with the result that a larger parcel is more likely to include land which is not usable unless significant costs are incurred.

The main difference in the real tax coefficients is the relatively high capitalization rate for residential parcels in SE Ohio of 7% as compared to 4.5% for Columbus and Dayton. This may be due to a relatively greater burden of the property tax on residential property in SE Ohio compared to Dayton and Columbus. Estimates based on subsamples of the SE Ohio data set indicate it is not caused by the inclusion of platted parcels. At the same time the estimated capitalization rates for commercial (5.1% to 5.6%) and agricultural (7.6% to 9.2%) parcels are of similar magnitude.

The coefficients of the use variables show that commercial and agricultural parcels in the Dayton area are priced higher relative to residential parcels than in Columbus or SE Ohio. While the Dayton and Columbus areas are similar in the extent of zoning ordinances, the use coefficients for Columbus are similar to those of SE Ohio which has very few zoning or other land use controls in force.

Land prices in all three areas respond to location variables. For Columbus and Dayton, land prices decline by about 4% for each additional mile from the urban center. Both urban cities are multicentered; Hepner, Lewis, and Muraco found similar results for Toledo. Large retail-industrial centers in the fringe areas of both Columbus and Dayton have stronger impacts on land prices than the central business districts. In both areas, distance from central business district is not significantly related to land prices. A multicentered concept is required. Land prices in both urban centers also respond to distance from smaller municipalities. In Dayton, cities of 10,000 or more population had a relatively stronger impact than smaller municipalities, while in Columbus smaller municipalities were relatively more important.

For SE Ohio, the urban center measures had to be structured differently because there is not a dominant urban center. Athens, with a 1970 population of about 24,000, is the largest center; Gallipolis and Jackson both have populations of less than 10,000. The coefficient of *location Athens* suggests that Athens is the strongest point of attraction in the five county area. Distances from Athens and Gallipolis both have negative and significant coefficients. While distance Jackson does not have a significant coefficient, this result may be due to Wellston, a city about three-fourths of the size of Jackson and only six miles from Jackson.[3] Distance from smaller municipalities did not affect land prices in this relatively rural region. However, coefficients of the two variables not shown in table 2 indicating whether land is located in a township or municipality relative to the three cities had high t-ratios and showed that land located in townships had the lowest price, followed by municipalities and the three cities.

The price of commercial parcels declines more rapidly with increasing distance from urban center than residential or agricultural parcels. In SE Ohio, where there are no urban centers, nearly all commercial parcels were in or near a municipality, and there are few major highways, a significant interaction between distance to highway and commercial parcels was found. Other variables were included in the SE Ohio data set to control for the inclusion of all types of land parcels and unique characteristics of the area. The coefficients of these variables generally conformed to conceptual expectations.

Conclusion

While there are differences in coefficients and differences in the general level of land prices across areas, the overall response of land prices to spatial characteristics with the transcendental model is remarkably similar across the three land market areas. The transcendental model provides relatively stable results, both within and across data sets. The two most critical specification issues are: (a) obtaining a consistent relationship between land price and the real tax rate and building value control variables which imply a nonarithmetic scaling of the price variable such as log price, and (b) allowing for nonlinear relationships with other variables, in particular parcel size. Arithmetic functions do not satisfy these conditions and result in different price response estimates, not only across data sets, but within data sets across alternative model specifications and subsamples of data.

[*Received April 1978; revision accepted May 1979.*]

[3] If Wellston has a larger impact on land prices than other incorporated municipalities, then the price of land parcels in or near Wellston but at some distance from Jackson will bias the coefficient of distance Jackson toward zero.

Accuracy of Least Squares Computer Programs: Another Reminder: Comment

J. C. Nash

In a recent issue of this *Journal*, Boehm, Menkhaus, and Penn present yet another warning concerning the accuracy of least squares programs. While their warning is valid and useful, the recommendations to users in the authors' conclusions are, at the very least, tedious. This is especially so when users have access to highly effective methods for coping with ill-conditioned data in least squares problems. This comment examines each of the recommendations of Boehm, Menkhaus, and Penn in the light of what can be done with a singular value decomposition algorithm, in particular demonstrating that this technique reveals collinearities and permits some assessment to be made of their seriousness. Statistical computing packages, for instance the TROLL system of the National Bureau of Economic Research, are beginning to incorporate such methods. While most packages do obtain reasonable answers to the least squares problems they attempt to solve, doubts can only be set aside if the computing techniques employed are able to reveal the structure of the problem. That such techniques are not more widely used is largely a matter of imperfect exchange of information between researchers in different disciplines, a fault which this note will try in part to correct.

In the following sections the recommendations of Boehm, Menkhaus, and Penn are reviewed. The difficulties which may be inherent in linear least squares problems are then outlined briefly in the light of principal components solution methods. The family of computational procedures based on the singular value decomposition of a matrix is recommended as a practical way to implement such methods, which provide valuable information about the numerical stability of the regression problem whether or not principal components estimators are desirable from a statistical point of view.

The fractional variation and explanation indices f_i and E_i presented below are, it is believed, novel. The rest of the material is a summary of ideas taken from several sources outside the literature commonly consulted by economists.

J. C. Nash is an economist with the Policy, Planning & Economics Branch, Agriculture Canada, Ottawa.

The author would like to acknowledge discussions with Z. Hassan and G. MacAulay pertinent to the preparation of this note. The development of equations (13) to (17) was suggested by the referee.

Recommendations

In summary, Boehm, Menkhaus, and Penn suggest (*a*) that least squares computer programs be tested by use of the Wampler problems generated by

$$(1)\qquad y_j = \sum_{i=0}^{5} j^i \quad \text{for} \quad j = 0, 1, \ldots, 20.$$

$$(2)\qquad y_j = \sum_{i=0}^{5} (0.1j)^i \quad \text{for} \quad j = 0, 1, \ldots, 20.$$

These polynomial least squares problems have no error term so should yield coefficients of 1 and $(0.1)^i$, respectively, for the powers of j when solved by least squares. It can be proved that power terms are linearly independent. Unfortunately, powers have the property of being "nearly dependent," which causes trouble in polynomial least squares. That is, due to the nature of floating-point arithmetic, it is unlikely that the computed regression matrix X defined by (1) or (2), whose elements are approximations to j^i or $(0.1j)^i$, can be distinguished in any practical way from a similarly approximated matrix which has columns known to be linearly dependent. Because linear dependence implies that at least one linear combination of the columns is null, then, given a set of regression coefficients that minimizes the residual sum of squares, one can obtain an infinity of regression solutions by adding arbitrary components of the null linear combination of columns. A given program operating in a specified environment will calculate an approximation to one of these solutions corresponding to a residual sum of squares very near the minimum—in the present case zero—hence an R^2 approaching 1 for the problems at hand. Thus, in the examples given by Boehm, Menkhaus, and Penn, nearly all the programs tested have succeeded in finding a solution which "explains" the data to the extent that the calculated R^2 is given as 1. That the residual sums of squares are not zero is very likely a result of the use of the formula

$$(3)\qquad S = \mathbf{y}^T\mathbf{y} - \mathbf{y}^T X\beta,$$

which obtains the sum of squares S by subtraction of nearly equal magnitudes. In this expression, X is the matrix for which element X_{ij} is the ith observation of the jth variable or the constant, $\mathbf{y}$ is the vector of observations on the dependent variable and β is

the vector of regression coefficients with T denoting matrix transposition. The use of equation (3) is unnecessary, because even in the case where the number of observations m is large, there is no need to calculate the residuals r via the formula

(4) $$\mathbf{r} = \mathbf{y} - X\beta$$

in order to be able to compute S as a genuine sum of squared terms (Nash and Lefkovitch). For problem (1), the quantity $\mathbf{y}^T\mathbf{y}$ is of the order of 10^{13}, while the sum of the squares of the elements of the constant column has the value 21. In IBM and Xerox machines the single precision mantissa consists of just six hexadecimal digits. (At the installations with which the author is acquainted, IBM and Xerox machines are identical in this respect, in contrast to a statement of Boehm, Menkhaus, and Penn.) Thus, addition or subtraction of these numbers cannot be carried out in such arithmetic without loss of information. It is hardly surprising, then, that while R^2 approximates 1, S is not zero in all cases cited.

The authors suggest (*b*) that parameters should be reestimated using alternative routines prior to publication or use. For problems (1) and (2), and a large class of real problems, different routines give different parameters. Such variation may be an indication that further investigation is necessary. However, the converse, that is the case where two programs give similar results, gives no assurance that the parameters so obtained are more trustworthy than any others. The approach outlined below is capable of alerting the user to the possibility of large program-to-program parameter differences while allowing a set of parameters to be computed.

Boehm, Menkhaus, and Penn also suggest (*c*) that calculations be performed using scaled or otherwise adjusted data. Certainly for regressions involving a constant term, adjusting variables by subtraction of means is helpful in reducing the loss of information which attends the formation of the normal equations

(5) $$X^TX\beta = X^T\mathbf{y}.$$

However, repetition of calculations is costly and, by and large, unnecessary. Perturbation of the data is useful for discovering sensitivity of the parameters to small changes, but can equally be determined internally in a single calculation as mentioned later. To do a proper job of a perturbation analysis, one must follow the lead of Beaton, Rubin, and Barone, who ran 1,000 sets of perturbed data through the program DORTHO, which was chosen for its reputed accuracy. They compared the distributions of the parameters with the parameters obtained from the unperturbed data using DORTHO and conclude that a highly accurate solution to the unperturbed problem may be far from the center of the distribution. In fact, while the perturbations were at most ± 0.5 in the last published digit of the data of Longley, only 2% of the solutions agreed with the unperturbed solution to one or more digits. Beaton, Rubin, and Barone show that even the Worst Algorithm You Are Likely to Get (*WRYALG*) performs comparatively well on a more stable problem. They propose a "perturbation index" calculable from the independent variables together with some information concerning the error of measurement of these variables.

Finally, the authors suggest (*d*) that the ordering of the variables in the regression be changed. Changing the order of the variables does have some influence on the rounding errors incurred in solving least squares problems (see the examples in table 1). However, it should only cause severe changes

in the results for very ill-conditioned systems, which in any event our methods should aim to detect.

The Linear Least Squares Problem

The linear least squares problem is stated: given a set of m values y_i ($i = 1, 2, \ldots, m$) and an m by n matrix X, minimize the sum of squares

$$Z = \sum_{i=1}^{m} \left(y_i - \sum_{j=1}^{n} X_{ij}\beta_j\right)^2 = \mathbf{r}^T\mathbf{r}, \tag{6}$$

with respect to the parameters β_j($j = 1, 2, \ldots, n$). While it is usually presumed that the problem has a unique solution, this is not always the case. It is the author's experience that problems whose computer representation is practically indistinguishable from the representation of a rank-deficient problem are quite common. For such problems a large number of vectors β will yield a computed residual sum of squares within some small tolerance of the minimum. Moreover, these vectors may exhibit very large differences if compared one with another. If a given program in a specified computer system calculates one of these least squares solutions, it has done its job. Far from leaving "the applied researcher with a feeling of helplessness," as Boehm, Menkhaus, and Penn have suggested, this merely implies that at least one of the columns of X is in some sense redundant in explaining $\mathbf{y}$. Furthermore, the degree to which such redundancy, or linear dependence, poses a difficulty depends largely on the application for which the least squares problem is solved.

For instance, one may be interested in computing the value of certain linear combinations of the coefficients β, of which predictions of y values are but one example. Such estimable functions will not depend on the particular set of coefficients β chosen—a choice made either consciously or by the sequence of arithmetic operations implied by the program and computer used.

Detecting linear dependencies or multicollinearity is not usually difficult, though Boehm, Menkhaus, and Penn are correct in warning that packaged programs may fail to take advantage of the known techniques. (Here a narrow definition of collinearity is used, that is, that X is computationally rank deficient to some specified precision.) In the face of commonly available regression programs, suggestions (*c*) and (*d*) above are probably the only means by which ill-conditioned problems may be detected, though such exercises can be systematized by methods similar to that of Mullet and Murray. Linear dependence among the independent variables in a regression corresponds to singularity of the matrix X^TX in the normal equations (5). The usual condition that the determinant of a singular matrix is zero is of little practical value in detecting singularities since the computed value of the determinant of a singular matrix may still be "large." The eigenvalues of X^TX, or better their square roots, which are the singular values of X (see Lawson and Hanson), provide a much better tool. Moreover, they can be computed as a step in finding the least squares solution and furnish a method by which principal components solutions may be calculated (Nash 1974). In one modification (Nash and Lefkovitch) such procedures allow the computation of uncorrelated residuals (Grossman and Styan) and permit regression calculations to be sequentially updated by additional observations. Lawson and Hanson discuss several similar techniques. Ideas along the same lines using the eigenvalues of X^TX are presented by Webster, Gunst, and Mason.

In essence, the technique proposed is to form the singular value decomposition (svd) of the matrix X, that is,

$$X = USV^T, \text{ where} \tag{7}$$

$$V^TV = VV^T = I_n, \tag{8}$$

where I_n is the identity matrix of order n, and

$$U^TU = I_n. \tag{9}$$

In the decomposition U will be taken to be m by n, S n by n and diagonal containing the (positive) singular values, and V n by n. The reader should note that other forms exist which are equivalent, for instance with U m by m and S m by n with rows n + 1 to m null, and that the form chosen may affect certain details in the presentation. When the matrix X has linearly dependent columns, one or more of the singular values S will be zero. Then, in order to avoid the difficulty presented by the existence of an infinity of solutions, extra conditions must be imposed on β. One such condition is that in addition to minimizing the residual sum of squares Z, β should minimize

$$\beta^T\beta = \sum_{j=1}^{n} \beta_j^2, \tag{10}$$

thus giving the minimum length least squares solution. It can be shown (see, for instance, Nash 1974 or Lawson and Hanson, chap. 7) that the minimum length least squares solution is given by

$$\beta^* = X^+\mathbf{y} = VS^+U^T\mathbf{y}, \tag{11}$$

where S^+ is the diagonal matrix

$$\begin{aligned} S_{ii}^+ &= 1/S_{ii} \quad \text{for} \quad S_{ii} > 0, \\ &= 0 \qquad\;\;\, \text{for} \quad S_{ii} = 0. \end{aligned} \tag{12}$$

The matrix X^+ as defined by (11) and (12) is the Moore-Penrose generalized inverse of X (Rao and Mitra). Substitution of the singular value decomposition into the normal equation (5) gives

$$VS^2V^T\beta = VSU^T\mathbf{y}, \tag{13}$$

which is easily transformed to

$$S^+SV^T\beta = S^+U^T\mathbf{y}. \tag{14}$$

From (12) it is obvious that if $(n - k)$ of the singular values S_{ii} are zero, only $k = \text{rank}(X)$ of the equation (14) place conditions on β, the rest being null. The matrix $(I_n - S^+S)$ has ones on the diagonal positions corresponding to these null equations and zeros elsewhere. The elements of $V^T\beta$ corresponding to the null equations are thus given by the nonzero components of $(I_n - S^+S)V^T\beta$. However, the values of these elements are arbitrary. Let them be given by

$$(I_n - S^+S)V^T\mathbf{e},$$

where $\mathbf{e}$, hence $V^T\mathbf{e}$, is an arbitrary vector. Therefore,

$$(15) \qquad (I_n - S^+S)V^T\beta = (I_n - S^+S)V^T\mathbf{e}.$$

Combining (14) and (15),

$$(16) \quad S^+SV^T\beta + (I_n - S^+S)V^T\beta = S^+U^T\mathbf{y} + (I_n - S^+S)V^T\mathbf{e}, \qquad \text{or}$$

$$(17) \qquad \beta = VS^+U^T\mathbf{y} + (I_n - VS^+SV^T)\mathbf{e} = X^+\mathbf{y} + (I_n - X^+X)\mathbf{e}.$$

Equation (17) gives the general expression for the ordinary least squares solution in both full-rank and rank-defective situations. Furthermore, the svd shows a way to compute least squares solutions in this form, at the same time allowing one to identify collinearities.

Principal Components Regression

Henceforth we shall assume that the matrix S is ordered so that

$$(18) \qquad S_{ii} \geq S_{jj} \quad \text{for} \quad i < j.$$

Thus, the matrix of principal components,

$$(19) \qquad B = XV = US,$$

has columns (the components) with decreasing size from left to right. That is, the first column explains the largest proportion of the variation of the independent variables, the second column the next largest proportion, and so on. However, when we regress on the principal components, that is, solve the least

$$(20) \qquad \text{minimize } Z = (\mathbf{y} - B\mathbf{w})^T(\mathbf{y} - B\mathbf{w}),$$

with respect to $\mathbf{w}$, the normal equations

$$(21) \qquad B^TB\mathbf{w} = S^2\mathbf{w} = B^T\mathbf{y}$$

have a minimum length solution

$$(22) \qquad \mathbf{w} = S^+U^T\mathbf{y} = (S^+)^2B^T\mathbf{y}.$$

That is, if only k of the singular values are positive $[\text{rank}(X) = k]$, then the last $(n - k)$ components of $\mathbf{w}$ are not restricted by (20) or (21) and may take arbitrary values. Setting them to zero yields the minimum length solution. Here it is now obvious that the principal components enter with weights which are the reciprocals of their respective sizes, i.e., singular values. The jth column of U, which will be labeled $\mathbf{u}_j$, can be thought of as defining the direction of principal component j. The inner product $\mathbf{u}_j^T\mathbf{y}$ determines the projection of $\mathbf{y}$ in the direction $\mathbf{u}_j$, which, weighted by the inverse of the singular value S_{jj}, gives a contribution

$$(23) \qquad w_j = (\mathbf{u}_j^T\mathbf{y})/S_{jj}$$

from the jth column of B, i.e., the jth principal component. When (19) is used to transform the solution into terms involving the original variables

$$(24) \qquad \beta = V\mathbf{w},$$

large elements in $\mathbf{w}$ may dominate smaller ones, giving a least squares solution β which has an entirely unexpected appearance from the point of view of signs and values.

The residual sum of squares is

$$(25) \qquad Z = \mathbf{y}^T\mathbf{y} - \mathbf{y}^TB\mathbf{w} = \mathbf{y}^T\mathbf{y} - \mathbf{y}^TX\beta.$$

But substitution of (22) in (25) gives

$$(26) \qquad Z = \mathbf{y}^T\mathbf{y} - \mathbf{y}^TUSS^+U^T\mathbf{y}.$$

The matrix S is ordered, so that if the last $(n - k)$ singular values are zero, then

$$(27) \qquad Z = \mathbf{y}^T\mathbf{y} - \sum_{j=1}^{k} (\mathbf{u}_j^T\mathbf{y})^2,$$

that is, only the nonzero (non-null) components are included. Moreover, each component included reduces the sum of squares by $(\mathbf{u}_j^T\mathbf{y})^2$, once again underlining the central role of these products. Note, however, that the singular value does not appear in this expression. Thus, if component j having a relatively small singular value S_{jj} has only a minimal effect in reducing the residual sum of squares, it may nevertheless introduce a large w_j, hence large elements in β, if the ratio of $(\mathbf{u}_j^T\mathbf{y})$ to S_{jj} is large. A principal component of this type could be dropped from the regression with very little effect on the fit but a very large alteration in the solution β, though such regression solutions may be of limited utility in econometric applications because of their statistical properties. Mittelhammer and Baritelle and Fomby and Hill discuss estimators formed by dropping components corresponding to small singular values. The reader is cautioned that the former of these two papers uses the expression "principal components regression technique" to refer to the use of such estimates, while the subject of the present discussion is the mechanism by which least squares estimates are produced. Thus, the information contained in the quantities S_{jj} and $(\mathbf{u}_j^T\mathbf{y})$ remains useful for diagnosing the nature and severity of collinearities.

Practical Considerations

Given the development above, it is possible to suggest some of the information which a least squares

program using an svd can provide. First, the singular values themselves, when they vary greatly in magnitude, indicate the presence of collinearity. Furthermore, while correlation coefficients may indicate the parallelism of two variables, the singular values permit relationships in several dimensions to be recognized. Because the singular values are proportional to the scale of the numbers in the problem, a criterion used by the author for deciding that the predictor variable set is linearly dependent is

$$(28) \qquad S_{11} > 1000\, S_{nn}.$$

That is, the ratio of the largest to the smallest singular value exceeds 1,000, where the singular values are ordered as in (18). The factor of 1,000 is chosen from experience. While this factor has been quite appropriate for the author's own econometric applications, no doubt a much larger factor should be used when more precise data are involved, for instance in engineering.

An equivalent viewpoint of collinearity is provided by computation of the fraction of total variation in the independent (predictor) variables due to a given component. This is, for the ith principal component,

$$(29) \qquad f_i = S_{ii}^2 \Big/ \left(\sum_{j=1}^{n} S_{jj}^2 \right) = S_{ii}^2 \Big/ Tr(X^TX).$$

If any f_i is small, say less than 10^{-6} if the factor 1,000 is considered appropriate above, then the predictor variable set is essentially linearly dependent. Once again, the choice of the test value is at the discretion of the user. Note that the f_i are ordered if (18) holds.

Consider now that all variables are in deviation from mean form. Then $\mathbf{y}^T\mathbf{y}$ is the total sum of squares. The fraction of the total variation of the dependent variable $\mathbf{y}$ explained by the ith principal component is then

$$(30) \qquad E_i = (\mathbf{u}_i^T\mathbf{y})^2/\mathbf{y}^T\mathbf{y}.$$

The sum of the E_i over all the principal components gives the square of the coefficient of multiple correlation, that is, R^2. The ratio of E_i to R^2 gives the proportion of the explainable variation of y which is explained by principal component i. Note that equation (30) is still valid even if the data are not in deviation from mean form, but the interpretation using R^2 is now less meaningful.

The quantities f_i and E_i provide a tool for deciding whether or not a given regression relationship suffers from multicollinearity and if so, then the extent to which this collinearity causes instability in the computed regression coefficients. That is, the presence of a small value f_i indicates collinearity. However, if the same component also gives a small value E_i, then the component contributes to neither the variation in the predictor set nor to explaining the dependent variable $\mathbf{y}$. Such components could be dropped from the regression. While this is easily accomplished in practice by changing the definition (12) to read

$$(31) \qquad \begin{aligned} S_{ii}^+ &= 1/S_{ii} \quad \text{for} \quad S_{ii} > q \\ &= 0 \qquad\quad \text{for} \quad S_{ii} \le q, \end{aligned}$$

where q is a tolerance supplied by the user, possibly interactively, one must be aware that the estimates which result have statistical properties different from ordinary least squares (Fomby and Hill). It is important to remember that results obtained by such a procedure are conditional on the assumption that the linear dependence actually exists. Deleting components is not therefore recommended as a routine procedure for general application.

When f_i is small but E_i is large, principal component i will contribute very largely to the regression coefficients. These coefficients unfortunately will be poorly determined because a linear combination of the predictor variables which accounts for very little of the variation in that data is being asked to describe much of the variation in $\mathbf{y}$. Small perturbations in the data will therefore give large changes in the regression coefficients. In this case component i is needed to explain $\mathbf{y}$, but the true linear combination of the predictor variables which go to make up this principal component can only be fixed if more information is found.

Finally, when f_i is large and E_i is small for all components, there is simply very little relationship between $\mathbf{y}$ and the predictor variables. Once again we are forced to find more information.

The cost of computing least squares solutions by means of a singular value decomposition as compared to a conventional method employing the normal equations depends on the algorithms used as well as their implementation. The author's own experience suggests that the svd requires three to five times as much computing effort as the formation and solution of the normal equations. This must be balanced against the costs both human and machine of rerunning conventional calculations to discover numerical instability as in suggestion (c) of Boehm, Menkhaus, and Penn.

Examples

The Wampler problems (1) and (2) were solved on a Data General NOVA minicomputer operating in 23 bit binary floating point arithmetic using the singular value decomposition algorithm described by Nash (1975). The method of Nash and Lefkovitch gives similar results, though the nature of the problems is such that the output of the programs need not be identical. This is especially true when the system, as in the present case, cannot represent the data exactly due to the limited precision of its operation. Table 1 gives a comparison of results obtained by three programs: (a) ENHSVA—the svd of Nash (1975), also given as algorithm 2 of Nash (1979); (b) ENHNLR—the method of Nash and Lefkovitch, also given as algorithm 4 of Nash (1979); (c) ENHCRR—regression by solution of the normal equations. In this program all data are in deviation from means form. The X^TX matrix is inverted by the algorithm of Bauer and Reinsch

(Nash 1979, algorithm 9). Note that the order in which variables are presented to the regression program has an effect on the coefficients as Boehm, Menkhaus, and Penn have remarked.

In contrast to the dependence of the regression coefficients on ordering exhibited by the normal equation solver ENHCRR, the singular values computed by ENHSVA are insensitive to such ordering. For instance, with the ordering 1, 2, 3, 4, 5, 0 for the variables, where 0 represents the constant, the singular values are computed as 4.92276E+6, 26458.3, 409.891, 15.8218, 1.99291, and 0.769307, and the coefficients, assuming full rank, as β = (0.905485, 0.884127, 0.838069, 1.04047, 0.997045, 1.00007)^T. Likewise, entering variables in the order 5, 4, 3, 2, 1, 0, into ENHNLR gives computed singular values

$$4.92276E+6,\ 26458.2,\ 409.892,\ 15.822,\ 1.99292,\ 0.769314,$$

and coefficients

$$\beta = (1.01441,\ 0.960911,\ 1.01602,\ 0.997811,\ 1.00011,\ 0.99997)^T.$$

If one is interested in simply performing ordinary least squares regression calculations, the following observations can be made.

(*a*) The normal equation method ENHCRR computes the least accurate regression coefficients, as may be expected from an analysis such as that of Stewart (pp. 225–30) which shows that the condition of the least squares problem is worsened in the formation of the normal equations. Furthermore, while correlation coefficients and standard errors of regression coefficients do in the present case provide a warning that the least squares solution is unstable, there is no measure of the "nearness" to collinearity of the polynomial data.

(*b*) The singular values computed using different methods and different variable orderings are essentially identical. Similar results were obtained on a Univac 1108 using the algorithm of Golub and Reinsch. From the large difference in magnitude between the largest and smallest singular values, it is reasonable to expect that the regression coefficients will be very sensitive to small perturbations in the data as well as to rounding errors during calculation. Nevertheless, the coefficients computed by svd techniques are much closer to the exact coefficients than those found via the normal equations. Moreover, the variations observed due to choice of algorithm or variable ordering are much smaller.

(*c*) The svd methods allow principal components regression calculation. In table 2, we see that component 1 accounts for nearly 100% of the variation in the variable y for Problem (1). Using program ENHNLR, regression on this one component gave the solution:

$$\beta = (5.3801E\text{-}7,\ 9.44152E\text{-}6,\ 1.69112E\text{-}4,\ 3.07656E\text{-}3,\ 5.66593E\text{-}2,\ 1.0538)^T,$$

with a residual sum of squares 8.04017E+8 but an R^2 of 0.999757. The same principal component explains approximately 98% of the variation of the dependent variable of Problem (2).

An additional point should be made concerning the programs used to prepare these examples: all three programs have been written for small machines, that is, those having less than 6,000 characters of memory. As such programs have short code lengths, they are relatively easy to implement and maintain, even in a large machine environment.

Table 2. Singular Values, Fractional Variation, Fractional Explanation

Conclusions

The singular value decomposition methods presented above are no longer a novelty in the computational world, but neither are they in widespread use in least squares regression programs. However, packaged programs are beginning to incorporate such techniques, and individual users are starting to employ programs such as those given by Lawson and Hanson. The gap, which this paper has tried to fill, lies in the appreciation of the utility of the intermediate output of an svd in identifying and coping with collinearity. The exercises proposed by Boehm are tedious and unnecessary when good methods exist for discovering instability in regression coefficients. Worse, their proposals offer no certainty that a problem has disclosed its pathological nature. While to some extent economists and others must live with other people's programs, they can and should be asking that these programs, as tools, be sharp and durable.

Books Reviewed

Breimyer, Harold F. ***Farm Policy: 13 Essays.*** **Ames: Iowa State University Press, 1977, vii + 121 pp., $7.50.**

These essays are directed toward an understanding of the philosophical foundations and value structures of American farm policy. They are discursive and retrospective, generally not a tract of advocacy, or a prescription for policy. For the most part, they do not analyze policy alternatives. They are, in Breimyer's words, intended to prick, stimulate, and stir imaginations; above all, to teach. In this objective, they succeed exceedingly well.

Breimyer begins by alluding to the paradoxes of farm policy. These include the drive for individual freedom and the attraction of combining to get the benefits of political power; the distinction between the material content of farm policy and the social organization of agriculture; the differences between crop and animal agriculture; and, finally, almost as a general theme, the contrast between the ancient agrarian root of farming and the industrial aspects now superimposed upon it.

According to Breimyer, these paradoxes give farm policy a mixed, ambiguous, agrarian and industrial content. Agrarian policies give rise to various programs to stabilize supply and raise price. The industrial orientation, however, is poised toward the imperious marketing system and its mechanism for influencing resource supply and demand, and the prices of farm products. Thus, on the one hand, the agrarian tradition gives credence to the family farm as a fundamental tenet of policy. But, most policies supported by farm organizations and generally adopted actually favor more and more industrialization of farming to the disadvantage of family farms. This is not accidental. The family farmer generally supports the industrial-type policies, but, in so doing, leads to what Breimyer calls the farmer's noninstinct for self preservation.

Examples of this noninstinct are widely dispersed, and Breimyer mentions most of them. There are the general policies of open competition for land and support for tax and credit policies that heighten this competition, often to the relative disadvantage of the family farm. The general tax laws give some important advantages to farm corporations, often especially the larger corporations. The liberal provisions for reporting important categories of farm income as capital gain favor the tax payer in high brackets. Cattle ranching is an especially attractive tax haven. The so-called reforms affecting taxation of farm inheritances and estates tend to favor the industrial-type operation. The opposition of the family farmer to effective labor unions for hired farm workers penalizes the family farmer relative to the larger-than-family farm operation. The failure of government to enforce the 160-acre limitation in sale of water from federally funded irrigation projects provides an important subsidy to the large irrigated farm. Farmers' cooperatives, theoretically at least under the policy direction of farmers, generally fail to provide competitive advantages to the family farm.

These basic paradoxes, which run as a continuing thread through Breimyer's essays, are importantly a product of the classic textbook fallacy of composition. The family farmer's noninstinct for self-preservation can be traced to the assumption that what is good for the individual family's farm is good for family farms as a whole. Thus, individual family farmers fight to retain the modest benefit they may gain from the capital gains tax, even though this hands a much larger windfall to the larger-than-family farm that competes for the same resources. Breimyer argues that the family farm will not necessarily survive just because of its technical efficiency; and farmers are chided on their divisiveness on income and estate tax rules, land use controls, pollution control, and foreign trade.

Breimyer generally avoids specific policy solutions except in certain cases, such as the use of programmed grain reserves to assure an export capability, more aids for resource adjustment, direct payments, and the like. But the general meaning is clear. The essays are succinct and, in some cases, terse. Overall, although some may question the benefits to be obtained in attempting to preserve the agrarian values that Breimyer sees slipping away, the essays make clear that important changes are required in current policy if these values are to be preserved. The essays do prick, stimulate, and stir imagination, and provide a general theme for teaching farm policy. The essays will be useful for collateral readings in farm policy, for the classroom, extension programs, and other occasions.

Doll, John P., and Frank Orazem. ***Production Economics, Theory with Applications.*** **Columbus, Ohio: Grid, 1978, x + 406 pp., $20.95.**

This book was written to be used as an undergraduate production economics text for students whose economics training includes only a principles of agricultural economics course. The book essentially can be divided into two parts. The first five chapters and chapter 7 develop the traditional neoclassical theory of production and distribution under perfect competition. The remainder of the book consists of discussions of production decision mak-

ing when one or more of the assumptions of neoclassical theory are relaxed. It contains chapters that address production decisions through time, production decisions under risk and uncertainty, the use of linear programming as a tool in decision making, and a historical perspective of farm adjustments in the United States.

In the preface, the authors allude to goals of merging abstract economic theory and applications of the theory to real situations in agriculture and maintaining flexibility so that the book can be used by students with a knowledge of differential calculus as well as those with mathematical training only in geometry and algebra. Doll and Orazem succeed in both goals. A thorough treatment of production theory is amplified by numerous production problems and applications. The authors also do an excellent job of presenting the material, such that those sections on calculus can be omitted without loss of continuity. They are not apologetic for the inclusion of calculus, and it is integrated throughout the text in theory, applications, and exercises.

The treatment of the neoclassical theory of production and distribution under perfect competition is well done. Tables, graphs, and calculus are merged such that the examples are explicit and easily understood. A good discussion of some often ignored topics (e.g., lumpy inputs, corner solutions, discontinuous production functions, linear isoquants, and constrained versus unconstrained optima) also is included. The authors begin their discussion of production functions with a simple approach assuming one input and one output and then address increasingly more complex production functions including the multiple input/multiple output case.

The chapter that addresses temporal production decisions contains a number of decision criteria for profit maximization and durable input acquisition over time. Most undergraduate students will likely have considerable difficulty choosing the appropriate criterion because this choice often hinges on a fairly subtle point. However, this problem can largely be overcome by meticulous, explicit instructor presentations.

The decision theory (under risk and uncertainty) chapter is somewhat superficial. The Frank Knight risk-uncertainty dichotomy is of little practical use, and could be played down considerably. It is somewhat unfortunate that the authors chose not to address alternative objective functions of decision makers, because the assumption of expected profit maximization is somewhat unrealistic. The treatment of game theory should either be expanded to include more than one decision criterion or it should be omitted.

More emphasis in the linear programming chapter could be given profitably to applications and examples and setting up production problems in an LP framework. The authors' discussions of the dual and the simplex procedure are somewhat detailed for a book of this type (and, in fact, employ 50% of the chapter).

Doll and Orazem have done a commendable job on their text. The presentation is economically and mathematically sound and contains a minimum of "first edition" errors and omissions. However, those instructors planning to go beyond the neoclassical theory will need to provide some supplementation of readings.

James K. Whittaker

Friedrick, Robert A. *Energy Conservation for American Agriculture*. Cambridge, Mass.: Ballinger Publishing Co., 1978, xiv + 173 pp., price unknown.

This book is one of a series of eight prepared by the Environmental Law Institute State and Local Energy Conservation project. Its primary purpose is to evaluate strategies that states might use to reduce energy consumption in agricultural production.

The book contains six chapters. Chapter 1 briefly reviews energy use in agriculture, reasons for energy conservation, and obstacles to energy conservation. Chapter 2 sets forth four broad categories of policy options that might be used by states to reduce energy use in agriculture: financial incentives, taxes, regulations, and information transfer programs. Advantages and disadvantages of each option are discussed at some length but there is no rigorous economic analysis. Chapters 3 and 4 discuss the potential for reducing direct and indirect uses of energy on farms in the broad categories of machinery operations, irrigation, crop drying, specialized operations (fruit, vegetables, and greenhouses), fertilizers, and pesticides. Chapter 5 covers meat, dairy, and poultry production. It points out that, in general, livestock is a net energy loser and discusses some options for change. These three chapters have similar formats. For each category of energy use, some or all of the policy options presented in chapter 2 are suggested as means of achieving reduction in energy use. The final chapter explores the potential for reduced energy use by increased urban gardening and the policy options for encouraging it.

The book draws heavily on the recent literature on energy use in agriculture and potentials for decreased use. Each chapter has extensive footnotes, including references to items such as USDA publications, CAST reports, and proposed or enacted state laws relative to energy conservation.

The author points out that energy use in agricultural production, while large, accounts for a small percentage of the total U.S. energy use. Direct and indirect energy use in agriculture are estimated to be 3% to 4% and 1% to 2%, respectively, of the U.S. total. The author concludes that there is potential for saving appreciable amounts of energy in the agricultural production sector. He also recog-

nizes that some of this potential may be difficult to achieve because there is insufficient incentive to save energy and, in many situations, plenty of incentive to use energy in agricultural production.

Most agricultural economists will find the book neither exciting nor one which contains rigorous economic analysis. Those who have studied energy use in agriculture will find little that is new. Many will find some errors, omissions, and misconceptions. However, the greatest disappointment will be that the approach is more from a legal than from an economic viewpoint. Economic issues related to the four policy options are treated in a very cursory manner. Discussion of the advantages and disadvantages of various policies, while reasonable, includes limited economic analysis.

One example of an apparent misconception is in the livestock chapter. It correctly points out that livestock use more energy than they produce but, in the case of ruminants, convert feed that humans would not eat. However, some of the suggestions about increased grassland and reduced feedlot production of cattle are based on faulty reasoning. There is an implication that large amounts of rangelands are currently unused or underutilized. While this could be true at the current stage of the cattle cycle, it is not a general phenomenon.

The discussion of information transfer suggests that there is a large amount of information available on energy conservation that is not being effectively communicated to farmers. There is also a suggestion that farmers are not adopting energy-saving technology because they are not being fed enough information on the economics of investing in energy-saving devices. The author does not seem to recognize that the economics of some proposed energy-saving technology is unfavorable to the farmer.

On the positive side, it is likely that persons in state governments who are unfamiliar with energy use in agriculture would find this book quite useful as an overview of energy use in agricultural production, possible areas for conservation, and options of states for encouraging conservation. Despite its shortcomings, I believe that most agricultural economists would agree that for a book produced by an attorney rather than by an economist, the result is quite reasonable.

Goldschmidt, Walter. ***As You Sow: Three Studies in the Social Consequences of Agribusiness.*** **Montclair, N.J.: Allanheld, Osmun & Co., 1978, 505 pp., $16.50.**

Drache, Hiram M. ***Tomorrow's Harvest: Thoughts and Opinions of Successful Farmers.*** **Danville, Ill.: Interstate Publishers, 1978, 314 pp., price unknown.**

Goldschmidt's lengthy book is divided into three parts. Part I, called "As You Sow," discusses the social consequences of industrialized (or corporate) farming in the town of Wasco, located in California's Central Valley. It is based on eight months of observation and field research starting in the fall of 1940, and was originally published in 1947 by Free Press. Part II, "Agribusiness and the Rural Community," is a comparative analysis of rural life in two neighboring towns, Arvin and Dinuba. This work, based on one month of field research in each town during the spring of 1944, is intended to provide a means of checking conclusions reached in Wasco. It was published as a committee print by the Senate Small Business Committee in 1946. Part III, "Agribusiness and Political Power," which appears for the first time in the new book, is an historical account of efforts to suppress Goldschmidt's research on the social effects of industrialized farming. The book has a 30-page introduction in which the author maintains that corporate control over farm production is expanding, helped by public policies. He sees the net outcome for society as a loss of personal independence, together with a decline in traditionally valued qualities such as egalitarianism and hard work.

According to Goldschmidt, the transformation of Wasco from a traditional farming community to a center of industrialized farming had its roots in land policy, irrigation technology, farm mechanization, crop specialization, an impoverished and impersonal labor supply, and large-scale operations. As the industrialization process proceeds, farmers have increasing contact with suppliers and marketing agents, while the rural community itself becomes more dependent upon outside corporations, big-city banks, and state and federal agencies. In this manner, urban values follow technology and mechanization into the rural community. Once urban values are introduced, they create additional pressures for more industrialization. Individuals adopt specialized functions (including a separation between labor and management), large-scale farming becomes dominant, the number of persons independently employed declines, the community comes to be composed overwhelmingly of laborers, and two social classes emerge. In short, the author believes that the rural equivalent of urban society is created.

Goldschmidt anticipates that urbanized rural society will substitute a system of social values based on occupational and pecuniary standards for the social unity, homogeneity, and personal values that characterize rural communities. To illustrate the point he describes the community of Wasco in terms of two social classes: an upper class of businessmen, farmers, and professionals; and a lower class of mostly agricultural laborers. He presents evidence from many aspects of life in Wasco to demonstrate a marked lack of social contact between the two classes including the exclusion of farm laborers from participation in community decisions, segregation in recreation and religious life, and poor housing and other urban slum conditions.

In Arvin (located near Bakersfield) and Dinuba (located near Fresno), Goldschmidt found evidence to support his thesis that industrialized farming leads to urbanization of rural communities. The two communities, selected because of their many similarities, differ in one important aspect: Arvin, surrounded by corporate-owned and other large-scale farming operations, is "a large farm community," while Dinuba, with many moderate- or family-sized farms, is a "small farm community." Thus, Arvin and Dinuba provide the basis for a controlled comparison of the effects of farm size on the character and quality of rural community life.

On the basis of personal interviews and other data collected in the two communities, Goldschmidt concludes that Dinuba is a superior place to live; it "fulfills rather well our normal expectations of social life." Arvin provides fewer opportunities for self-employment, lower standards of housing and public services, fewer nonfarm businesses, a lower volume of retail trade, less community loyalty, and a much greater degree of social segregation. Indeed, there are significant differences between the two communities.

The final section of the book describes the controversy surrounding the study of Arvin and Dinuba, and efforts to suppress publication of the research. It is not surprising that field research involving questions on housing conditions, standards of living, and social and religious participation should come under critical scrutiny. But in this case, the attack was systematically conducted by the representatives of corporations and other owners of large amounts of farmland, in a manner apparently common to California water politics. The ability of a few powerful interests to alter the course of publicly supported research certainly lends credibility to the author's view of it as a small part of a much broader effort to subvert the intent of Reclamation policy.

Yet, Goldschmidt's analysis has many shortcomings. Most of these relate to the weaknesses of the case study approach, and the difficulties of establishing causal links among many interrelated variables. Are the social differences between Arvin and Dinuba really the result of large-scale farming? Or do they perhaps stem from a combination of other factors—such as sources of water, types of crops, dates of settlement, and goals of community leaders? And are the findings perhaps unique to irrigated farming and rural life in California? The author does not always succeed in separating conceptual reasoning and objective description from personal bias and nostalgia for community life. Moreover, he does not fully explore the potential benefits of industrialized farming. It is likely that mechanization has reduced the drudgery of farm work, provided farm people with additional time to pursue community activities, and, in some cases, even eliminated the need for a separate class of agricultural laborers.

Tomorrow's Harvest, by Hiram Drache, is an extensive description of what a group of progressive, innovative farmers and their wives think of the business of farming and its future. In sum, the book is a pitch for large-scale, technologically modern, family-oriented farms and a stiff warning against public policies restricting farm size. Drache's analysis is based on personal interviews with more than 200 farm families in the Upper Midwest, Southern Canada, and Europe. Written in anecdotal style, the book is structured around a series of chapters that present the opinions of farm people on a variety of subjects: world food supply; farm size and growth; the management of farm labor; buying and selling practices; farm organizations and public policy; and European agriculture.

Drache emphasizes that it is the collective view of those interviewed and his own personal opinion, that the goal of agriculture should be to provide an abundant supply of food to consumers at the lowest possible cost and, at the same time, to achieve adequate returns to farmers who use the best available technology and business practices.

The trend toward fewer, larger, and more capital-intensive farms is viewed as a natural consequence of technological innovation and as synonymous with greater economic efficiency. Society's most pressing problems include finding ways to reduce the time lag between the invention of a new technology and its widespread adoption, and making sure that financial institutions keep up with the rising capital needs of modern farming.

Drache's interviews lead him to conclude that family farming has an edge over corporate-controlled agriculture. Two noneconomic factors—personal motivation and the choice of the right spouse—are primary determinants of success. Large corporations cannot provide sufficient incentives to compete with highly motivated farm families, and they definitely cannot "tighten the belt" and live with a very limited cash flow.

This book will prove interesting reading to those wanting to know more about the personal attributes and business strategies of a select group of farm people who have succeeded in adopting new technologies and management practices resulting in remarkable growth of farm size. Readers with other notions of success will be disappointed. It seems likely that Drache overstates the benefits to consumers of large-scale farming, because most of the farms considered are much larger than the minimum size necessary to capture known economies of scale. Economic efficiency is defined in the narrow sense, without regard for negative effects such as externalities, concentration of ownership, and socioeconomic consequences for rural communities. Drache's book supports the notion that knowledge of human behavior is essential to understanding the behavior of the firm. Beyond that, it is generally a gee-whiz story about four-wheel drive tractors and superfarms.

Goldschmidt and Drache both have a lot to say about changes in farming, personal values, and cul-

tural patterns. Both authors agree that family farming can reap most of the benefits of specialization, bigness, and modern technology without forcing society to sacrifice traditional goals such as individual initiative, freedom, and democracy. A major difference is that Goldschmidt argues for policies favoring moderate-sized farms, with government intervention to prevent land monopolies and to facilitate entry into farming. Drache, on the other hand, argues for a smaller number of large farms and against government intervention which he sees as tending to impede the expansion of family enterprises.

Hagman, Donald G., and Dean J. Misczynski, eds. *Windfalls for Wipeouts: Land Value Capture and Compensation.* Chicago: American Society of Planning Officials, 1978, xliv + 660 pp., $23.95.

Actions by local, regional, state, and federal governments that directly or indirectly affect land use cause gains and losses for real estate owners. With the increasing occurrences of growth controls and other environmental regulations, the severity and number of these effects can be expected also to increase, perhaps dramatically. This book concerns those gains and losses, termed windfalls and wipeouts, respectively. Contributors include the editors, who are also the primary co-authors, Frank Schnidman, Urban Land Institute Research Counsel, and seven UCLA law, planning, and economics graduate students who worked on this ambitious HUD-sponsored project.

The book is organized into six major sections. The first introduces the concepts of windfalls and wipeouts. Recommendations on how to design and implement two windfalls for wipeouts (WFW) systems, one an omnibus proposal and the other an incremental step, follow in the second section. Economic aspects are discussed in the third section, including the theoretical occurrences of windfalls and wipeouts, the probable incidences of windfall recapture and wipeout compensation, and potential efficiency and equity effects of a WFW system. The fourth section considers four approaches to compensate wipeouts (e.g., inverse condemnation), while section five discusses nine techniques for recapturing windfalls (e.g., special assessments). The final section then turns to techniques that have been used or proposed to recapture simultaneously windfalls and compensate wipeouts (e.g., transferable development rights). Comprehensive reviews of windfall recapture and wipeout compensation in Canada, Australia, New Zealand, England, and the U.S. (collectively referred to as CANZEUS) are contained in the last three sections.

Although not stated explicitly, the book seems to have twin purposes. The first is to build a rationale for a WFW system. This is consistent with the following premise that opens the book:

> We believe that windfalls and wipeouts lead to inequities that impair the ability of both the private and public sector to achieve desirable patterns of land use. These inequities would be reduced if the public "taxed" some windfalls in order to compensate some wipeouts, which, in turn, would lead to more desirable land-use patterns (p. 1).

"Desirable" land-use patterns are not defined in the context quoted but one suspects that efficiency, equity, and other planning criteria are involved. The prescription to institute WFW systems is predominantly based on the hypothesis that requiring at least partial wipeout compensation and windfall recapture will cause public decision makers to be more aware of all costs and benefits from their actions that affect land use, and thereby increase the efficiency of land planning. However, the analysis by Misczynski (chap. 7), concludes that it is unclear whether a WFW system will increase or decrease efficiency. The equity analysis concludes that WFW policies will reduce planning impact inequities among real estate owners (i.e., promote horizontal equity), but will probably not alter the vertical income distribution pattern. The reader is left to ponder the apparent lack of strong support by the efficiency and equity analyses for the prescription. The strongest argument may be that unmitigated wipeouts and unrecaptured windfalls create strong incentives to break well-designed land use plans (chap. 3).

The second purpose is to provide a comprehensive reference on wipeout mitigation and windfall recapture techniques. The primary intended audience is land economists, planners, and lawyers, but other academic disciplines and real estate-associated occupations should also benefit. Chapters 8–23 are the most comprehensive reviews of wipeout mitigation, windfall recapture, and windfall for wipeout techniques in CANZEUS. These chapters are excellent summaries of administrative and legal histories, and analyses of strengths and weaknesses; they should be required reading for those currently conducting or contemplating research in this area. The methodology is one of planning and economics liberally dosed with legal analysis.

Based upon the study's analyses, the authors recommend two alternative WFW systems. In large part, they are modeled on the WFW system termed zoning by special assessment-financed eminent domain (chap. 22). The most critical technical problem with either alternative is to accurately identify and measure the publicly induced changes in land or real estate values. If a WFW system is to provide the correct incentives to effectuate "desirable" land-use patterns, then a reliable, and probably inexpensive, mechanism must be found. The property tax assessment system is proposed for this role. To propose otherwise would mean a substantial increase in administrative costs and negate any

chance of seriously considering a WFW system in the current government fiscal climate. Recognizing the nasty theoretical measurement problems, the authors argue that the pressure placed on the property tax assessment system by a WFW policy would serve to upgrade the quality of assessments. One could alternatively argue that given the significant stakes involved in many windfall and wipeout cases, the WFW system might be the straw that breaks many property tax assessors' backs.

The editors conclude that adoption of a WFW system in the United States is problematical—an observation consistent with this reviewer's feeling that those who perceive potential losses under a WFW system are more numerous and politically stronger than those expecting gains (compensation). This pessimistic conclusion should not, however, deter potential readers from this very useful addition to the land-use planning and control literature.

Dave Ervin
University of Missouri

Pimentel, David, ed. *World Food, Pest Losses, and the Environment.* Boulder, Colo.: Westview Press, 1978, xxv + 206 pp., $16.50.

A hazard of today's largely discipline-oriented research in agriculture is that perspective is often lost. Such specialists as pathologists, entomologists, and ecologists tend to view the world as having finite quantities of natural resources that can produce some maximum quantity of food. Any losses from pest attacks subtract from this total food stock and ought not to be tolerated in a civilized, humane society. Economists recognize the role of price ratios in the substitution among resources used and quantities of commodities produced as well as the role of new technology in producing greater food stocks from a given quantity of natural resources. Economists, however, in their zeal to examine increased efficiencies in production, generally underestimate the magnitude of pest losses—the authors' "bottom line" is that "pest populations are consuming and/or destroying nearly ½ of the world's food supply" (p. 13)—and the tremendous research input normally required to maintain current levels of output and production efficiency. (In Canada, about 40% of all publicly funded research in agriculture is protection-oriented—weeds, insects, and diseases.)

The papers included in this book were presented at a symposium of the American Association for the Advancement of Science meeting in Denver, Colorado, in February 1977. The objective of the symposium was to examine current food shortages and the role that pests play in reducing world food supplies. Papers were presented on all major types of pest losses—insect, disease, and weed losses in crops; post-harvesting losses in storage, processing, and transportation; and animal losses from parasites. Environmental aspects of pest control were discussed in one paper. The book is completed by two papers of a more specific nature: one describing pest problems in the production of millet in Mali, the other justifying research on post-harvest losses as a priority of the new United Nations University.

The papers offer excellent reviews of the literature on pest losses. Though probably not comprehensive with respect to any particular pest, the discussion illustrates a thorough knowledge of the subject assigned to each author. Most papers include a long list of references. This book ought to be read by agricultural economists who are concerned with food production problems on a global scale, even though it offers few insights into economics of pest management problems. Though written by recognized authorities on pest problems, these papers display an alarming lack of understanding of the economic principles that govern rational pest control procedures. Furthermore, the quality of loss assessment data upon which pest control decisions and recommendations are being made appears to be woefully inadequate. One author claimed that only nine references out of 200 surveyed in the area of post-harvest losses have somewhat thorough analyses of losses under field conditions.

It is difficult to understand why the agricultural economics profession has continued largely to ignore this very important area of research. It would appear that substantial payoffs could be realized from closer collaboration between pest researchers and agricultural economists. These would result from a better allocation of research resources, easing of information constraints in the transfer of technology, and policy alternatives to deal with externalities found in pest control programs.

References to economic concepts are found everywhere in the book—the notion of an economic threshold, integrated pest management schemes to optimize benefit-cost ratios, increased costs of production when pests are present, accurate assessment of losses, benefit-cost ratios for alternative research strategies, externalities in pesticide use, increased resistance to continued use of pesticides. However the authors, who were trained in biological sciences, seldom have the expertise required to deal adequately with these issues. They continue to estimate area or country-wide losses from an accounting viewpoint, i.e., they extend production losses from one animal or hectare across a region with no recognition that price changes normally accompany quantity changes. Pest researchers continue to assess losses from the point of maximum total product rather than from the economically optimal point of total product. These and other economic *faux-pas* can be forgiven easily until it is remembered that many decisions about funding research, extension, and pest control programs are taken on the basis of this type of information. Agricultural economists can learn something from this book—not about economics, but about something

far more relevant, the level at which our science is being used and understood by other prominent, professional agriculturists.

Kurt K. Klein
Agriculture Canada

Schultz, Theodore W., ed. ***Distortions of Agricultural Incentives.*** **Bloomington: Indiana University Press, 1978, viii + 343 p., $12.95.**

This book presents the papers given at a three-day workshop, Resources, Incentives and Agriculture in 1977, sponsored by the American Academy of Arts and Sciences and organized by T. W. Schultz. The main focus of the book is clearly expressed by the editor in the preface: "The biological constraints on food production have been substantially reduced by the advances in agricultural research and by the availability of additional capital. But it has become increasingly evident that the adoption of the research contributions and efficient allocation of the additional capital are being seriously thwarted by the distortion of agricultural incentives. For lack of optimum incentives it is not possible for farmers in many low-income countries to produce the potential supply of food" (vii).

Accordingly, three preliminary papers by T. W. Schultz, Sir Charles Pereira, and H. A. Steppler are designed to make the point that "although many scientific and technical problems remain to be solved, their scale is now minor in comparison with that of the 'social engineering' required" to overcome the political, social and economic constraints hampering the growth in food production (Pereira, p. 25). These constraints are due to the fact that governments undervalue agriculture and negatively distort the incentives faced by farmers. To speak of distortion, one must compare actuality with a reference. For Schultz "an *optimum* economic incentive provides the information that leads producers to allocate resources in ways that result in a maximum of production that will clear the market at the price that maximizes the utility of consumers" (p. 6).

In the core of the book, entitled "Distortions of Incentives," a series of papers by David Hopper, Gilbert Brown, Reed Hertford, Randolph Barker, and Martin Abel review the various types of government interventions which distort incentives and present analyses of the reasons why many governments do so. The rest of the book is devoted to discussions of related issues presented in papers on international markets (D. Gale Johnson), the organization of research (Robert Evenson), investments in human capital (Finis Welch), institutional innovations (Vernon Ruttan), and the quest for equity (Edward Schuh).

The list of contributors (papers' authors and those who commented on them) is very impressive: it includes professionals who are the most, or among the most, competent experts in the field. Accordingly all the papers reach a very high standard of professional excellence. In addition, the workshop must have been well prepared because the book avoids the usual trap of being only a collection of disparate essays. On the contrary, most papers are focused on the central problem. The few exceptions deserve attention because, in my opinion, it is the subject matter of these papers which, in the present state of knowledge, does not lend itself to be well related to the main theme of the book.

Coming back to the definition of optimum incentive given by T. W. Schultz, the reference to a dual optimization (maximum of production and maximum utility of consumers) raises a thorny theoretical question which I have not fully elucidated. Usually, optimization problems are formulated as searching for one optimum under a set of constraints (which *inter alia* may reflect other economic objectives). Actually, in their discussions the authors do not use this theoretical reference. In discussing prices they all use world market prices in spite of the general recognition that the functioning of international markets for agricultural products leaves much to be desired, resulting particularly in great price instability. The point is made by several contributors. D. Gale Johnson asserts, it is true; "Yet with all these defects, the international market prices of agricultural products come much closer to reflecting the true alternative costs of various commodities than do the managed domestic prices of many, if not most, developing countries" (p. 213). But the evidence supporting this statement is, and can only be, very limited. D. Gale Johnson is more convincing when he argues that, in many instances, developing countries could benefit much from a greater involvement in world trade. Sir John Crawford, however, points out that "entering world trade is not the simple decision that I think Gale Johnson implies in his paper" (p. 186). These few points should be sufficient to illustrate that, from both a theoretical and a practical standpoint, defining price distortion is never a clearcut operation.

Another open issue is that of appropriate technology. Both Sir Charles Pereira and Edward Schuh denounce the demands that science be used not only to increase agricultural productivity but also to correct the maldistribution of wealth in the poorer nations. Yet the very creation of the international agricultural research centers and their success illustrate that science can be used to correct a bias in the orientation of agricultural research. Tropical research, until then, was focused mainly on plantation crops, of interest to colonial powers, and very little on food crops, of particular interest to the poor. Besides, the induced innovation hypothesis, so eloquently presented by Ruttan and for which there exists substantial empirical support, implies that the agricultural research and extension system can and does respond to economic needs, particularly to changes in resource endowments.

The most serious limitation of the book is the inadequacy of our knowledge regarding how government policies are determined. If we accept, in

spite of the questions raised above, that agricultural incentives are indeed distorted against agriculture, the "positive economics" advocated by T. W. Schultz should deal with the question: why is it so? Here, we can only agree with Reed Hertford's statement: "We economists do not really have, as yet, a robust and thorough-going explanation of why agriculture is mistreated by the economic policies of developing countries" (p. 137). Similar points are made by several contributors. In his discussion of Schuh's paper, Castle rejects the idea that economists know the "best" policies and argues that our "behavioral theory for the public sector is not comparable to that which exists for the private sector" (p. 332). Similarly, Ruttan writes that it is desirable "that economists and other social scientists begin to develop greater depth in the positive analysis of the social and political forces bearing on the choice of economic policy" (p. 300). Incidentally, this lack of knowledge is probably responsible for the less-than-clear relationship between the main theme of the book and the otherwise interesting papers on research (Evenson), human capital (Welch), and institutional innovations (Ruttan). Our knowledge of the relationships between policies in these fields and incentives faced by farmers is quite vague. This leads me to make a plea for developing an analytical political economy in order to improve our understanding of the policy-making process. In doing so, economists should avoid the danger, so well pointed out by Schultz, i.e., only to rationalize what is being done by government, and thus "become 'Yes-men' in the halls of political economy" (p. 9).

Given our inadequate knowledge of the policy-making process, I could not help but be somewhat irritated by the complacent tone of some papers preaching the free market ideology. Fortunately, the book is much more balanced than suggested by these over-simplifications. All agricultural economists are strongly urged to read it because it deals with essential problems, and to read all of it because the issues are complex and deserve careful analysis, and because *Distortions* should invite us all to intellectual modesty.

Shaffer, Harry G., ed. ***Soviet Agriculture: An Assessment of Its Contributions to Economic Development.*** **New York: Praeger Publishers, 1977, xvi + 166 pp., $18.95.**

"It is the purpose of this volume to expose the reader to the whole spectrum of views on Soviet agriculture," says the preface (vii). This indeed has been attained, as far as views and beliefs are concerned, less so with regard to a serious discussion of the facts.

The book opens with M. Gardner Clark's overview of Soviet agricultural performance and policy from collectivization to the mid-1970s. Concise and, at the same time, rather comprehensive as it is, the treatment of the subject is one of the best of this kind published in recent years and presents a rich array of information interspersed with critical comments. While most Sovietologist writings suffer from concentrating on Soviet sources and disregarding parallel Western research on the subject, Clark almost falls into the opposite extreme. His contribution further suggests that only by later additions was it brought up to the mid-1970s; essentially it was an earlier article ending at the beginning of the decade. This reviewer would take issue with some of the assessments of the reform of the labor remuneration system, of the economic rationality and success of the small-scale nonagricultural subsidiary enterprises on farms, and, most of all, with the presentation of the pros (no cons) of the unsupervised link system. On the latter subject, Gardner Clark does not differentiate between links of earlier years and on labor-intensive crops as distinct from comparable sub-units on a higher level of mechanization and for grain growing. The case in favor of the USSR becoming a permanent food importer on a large scale does not seem so unambiguous to the reviewer as to Gardner Clark. Yet, these are points for dispute and not all for authoritatively deciding on who is right or wrong.

Harry G. Shaffer—an economist not specializing in agriculture—takes issue with and quotes some Western, primarily U.S., extremely negative statements on Soviet agricultural performance and seems to imply that these represent an evaluation predominant among Western observers. At the same time, to prove his points, he quotes many equally Western publications, yet disregards the recent discussions on the merits or demerits of Soviet collectivization (Millar, Nove, Ellman, Grosskopf). His wording "human sufferings" (p. 58) hushes over the millions of deaths caused by Soviet collectivization, and he forgets to mention, when speaking of output growth, that still by 1950 the reluctantly tolerated private household plots produced nearly half of the gross total, and surely half of net agricultural output. Of the more than a few inaccuracies or doubtful interpretations of facts and figures, only a few examples can be pointed out here. Thus, Shaffer speaks of high rates of labor outflow from agriculture, allegedly indispensible for Soviet industrialization, but according to his own data, the annual average rate barely was an inconspicuous 1% most of the time. (See pp. 61, 79, and table 2.23, from which he wrongly deduces 24% over ten years, instead of 12%.) On page 81, he compares feed conversion rates per pound of gain in weight of calves over a certain age with total feed requirements per pound for raising a beef steer, and he misses the main point of Western deduction estimates from Soviet grain statistics, namely that

they serve to make Soviet "bunker" harvest data comparable to Western barn weight (p. 88). Following Shaffer's argument, one can but wonder why after the 1953 and 1964 changes in supreme Soviet leadership, agrarian policies came in for such harsh criticism by the Soviets themselves. Generally, it is not difficult to refute exaggerated statements of some Western observers (including the more naive cases of USSR-US comparisons), but Shaffer takes his points too far and, in a number of cases, simply errs in the opposite direction.

Victor Perlo pretends to put unfounded comparisons right—and makes highly doubtful comparisons, himself. Thus, in equalling (p. 109) the rate of U.S. (1850–1960) with Soviet (1928–75) urbanization speed, he is silent about the tremendous immigration in America and the periods of misery and starvation on the Soviet countryside. He enumerates reasons for collectivization (p. 111), which have little bearing on what happened in reality: efficient use of machinery (which actually was produced in sizable amounts only after collectivization), provision of a "surplus" of farm products (while the coercive system of extraction itself was proof of the nonexistence of a surplus), release of surplus manpower (for the actual outflow, see above), bringing closer the peasants and workers (whereas later Soviet statements testify to the existence of a deep gulf at least up to the mid-1950s). Perlo conceals that not only *kulaks* were terrorized during collectivization and attributes the resistance of the peasantry not to the Stalinist methods, but to "the pressure of world capitalism" (p. 112). He compares grain yields in the fertile Ukraine and Moldavia with U.S. average yields, which include large dry-farming areas (p. 115). One savors his contention (p. 137) that "anti-Communist revolts in Hungary [in 1956] . . . failed to win support in the countryside," while it is a fact, not disputed by Hungarian sources, that most collective farms in Hungary were spontaneously disbanded during 1956/57. These few of many examples may suffice. Yet it has also to be said that on some points Perlo's criticism of Western views is justified. Moreover, in his section on recent "Problems and Prospects," he gives a more balanced picture, thereby mirroring the Soviet treatment of the subject, which has become more realistic in recent times.

The concluding contribution to the volume consists of semi-official texts supplied by the Soviet press agency "Novosti." This text yields considerably less information than a selection of excerpts from some of the more sophisticated scholarly Soviet publications would have done.

Abstracting from Gardner Clark's contribution, the reviewer feels that the uninitiated reader will not gain a balanced picture from the volume as a whole, that the Sovietologist not versed in agriculture and the agriculturalist not knowing the Soviet Union may be induced to reconsider some too simple Western evaluations, and that the specialist in both fields is likely to find Shaffer's article provocative, but changing the more serious judgments only in some details. As to the rest of the volume, it is interesting as a Marxist partisan view.

Necrology

Marlin L. Hanson, an economist with ESCS USDA, died 10 January in Washington, D.C. He was 48 years old.

Theodor Heidhues, professor at the University of Göttingen, Germany, died in Göttingen, 11 November 1978 after a long illness. He was 45 years old.

Joseph M. Johnson, professor emeritus, Virginia Polytechnic Institute and State University, died 22 April at age 61.

Sherman Ellsworth Johnson, past president ICEA and AAEA Fellow, died in April 1978 at 81 years. Johnson had been a deputy administrator of ERS USDA.

Donald R. Kaldor died 9 October 1978 at age 61. He was a professor of economics at Iowa State University.

W. J. "Aggie" Nucholls, associate professor emeritus, Virginia Polytechnic Institute and State University, died in Roanoke in March, aged 74.

Ben J. Pubols, retired agricultural economist with ERS USDA, died in Arlington on 17 December 1978 at age 79.

John L. Shipley, professor of agricultural economics, Texas A&M University-Amarillo Research and Extension Center, died 16 January at age 57 years.

Theodore S. Thorfinnson, retired agricultural economist with ERS USDA and professor of agricultural economics, University of Nebraska, died 29 January, at 84 years of age.

Harold N. Young, retired Director of the Virginia Agricultural Experiment Station and former head of the Department of Agricultural Economics and Rural Sociology at Virginia Polytechnic Institute and State University, died 23 October 1978, aged 83.

Statement of Ownership, Management, and Circulation (Act of 23 October 1962; Section 4869 Title 39, United States Code)

1. Title of Publication: *American Journal of Agricultural Economics*
2. Date of filing: 17 August 1979.
3. Frequency of issue: Quarterly and December Proceedings issue (February, May, August, November, and December). (*a*) No. of issues published annually: 5. (*b*) Annual subscription rate: $12.50; $25.00 and $35.00.
4. Location of known office of publication: Agricultural Experiment Station, University of Kentucky, Lexington, Kentucky 40506.
5. Location of headquarters or general business office: Agricultural Experiment Station, University of Kentucky, Lexington, Kentucky 40506.
6. Name and addresses of publisher, editor: American Agricultural Economics Association, Agricultural Experiment Station, University of Kentucky, Lexington, Kentucky 40506; Editor: V. James Rhodes, Department of Agricultural Economics, 200 Mumford Hall, University of Missouri, Columbia, Missouri 65211.
7. Owner: American Agricultural Economics Association, Agricultural Experiment Station, University of Kentucky, Lexington, Kentucky 40506.
8. Bondholders, mortgagees, and other security holders: none.
9. Nonprofit organization: Status unchanged during preceding twelve months.
10. The following circulation figures are provided for (*a*) the average number of copies of each issue during the preceding twelve months and (*b*) the single issue nearest to filing date:

	Average Copies	Actual Copies
Total number of copies printed	(*a*) 7,050	(*b*) 7,050
Circulation		
Sales through dealers, carriers, etc.	(*a*) None	(*b*) None
Mail subscriptions	(*a*) 6,278	(*b*) 6,278
Total paid circulation	(*a*) 6,278	(*b*) 6,278

Total	(*a*) 7,050	(*b*) 7,050

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in this manuscript has not been published and is not being published or being considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in this manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of this manuscript gives the AAEA the exclusive right to publish, to copyright, and to allow or to deny reproduction of the manuscript, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) should explain.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal.*
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** Major support for this *Journal* is provided by page charges of $40 per printed page, or fraction thereof, payable by the supportive institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for making payment are provided with galley proofs.

American Agricultural Economics Association

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri Columbia, MO 65211

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

American Journal of Agricultural Economics

Volume 61 Number 4 Part 2
November 1979

Special Editor
Victoria S. Smith

Foreword

This special issue of the *American Journal of Agricultural Economics* contains papers presented at the Economic Research Conference on Regulation in the U.S. Food System. The conference was held at Airlie House, Virginia, 16–18 April 1979. It was sponsored by the American Agricultural Economics Association, the Economics, Statistics and Cooperatives Service of the U.S. Department of Agriculture, the Farm Foundation and NC-117, the Food System Research Group located at the University of Wisconsin, Madison.

The purpose of the conference was to stimulate the interest of agricultural economists in doing research on regulatory issues relating to agriculture and the food system. The conference had four sessions. The purpose of the first was to define regulation, putting it within a theoretical context. Speakers in the second attempted to isolate the role of economic research in the decision-making process. The goal of the third was to develop a research agenda in the regulatory area. During the fourth, speakers discussed a wide variety of regulation research issues—issues which deserve the attention of agricultural economists.

Speakers were drawn from a wide variety of backgrounds, both within the agricultural economics profession and from outside. In order to provide a view on how economic research on regulation can be useful in the public decision-making process, the speakers included people directly involved in that process.

The sponsors appreciate the decision of the *American Journal of Agricultural Economics* to publish these papers. We hope the information provided at the conference and the issues raised there will serve as a catalyst for future economic research in food system regulation. Our special thanks are extended to Vicki Smith, conference coordinator and the editor of this issue.

The Economics of Regulation
(R. James Hildreth, Farm Foundation, Chairperson)

Observations on the Political Economics of Regulations

James D. Shaffer

This conference on regulation responds to a demand for better understanding of the U.S. regulatory system. Public officials, business leaders, news reporters and citizens in general are raising serious questions about existing government regulations. Questions are raised about the benefits and costs, the complexity, the apparent irrationality, the unanticipated outcomes and failures to achieve perceived objectives. At the same time newly defined problems and public concerns, and new groups with political awareness and power have created a demand for additional regulations.

I assume that to regulate means to control, to direct, to govern directly and indirectly. To define regulation broadly emphasizes the ubiquity and complexity of regulations and focuses attention on alternatives and problems in regulating economic behavior rather than on the meaningless question of whether to regulate or not. It focuses attention on the political economy as a regulatory system.

Economic behavior is regulated in many ways. Resources are never allocated simply by the market. A regulatory system is always assumed. It is useful to think of the market as an instrument of regulation rather than an object of regulation. Prices always reflect political decisions defining inputs and outputs, and what has to be taken into account in economic decisions. The law and economics are inseparable.

Modern economists have had a tendency to avoid the difficult issues of regulation by assuming large parts of the law as given. The ideology of *laissez-faire* has continued to influence economic analysis and the discussion of economic policy even though the modern political economy has little resemblance to an idealized, unregulated, competitive market. Perhaps the idea that our economic system operates in some magical way with production controlled by preferences expressed principally through the market has tended to divert attention of economists from the study of market phenomena in terms of their regulatory underpinnings and to minimize the study of the extensive use of nonmarket mechanisms in allocating resources. The politics of regulation and the economics of political power are central aspects of a realistic study of resource allocation. This conference on regulation hopefully will contribute to a better understanding of the relationship of law and economics.

In this paper I comment upon the concept of the unregulated competitive market as a norm, discuss the nature of regulation and the regulatory process, suggest concepts which seem to be relevant for developing a theory of regulation and briefly comment on some relevant research. The focus of attention is on economic and political behavior in the modification of the regulatory system and in response to regulations.

The Unregulated Competitive Market

First let me express a concern: much of the research and debate on regulation seems to be out of context. The concept, objectives, and consequences of regulation are often narrowly defined. Simplified models, abstracting from the complex reality of the regulatory process, are sometimes inappropriately used in policy debates. It is often assumed that preferences expressed through political processes are less legitimate or perhaps less accurate expressions of real preferences than those expressed through market processes, ignoring the fact that the market always reflects political decisions as well as the decisions of individuals

---

James D. Shaffer is a professor of agricultural economics, Michigan State University.

Michigan Agricultural Experiment Station Journal Article No. 9040. The author wishes to express appreciation for helpful comments on an earlier draft of this paper to C. Kramer, D. Dahl, A. Schmid, P. Wandschneider, D. Ricks, L. Libby, W. Samuels, B. Ferres, and C. Cordes.

seeking their individual advantage in the market.

Let me quote a few sentences from recent reports which illustrate the cause of my concern. A report on the regulation of railroad grain rates states: "Much of this analysis hinges on two assumptions drawn from basic economic theory. First, perfectly competitive markets serve to optimize efficiency in allocating resources and forming prices. Thus, opportunity costs of production and income redistribution effects are minimized for society under such a market structure. Recognizing that no existing market is 'perfectly' competitive, one can still argue that *any* move toward more effective competition or any move that serves to stimulate competition will have positive social benefits" (Martin and Dahl, p. 9). It appears that the competitive model is posited as a norm and a regulation is judged against this norm. Actually, the study makes useful comparisons of costs among modes of transportation, given all the rules and entitlements which define costs, and shows the effect of rate regulation on the selection of mode. The competitive model norm is not needed to make this point.

The *Study on Federal Regulations* by the Senate Committee on Governmental Affairs, a report which provides significant insights into the problems of federal regulation and recognizes objectives other than "efficiency," begins a chapter with the statement: "Unregulated markets can, under proper circumstances, result in an efficient allocation of resources" (U.S. Congress, p. 9). And under the heading "Effects of controls on resource allocation and efficiency" it states: "Prices above or below competitive levels do cause a net loss to society . . ." (U.S. Congress, p. 58). This is but an example of the frequent implicit use of the competitive model as a social norm and the facile use of that fictional concept, the unregulated market.

What does an unregulated competitive market mean? Does it mean the absence of rules affecting economic behavior? Does it mean an absence of property? If so, what would be traded? Would there be no rules defining fraud? Would there be no rules about liability? Would there be no rules legitimizing the corporation? Would there be no legal tender? Would there be no rules in regard to peonage? Obviously this is not what is meant. Some existing set of rights, rules, laws—that is, a regulatory system—is assumed, taken for granted or ignored in any analysis of regulation.

I use these examples only to show the need to make a point which has often been made and should not require repeating. There is no logical basis for normative statements that regulations which are inconsistent with the structure of the perfectly competitive model necessarily reduce welfare. It is not logical to assume the institutions and distribution of wealth and power to be given, and to remain thus unevaluated, and then to use the model to conclude that a particular rule which affects such distribution reduces total welfare. This is a judgment that one set of rights is better than another and should be acknowledged as such a judgment.

In addition, the theorem of "second best" postulates that a rule to make a market more nearly meet the conditions of a perfectly competitive market will not necessarily lead to improved welfare within the context of the theory unless all the other conditions of the competitive market are met. Such conditions are never met in the real world.

It is instructive to think of the set of regulations that would be necessary to establish the conditions of a perfectly competitive market. Clearly all markets are regulated. Regulation is not a means of dealing with market failure; without regulation in the broadest sense there would be no market.

What Is Taken into Account?

Economists now possess the foundation of a framework useful in contributing to the analysis of regulatory systems and problems. Economics as a behavioral science predicts behavior and some of the consequences of behavior in response to a set of constraints. The usual assumption is that individuals seek utility, but more usefully the assumption is that individuals and groups have objectives which are sought within a set of physical and institutional constraints. The literature of institutional and public choice economics is concerned with the question of the relationship of institutional constraints—what has to be taken into account—and certain aspects of performance. Understanding the interaction of individuals as a system allows economists to predict certain outcomes.

Some consequences of behavior are taken into account and some are not. Those which

are not are referred to as externalities and bringing the externalities into account is called internalizing the externality. It is generally accepted among economists that an appropriate role of government is to internalize externalities. The argument goes that if property rights are structured so that benefits and costs are considered by the decision makers then market interaction will lead to appropriate resource allocation. Rights do determine what is taken into account in decision making. The underlying principle is powerful. However, the simple prescription to internalize consequences begs the question. Externalities are ubiquitous. The question is, which consequences are to be counted by whom? For example, inflation is an important consequence of economic behavior. Should this consequence be internalized by making it illegal to impose this negative externality? Does that imply wage and price control? Or should my mother be able to sue for the theft of her savings due to inflation? A consequence of high consumption of energy by those who can afford it is that the poor may not be able to heat their homes. Should this consequence be internalized? It may be argued that this is an equity question and should be dealt with by income transfers. But taxes and transfers also have effects on incentives and, thus, consequences for resource allocation.

The public good is characterized by a just society as much as by a national defense. How can the benefits of a just society be internalized so that we produce the appropriate amount of justice? Endless examples could be given. Let me restate my point. Economic activity produces many complex products or consequences. The incidence of the benefits and costs is affected by rights. The rights system is selective of the benefits and costs which are internalized. It is neither possible nor desirable to internalize and privatize all consequences. There is no avoiding the political decisions about rights and thus making collective judgments about the desired performance of the economy. Schmid, in his book *Property, Power and Public Choice,* provides an in-depth discussion of these issues.

Behavioral psychologists argue that individual behavior is shaped by the consequences of particular patterns of behavior. That is, individuals learn as a result of the benefits and costs associated with certain behavior. An individual's environment consists of complex "if . . . then" situations. If the individual responds with particular patterns of behavior then the environment will respond with positive and negative payoffs. For example, if the proper coin is inserted in a vending machine the reward is a soft drink. Obtaining the drink is contingent on inserting the coin. This is an important concept. Regulations change the contingencies of reinforcement in individual environments. They change what is taken into account. They affect the benefits and costs, associated with individuals' patterns of behavior. At the most fundamental level, then, the study of regulation is the study of the relationship between regulation and the benefits and costs to individuals, the response of individuals to this pattern of benefits and costs, and the aggregate consequences of this behavior, which we will call performance. Regulations structure the opportunity set and thus shape behavior and consequently performance.

Types of Regulations

In my struggle to understand the nature of the regulatory process I find it useful to review the types of regulation and to contemplate an analytical framework which would relate these regulations first to economic behavior, and then to performance.

Laws

A great body of common and statutory law establishes a set of rights and obligations. These laws determine whose interests or preferences get counted, what is considered a cost and what part of output the producer may keep, be rewarded for, or be liable for. For example, the law defines theft. If a poor man snatches my mother's purse and takes $10, that is theft. If those with economic power increase prices resulting in the loss of half the value of my mother's savings, that is not theft, but inflation. If my cow gets out I may be liable for damage she causes my neighbor. If I adopt a new technology and my neighbor loses his job because of it, I will not be liable. If I overgraze my land and the soil erodes leading to dust storms and higher food prices result, I am not liable for the damage to others. I may or may not have to pay for water, will probably not have to pay for dumping some chemicals in the air and would probably have to pay for dumping junk in a dump. A prostitute may not be allowed to sell sexual services, but executives of a TV network can produce a show

called "The Newlywed Game" and debase the culture using a property right to the channel, granted and protected by the government. Examples could go on and on. The point is that laws of property, liability, bankruptcy and the like establish contingencies of reinforcement by influencing what is considered a cost and benefit. To own something permits the owner to impose a cost on someone else and to claim benefits from it. A common law rule enforced by a district judge is just as much a regulation of economic activity as a rule promulgated by the Environmental Protection Agency (EPA).

Customs

Closely related to the common law and basic property rights is a great variety of customs and practices that regulate economic behavior. Most rights are defined and respected as a matter of custom or socialization. The common law is in part a reflection of customs and the contingencies of the law are important in the socialization process. Customs defining rights are a part of the common law in the sense that that which is not prohibited is allowed or protected. Many private practices, in addition to the usual notions of property, regulate economic behavior. Examples are: the custom of requiring an education credential for jobs unrelated to the underlying education; personnel selection and promotion practices which advantage some groups and discriminate against others; "red lining" areas or groups in granting credit. The monetary-credit system—where money is created—can grant funds to selected groups who then can bid real resources away from others, and define property rights. This is a part of the regulatory system which is based on business practices and customs.

Standard Operating Procedures

Firms adopt many standard operating procedures which regulate economic behavior. Accepted practices in the allocation of costs in multi-product firms provide one example. Private cross-subsidies are extensive. A grocery store has many different margins meaning that it is charging different prices for the same services. Posner has an interesting article discussing what he calls taxation by regulation. He points out that one of the results of regulation of common carriers and public utilities is, in effect, to tax some customers and then use those taxes to subsidize service to others, that is, cross-subsidizing. But private companies do this consistently as a matter of practice. If cross-subsidies were enforced by government or if cross-subsidies were to be prohibited by government it would be called regulation of the market. My argument is that the private practice of cross-subsidization is in effect a right and is functionally similar to regulation as described by Posner. Without reference to common practice, cross-subsidies cannot even be defined, for overhead costs are not linked to particular units or kinds of output. The possible list of customs and practices which regulate economic behavior would be a long one.

Taxes, Payments and Services

Another major set of governmental actions regulating economic behavior is taxes, subsidies, transfers and government provision of goods and services. Taxes create a great variety of contingencies which are functionally equivalent to direct regulation and common law property rights. We have even coined the word tax subsidy for the case where a tax is not imposed as a reward for some behavior. Taxes, which currently represent about one-third of the U.S. Gross National Product (GNP), influence almost every economic activity, promoting some and inhibiting others. A study of the regulatory aspects of taxes on the food system would be a very big study. Similarly, subsidies and transfers are extensive and are often designed to regulate behavior. Subsidies and tax advantages foster cooperatives, for example. Perhaps the most direct government control of economic activity is public ownership and direct provision of goods and services.

It is useful to consider taxes, subsidies, transfers and government provision of services as a group because they are obviously interrelated. Taxes (or a fiscal deficit) are necessary to finance the others. A decision to achieve an objective by providing a subsidy, for example, should be made with knowledge of the effect of the supporting taxation as well as the subsidy. The unintended consequences may be more important than the intended. The intent behind imposing taxes or making transfers may not be to regulate but the regulatory consequences are real nonetheless; both affect economic incentives.

Statutory-Administrative Rules

Finally, there is a broad class of statutory-administrative regulations. These are the governmental rules which are most often thought of as regulations. It is difficult to differentiate this type of regulation from rights. Rights are always reciprocal in the sense that a right implies the obligation of others to respect the right. And rights are always limited by other rights and rules. Statutory-administrative regulations define rights and obligations. These include regulations dealing with competition; rates and quality of service; collective action by unions, cooperatives, corporations; consumer protection; worker health and safety; environmental protection; money and credit; and many other areas of life.

Toward a Taxonomy

All of these types of regulations are functionally equivalent in the sense that they govern economic behavior by influencing what is taken into account by decision makers. There are, of course, significant differences among these types. A taxonomy would be useful. Let me mention some of the elements of such a taxonomy.

(*a*) The enforcement mechanisms. Civil or criminal sanctions can be used. The courts can be the first or the final resort. A specific agency can be created to achieve the regulatory objectives.

(*b*) Regulation of structure, conduct or performance. A set of rights establishes a structure for market interactions. Given the structure of rights, preferences are articulated through the market process. Regulation of conduct usually involves a lesser reliance on market processes for preference information. Regulation of performance attempts to specify the outcomes or product more directly by the political process.

(*c*) The degree of specification. This element involves the use of specific versus performance standards. For example, in attempting to provide worker safety two extremes of specification are first, the common law principles of employer liability for damages to a worker and second, establishing detailed rules relating to work environments and worker behavior.

(*d*) The nature of the incentives. The choice is between negative and positive reinforcement.

(*e*) The nature of the contingencies for application of the regulation. For example, the application of a marketing order to a group of growers is contingent upon a vote of the growers. A subsidy may be contingent on compliance with other regulations. Some regulations are voluntary. It is possible to avoid some regulations by avoiding an activity.

(*f*) The jurisdictional boundaries. What unit of government adopts and applies the regulation and how is the regulated group defined? This has important implications with respect to external effects and effectiveness.

Perhaps the most important dimension of a regulatory system is the way in which political and market processes are combined in articulating the preferences and in searching the production opportunity set. An enterprise system offers incentives to identify and cater to individual preferences and to search for means of meeting those preferences. The political system provides the rules which make the game possible and influence the outcome in order to meet politically defined standards of performance.

This is not a complete list of either types or dimensions of regulations. There are many types of regulations. The design of regulations offers many options, and regulation has many different objectives. Economic behavior is governed in many different ways.

I am attempting to convey an impression of the problems involved in analyzing the regulatory system and to suggest an approach to the analysis. I believe it is essential to understand that the market is never unregulated and to understand the market as an instrument of the regulatory process rather than an object of regulation. Consumers and producers respond to prices, and prices always reflect both politically determined rights, defined by a set of rules, and the interactions of those who have rights as they exercise their options to buy, sell, use, and produce. Thus, the market translates political decisions into economic incentives.

The Regulatory Process

The previous sections made observations about the nature of regulations. This section contains observations about the regulatory process. By the regulatory process I mean the processes by which regulations are instituted. I will discuss some characteristics of the sup-

ply and demand for government regulations.[1] This includes both enactment and implementation.

The analysis of the regulatory process requires the identification of participants and characteristics of their motivation and behavior. It is useful to identify participants by classes based upon roles. The major roles to be considered are citizen, consumer, firm manager, worker, political party, legislator, the bureaucracy, the judiciary, and the media. In the study of a particular problem or area of regulation the participants would need to be more specifically identified. The participants operate in an environment which shapes their behavior. The environment includes physical constraints, an inherited institutional structure, an ideology, and great uncertainty about both the effects of existing and proposed regulations.

The regulatory system evolves. It has a history. A regulatory system and ideology supporting that system are inherited. Much of it remains unevaluated most of the time. Changes in the environment such as new technology, availability of resources, changes in distribution of wealth and power, extent of the market, new knowledge and ideas about the effects of the current system and potential benefits from new institutional arrangements create a demand for change in regulations and incentives to supply them. A theory of regulation would require consideration of this evolutionary process.

The key concept is a simple one. The behavior of individuals and groups is governed by the consequences of their behavior: feedback modifies the system. Not only is performance of the political economy the product, but it is the major input to the evolving system. Preferences, regulation, ideologies cannot be treated analytically as exogenous to the system for they are both input and output.

The Government Regulation Enterprise

Consider government as an "enterprise" which supplies regulatory services. It responds to demands for particular regulations or outcomes, and it provides regulatory implementation and enforcement. Like all complex organizations government is operated by many types of participants, each with his or her own preferences and ideologies, responding to unique opportunity sets or contingencies of reinforcement.

Elected policy makers, legislators, and executives are constrained by the necessity of being elected. Each is an entrepreneur promising to deliver benefits to constituents in return for votes. The incentive will not necessarily only be to maximize votes. Officials have their own views as to characteristics of a good society and have interests which may be different from those of some of their constituents. In order to be elected, an individual must have money and other resources, thus election support is provided by individuals and groups seeking influence in promoting their own interests. The rules and technology of elections affect the outcome. For example, the development of TV, which has great capacity for influence and is expensive, changed the patterns of influence. Votes are based upon anticipated services. Those seeking election attempt to identify products which will sell, and they also promote their products, like private firms.

There is a great deal of slack in the system, partly due to uncertainty and ignorance. Voters have great difficulty in identifying what an official does and an even greater problem in identifying the consequences of what is done. There may be little connection between what is promised and what is delivered. There is limited accountability or voter protection. Competition creates an incentive for officials to promise to solve all problems, often with regulation of some type, and to vote for regulations which have uncertain outcomes. This may explain some of the proliferation of regulations.

Because of the uncertainty as to both constituent preferences and outcomes of specific regulations, officials are responsive to information about both. This creates a demand for information and potential benefits for those who supply needed information. A lobbying enterprise provides subsidized information and sells influence. The result is differential influence among groups related to wealth and concentration of interests. It can be expected that elected officials respond to material incentives within a code of ethics, the same as businessmen or workers. Thus, they may be influenced by the prospects of future employment or other inducements.

Regulations are promulgated and im-

[1] The observations are drawn from many sources but special reference should be made to Bartlett and Stigler.

plemented by agency bureaucrats, the courts, and the police within a general legislative mandate. The effect of a law on behavior obviously depends upon how it is enforced. Enforcement is often selective and subject to influence. The Sherman Act, for example, does not determine which firms are selected for anti-trust prosecution. A set of rewards and constraints operating on the lawyers in the Federal Trade Commission does. Wellford has made an interesting study of food safety regulation in which he describes the contingencies of reinforcement for meat inspectors which included bribes and threats on the job and pressures from superiors who do not want to upset the industry. This is part of the reality of the regulation of purchasing agents by private sales agents.

Administrative procedures acts are instituted to regulate the procedures of regulatory agencies in promulgating regulations. These acts affect the flow of influence in establishing specific rules by determining hearing and legislative review procedures.

Regulatory agency bureaucrats have goals of their own. For example, bureaucracies create a perverse incentive by rewarding managers according to size of staff and budget. One way of expanding both is to extend the scope and intensity of regulatory activity. Thus, both legislators and bureaucrats may expand the supply of regulations independent of original citizen preference. This is the same as the dependence effect in the private economy where producers influence the demand for their products.

The rôle of the courts in regulating economic behavior is, of course, complex. Influence is involved in the selection of judges but the influence system is quite different than for the legislature. Judges make regulations, interpret regulations and give orders enforcing regulations. That great body of rights regulating economic behavior known as the common law is in their hands. When the courts are slow in adapting the common law to changing political preferences, legislatures may respond with statutory law. The position of judge requires behavior which probably makes the judge less subject to immediate influence of concentrated interest than other regulatory participants. At the same time, the costs of litigation and the advantage of superior legal services seems to bias the system in favor of the concentrated rather than dispersed interests.

Demand Articulation

In the market for products, effective demand reflects both preferences and ability to pay. Preferences of different people receive differential weights. Similarly, the demand for government regulations reflects both preferences and ability to influence the government, the supplier of major classes of regulations. Thus, the economics of political influence is a major aspect of the demand for regulations.

Citizen behavior is similar to consumer behavior in that much of it is habitual. Preferences are learned. The demand for regulation is embedded in ideology. Citizens learn concepts about the characteristics of a good society. This concept changes with experience as the conditions in the physical and social environment change. Just as in the case of the demand for products in the market, the demand for regulation is affected by the products which are supplied and promoted.

There are problems in articulating preferences. Individuals may lack incentive to investigate and weigh the costs and benefits of a vote because the consequences of the vote are not clear or immediate. Transaction costs are high in political decision making. Each voter cannot afford to analyze the costs and benefits of every decision made by government, thus it is necessary to vote for representatives to express preferences for the group. This creates what is sometimes referred to as the problem of the blue plate special. The voter must choose between candidates with a bundle of characteristics, some he likes, some he dislikes and many about which he knows nothing. The product of the political process also has the characteristics of a public good: each within a jurisdictional boundary gets the same regulatory system whether they like it or not. And the nature of the voting process is that all who are franchised get to vote whether they use the product or not. Thus, it is difficult to express intensity of preferences.

Because of the economy of representative government, representatives are required, but representatives have motives of their own. One of these motives is to get elected. Getting elected is facilitated by belonging to a political party. Where the party is strong voters may vote for the party rather than the candidate.

The political party is a complex organization which does more than sell influence to those who finance it. In attempting to organize support of large groups, it collects information

about preferences, and works out compromises. It provides discipline. It identifies an ideology and an image. It has many participants, each of whom has incentives independent of those of the organization.

In addition to political parties, there are independent political entrepreneurs who make a career of influence production by representing such dispersed interests as the consumer activist and poor peoples' lobbies. And there are movements, such as women's liberation, and special single interest groups such as the National Rifle Association attempting to influence specific regulations. Again, each of these involves participants with different positions and roles operating under specific contingencies of reinforcement. A theory of regulation that did not include subtheories on social movements and political parties would not be complete.

Almost all voters have a stake in regulation both as consumers and producers. For most, the interest in any particular regulation is greater as a producer than as a consumer. Large corporations would be expected to possess both the incentive and resources for influence. It is assumed that firms which have an incentive to maximize profits will spend resources to influence regulation in their favor if the return per dollar is better than than spending it on the next best alternative. Since the rewards may be substantial, the industry incentive to influence regulation is also substantial. At the same time, the benefits to individual citizens are small relative to the transaction costs of organizing influence in opposition to the regulated firms. Few voters will oppose a politician simply because he does not put pressure on a regulatory agency on a particular rate decision. Thus, it is reasonable to expect more resources to be allocated to influence representatives to favor producer interests. These principles could be generalized to an economic theory of the captured regulatory agency. They also have implications for anti-trust policy.

The transaction costs for collective action for some groups are smaller than for others. Groups already organized for other purposes or brought together by some other collective good would have an economic advantage in producing influence. Unionized workers, for example, would be expected to devote more resources to political influence than the nonunionized. Where unions and corporations have a common interest, such as in a trade restriction, they would be expected to combine resources for influencing the rule.

The economics of influence suggests that dispersed groups like consumers have relatively more influence in getting a bill passed than in the more difficult and long-term job of monitoring and influencing the implementation of a regulation. Regulations affecting consumers directly and noticeably would be more likely to be the focus of consumer influence and thus to favor consumer interests than those with more indirect effects.

Another set of participants is those who work in the news media. The selection and treatment of news have a pervasive influence on the political system and thus the regulatory system. Political participants attempt to avoid actions leading to bad press and they seek favorable publicity. Media participants also operate under a unique set of incentives and constraints involving advertising, professional associations, news sources, rating services, public relations firms, and their own ideologies. The emergence of the local monopoly and chain newspapers and of television, with its unique power to influence, is a recent development which is greatly influencing the regulatory system. The news media coverage of an accident involving a chemical fire retardant in the Michigan food supply significantly influenced legislation designed to regulate that chemical and other toxic substances. To predict changes in regulation one would need a model to predict news media behavior. The news media alter the opportunity set within which elected officials, bureaucrats and firm managers make decisions.

In this system of influence what can be said about the articulation of voter preferences? It appears that in a complex democratic society the majority of citizens express preferences very indirectly. It is difficult for them to know what elected officials do, let alone what the consequences of those officials' actions will be. What they do know is how the political economy is treating them. They have concepts about performance, and, since enough citizens will vote against what they believe to be poor performance, elected officials and parties will attempt to deliver an acceptable product. This relationship is not too different from that between the stockholders and management of a large corporation. If the management performs reasonably well it gets little attention

from the stockholders. If performance is below some acceptable standard the management is in trouble.

A recent article reports results of opinion polls regarding certain types of national regulations on business (Lipset and Schneider). They conclude that voters are becoming more sophisticated about benefits and costs of these regulations, and support regulation in a number of areas. They report a 1978 survey which found a much higher percentage of "yes" to "no" answers to the question of whether costs added by regulations are worth it if they: protect workers' health and safety; protect workers' pension plans; ensure safety, and dependability of products or services; ensure equal employment opportunities; and protect the environment. Another finding of special interest results from their review of opinion data since the 1930s. They conclude that Americans have ambivalent attitudes toward regulation. Their opinion data has indicated that a majority opposes more regulation in general, but, even as more regulations have been enacted, a majority has also voiced approval of specific existing regulations and indicated support for keeping those regulations in effect. I realize this is weak evidence but it implies to me that the political system has responded to preferences for regulation and that the preference expression in the polls was based upon perceived consequences of regulations not specific regulation. It may also suggest that the supply of regulations creates its own demand.

About Research

The study of regulations has the burden of evaluating and predicting the consequences of alternative configurations of regulations. It must be recognized that the output of the analyst is an input to the evolving system. Thus, the researcher is an important participant in both the influence system affecting the demand for regulations and in the production of regulations. There is no escaping that fact. The selection of methods and problems carries a social responsibility.

The research agenda implied by this perspective is enormous. As in all economic behavior, choices must be made because of the reality of scarcity. I suggest high priority be given to development of theory and description of the evolution of the regulatory system. This will require behavioral models of important components of the system. To adequately understand and predict the development and consequences of regulations we need at least minimal behavioral theories of voting, markets, firms, households, political parties, bureaucracies, courts, unions, and social movements.

For example, it cannot be assumed that regulations of firm behavior will have intended consequences. Assuming firms will maximize profits is not enough. Firms develop standard operating procedures and an ideology which influence their responses to specific regulations. It can be expected that they will attempt to influence both the design and the implementation of the regulations. They will anticipate regulations and their response to the expected regulations may have significant consequences. Clearly an understanding of the behavior of the firm is required.

My observations on the behavior of important groups in the political influence system should be taken as hypotheses grounded in observations of the real world but not carefully done analysis. A good deal of research has been completed, but it has not been integrated, partly because it has involved different disciplines.

A good taxonomy of the regulatory system is essential. Comparisons of consequences generally associated with alternative types of regulation would be very useful. At least we need to develop systematic ways of analyzing the alternatives. Interesting work has been done analyzing alternative approaches to regulation for environmental quality—comparing specification standards, performance standards, marketable rights and pollution taxes, for example. It would be useful to compare the effects of requiring commercial insurance to protect workers to the detailed standards for worker safety as applied by the Occupational Safety and Health Administration (OSHA). Many examples could be listed.

We need research examining the mechanisms of political preference articulation. Such research would include study of the economics of political and jurisdictional boundaries. This kind of activity is especially appropriate for economists because it involves the familiar subject of externalities. There are also a variety of institutions which might be developed to provide policy makers with critical information about citizen preferences.

We need studies of the performance of specific subsectors of the economy. Develop-

ing relevant dimensions of performance is itself an important research task. Then links need to be established between sets of regulation and performance.

Realistically, most of the analysis of regulation will contribute to diagnosis and prescription in response to specific political demands. This is extremely important work. I know of no substitute for detailed analysis which attempts to identify all of the relevant groups of participants and asks how specific rules change the consequences of their behavior, predicting in turn how this will affect the performance of the larger system. My observation is that much of the so-called failure of regulation has resulted from unintended consequences due to failure to understand the behavioral responses of critical participants. Good intentions are not enough and legislating well-intended regulations without attention to the details of design and the real consequences for participants is never enough.

The problems addressed in the discussion of market failure are critical ones. I believe, however, that they should be understood as problems of regulation. The problems are created by the fact that individuals and groups seeking their advantage in the short run produce consequences inconsistent with the long-run well-being of the group. Microeconomic behavior leads to undesirable macroeconomic results. The diagnostic function of regulatory analysis is to identify such situations in the political economy. The prescriptive function is to identify alternative institutional designs more congruent with politically articulated standards of performance.

Finally, let me briefly discuss an important contemporary problem from this perspective. Almost every group in the political economy has developed a capacity to protect its nominal position in the income distribution by a threat to collectively withhold services, by restricting production, or by somehow indexing its right to a flow of income to a measure of inflation. Many of these protective practices by firms and workers reduce productivity. The capacity to protect nominal shares of income derives from the structure of the regulatory-rights system. This is usually the right to collective action or to administer prices. At the same time the prices of natural resources, especially oil, have increased and the costs of worker safety, product safety, and environmental protection have been shifted and have to be paid for by new groups. No group seems willing to pay these added costs if it decreases their real income. We are perhaps trapped by unrealistic expectations of continuing increases in real personal income as measured by direct goods and services. In addition, many areas of economic activity, including governmental, are not under control of the aggregate consequences of their behavior. The dynamics of this situation lead to inflation, unemployment and reduced output (compared with potential).

The general diagnosis of this problem is, of course, much easier than the prescription. From the perspective of this paper it is suggested that many regulations need to be examined, first for their impact on raising prices, second for possible changes in them and the consequences of such changes, and third for the political feasibility of change which may require some political trade-offs. For example, hospital costs have risen more in recent years than any other major component of the price index. Even a casual study indicates that the consequences of the increased costs do not fall directly on those who make the decisions. About 91% of hospital costs are paid for by third parties, either governments or insurance companies. Even the insurance costs, which are affected by use of hospital resources, do not fall directly on the decision makers—the doctors, patients, and administrators—because of the fact that hospitalization insurance as a fringe benefit is not taxed and thus this benefit appears free to the users. Simply changing this tax situation would at least bring some of the consequences of hospital decisions to bear on those who make decisions. Of course, many other factors, including the fact that the suppliers are frequently in a position to create the demand, are involved. The political feasibility of a change in the tax and health delivery system is another question. But a package of reforms, with a broad set of trade-offs, might be feasible. This suggests the nature of institutional diagnosis and prescription.

Final Comments

The discussion of the problems in articulating preferences in the political system and the implications of the influence system may be taken as an argument against regulation. It is not. There is no alternative to regulation. The relevant questions have to do with designing political and economic institutions which im-

prove the capacity to identify information about preferences and the production opportunity sets. There is no avoiding the fact of conflicts of interests and political and economic power. It may be an act of faith that a better understanding of the system will contribute to improved performance, however that is defined politically, but for scientists that faith is necessary.

It should not be assumed that because the regulatory system is the result of influence that a just society is impossible. Participants are members of communities. They have all been socialized. In the end, ideology—the basic accepted beliefs about the good society—affects the decisions of most of the participants. The political economy produces the belief system and is subsequently controlled by it. If we are to understand the regulatory system we must understand the evolution of the prevailing ideology and attend to the problem of shaping the ideology which will control our future.

Economic Analysis of the Regulation of Agriculture

Bruce L. Gardner

This paper consists of two unequal parts. The first treats the normative economics of regulation—why and how it ought to be done. The second part is about positive economics—how to analyze the consequences of regulatory alternatives. The bulk of the paper concerns positive economics, but a brief recap of a standard normative framework for regulation is an essential preliminary.

The Rationale for Regulation

Theoretical welfare economics has not succeeded in giving scientific status to value judgements, but it does provide results that help us think reasonably about issues in political economy in general and about regulatory activities in particular. It helps first of all by insisting that governmental activity must be justified in terms of making us collectively better off. It is not enough that somebody be made better off; in some meaningful sense, we must be made better off collectively. This view focuses attention on the community's welfare, a concept which may not be precisely definable, much less measurable, but which is nonetheless a useful focal point for thinking about the justification of regulation.

An elementary but helpful way to think about the reasons for regulation is provided in Figure 1. It depicts some socially valued activity—for instance, the production and consumption of beef. The figure represents two general realities. First, successive increments in the quantity of the good or service, Q_i, yield reduced incremental social benefits. Thus, the function labelled MSB_i (marginal social benefits) has a negative slope. The reason is that when small quantities are available, they can be used to satisfy the most urgent and important uses, while successive increments are used to satisfy less urgent and important uses. Second, successive increments in Q_i require increased incremental cost. Thus, the function labelled MSC_i (marginal social cost) has a positive slope. The reason is that when increased quantities of resources are used to produce Q_i, the marginal value of other goods and services that must be sacrificed to produce an additional unit of Q_i increases.

The community is made best off when its resources are allocated to activities such that $MSB_i = MSC_i$ for all i, e.g., at $\hat{Q}$ in Figure 1. While the diagram is a partial equilibrium depiction of the Q_i activity, the identification of MSC_i as opportunity cost implies the many-activity optimality condition that the community's resources should be allocated such that a given value of resources yield the same MSB in all activities. If the economy were operating at some suboptimal level such as Q', a move to $\hat{Q}$ would generate additional benefits equal to the area under MSB_i and additional costs equal to the area under MSC_i. Therefore, there is a net social gain which can be quantified as the roughly triangular hatched area. The gain can be thought of as the welfare loss resulting from being at Q' rather than $\hat{Q}$.

In the context of a market economy, the question is where the market-determined activity level Q_i is located in relation to $\hat{Q}$. One can imagine an ideal case in which: (*a*) the market price of a product is identical with its marginal social value; (*b*) the marginal private costs are identical to the marginal social costs; (*c*) there exists a market demand function identical to MSB_i as a function of Q_i; (*d*) there exists a market supply function identical to MSC_i as a function of Q_i; and (*e*) the market institutions generate equilibrium at $\hat{Q}$. There can easily be divergence at any of these points. Let me give an example. The social value of stored grain—its potential value in time of shortage—differs from its market value if the social value includes the desires of poor people abroad who could not afford the high prices in time of shortage. The market demand function differs from the marginal social benefit function if the private stockpilers' discount rate differs from the relevant social dis-

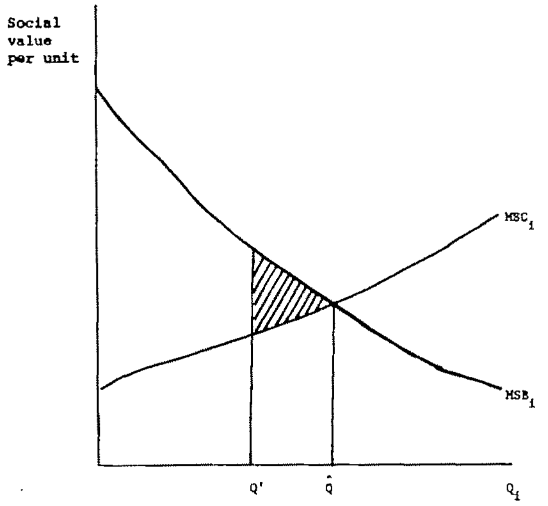
Figure 1. Optimal and Suboptimal Activity Levels.



count rate. The private costs of producing grain differ from the social costs if external costs occur, e.g., fertilizer runoff polluting streams. Even if private and social costs are equal, the market supply curve yielding output $\hat{Q}$ will not be observed if monopoly power exists. And, even if all else is in order, the market may not operate efficiently to find position $\hat{Q}$ because of irrationality, imperfect information, or inflexibility under rapid change.

The justification for regulation of markets is to move toward positions like $\hat{Q}$ from positions like Q' generated in unregulated markets. This view suggests defining regulation as governmental intervention in markets in search of $\hat{Q}$. However, the definition should not turn on the goal of the intervention. Any systematic direction or management of markets in the food and fiber sector by government can be considered "regulation of agriculture," regardless of the goal sought. This definition is not so broad as to include all governmental activity that has an economic impact on agriculture. It excludes general revenue-raising or expenditure measures (income taxes or welfare programs), and it excludes the legal background that establishes property rights, defines fraud and otherwise specifies fair dealing. Thus, the term "unregulated market" does not refer to a fictional state of anarchy, but simply to the absence of direct intervention in market pricing, production, consumption, or trade.

Regulation of Agriculture

Weidenbaum (pp. 6–8) lists thirty-seven major expansions of U.S. federal regulatory activities under congressional mandate between 1962 and 1974. Of these, twelve have significant implications for farming or markets for agricultural products, and five of the twelve are aimed exclusively or primarily at agricultural products (Cigarettes and Health Act, 1965; Fair Packaging and Labeling Act, 1966; Flammable Fabrics Act, 1967; Wholesome Meat Act, 1967; Wholesome Poultry Products Act, 1968; Public Health Smoking Act, 1970). Weidenbaum's list excludes such pertinent legislation as the "Delaney Amendment" (21 U.S.C. 348(C) (A)) and other legal restraints on cancer-causing agents in food, the successive extensions of the Fair Labor Standards Act to more farmers, the act establishing the Commodity Futures Trading Commission, the act establishing the Federal Grain Inspection Service, and the commodity programs authorized and put into place under the Food and Agriculture Act of 1977 and the Emergency Agriculture Assistance Act of 1978, as well as other regulatory activities to be mentioned below. Thus, farmers' perception that their regulatory environment is becoming congested, absolutely and relative to other sectors, appears justified.

Moreover, there is evidence that some general regulatory activities have larger effects, with greater cost relative to benefits, on agriculture as compared to other sectors. For example, Peskin and Peskin (p. 85) estimate that while agriculture (Standard Industrialization Code 01) accounts for about \$200 million annually or 1% of U.S. air pollution damages, costs to meet the Environmental Protection Agency (EPA) standards in agriculture would be \$1.1 billion annually (in 1970 dollars), 5% of U.S. total costs to meet EPA standards.

The main justification for regulation of agriculture seems to be that welfare losses may be reduced in the following ways: (*a*) fostering competition or otherwise improving the functioning of markets; (*b*) equating marginal social benefits to marginal social costs when externalities (on either the demand or supply side) exist; and (*c*) redistributing wealth efficiently.

Regulation can be aimed to foster competition by intervening to increase the number of firms or to dictate certain courses of action—

actions such as those currently being required of breakfast cereal manufacturers and retail grocery stores in concentrated markets. Another example is the concern that the performance of the livestock/wholesale meat markets has been hampered by the practice of formula pricing based on the National Provisioner's "yellow sheet."

Regulation intended to improve resource allocation in the presence of externalities justifies a broad range of activities. Fertilizer runoff, by-products of feedlots, and wind-blown pesticides are obvious externalities suggesting an environmental regulatory effort. In addition, some agricultural activities provide external *benefits,* and these may justify regulation to preserve open space, land-use planning, and so forth. In addition, externality arguments have been extended to worker-safety and food-safety issues on the grounds that if Mr. A becomes ill, the rest of us pay more taxes for public health purposes. Therefore, regulation of Mr. A's workplace, diet, and so forth to promote and protect his good health is justified.[1]

The third listed reason for regulation—redistributing wealth efficiently—gets less attention in most discussions. It is probably true that promoting competitive market pricing and dealing with externalities are the two most prominent general regulatory fields of action that can potentially move the nation's agricultural activities toward a position like $\hat{Q}$ in Figure 1. Yet, and here I am driven into the impressionistic realm of personal experience, these considerations leave out a great deal of what regulation is all about. What regulation is all about is a matter of what the regulators are, in fact, doing and why. In my own experience, which was as the staff member of the Council of Economic Advisers (CEA) covering food and agriculture during 1975–1977, most issues that came up were regulatory issues. However, people who were making or recommending decisions on these matters rarely did so as part of an attempt to manage markets so as to minimize areas of triangular welfare losses as shown in Figure 1.

What are the real issues, then? It seems so evident as to be a truism that the definition implicit in the title of Harold Lasswell's book is right: *Politics: Who Gets What, When, How.* The real issue in the economics of regulation as practiced is, how (or by how much) shall the economic well-being of one worthy group of citizens be reduced in order to benefit another (presumably even more worthy) group of citizens. It might be thought that this issue has nothing to do with $\hat{Q}$ or welfare losses, but this idea is incorrect on two counts. First, while economists often speak of an efficiency/equity trade off or words to similar effect, one can think of the achievement of fairness or justice of market outcomes as part of what determines $\hat{Q}$. Thinking along these lines is encouraged by philosophers like Rawls who have made it their business to analyze concepts like justice in a nonsentimental and rigorous way. Second, and more practically relevant, putting redistributional measures into effect thereby places the economy at a point away from $\hat{Q}$. The regulatory issue is how to manage redistribution in such a way as to minimize the welfare costs resulting from it.

Example: The Jones Act (46 U.S.C. 883) requires, basically, that goods shipped from one point on the coast of the United States to another point on the coast of the United States must be transported on American ships. However, the Act permits exceptions in the case of national emergency or the overriding interest of the country, if the President officially so determines. My reading of the Jones Act is that Congress decided to transfer wealth from people who use shipping services to our ocean shipping industry by means of limiting foreign competition, unless the social costs of doing so became too great. Now, during the time I was at the CEA certain lack of nitrogen fertilizer occurred in the Pacific Northwest, and it was found profitable to ship the product from Alaska. But it was said that no appropriate American shipping was available, while a foreign-owned barge that could perform the required services was available. Regulation involved the preparation of a report on the issues and a recommendation as to whether the President should find danger to the U.S. economy sufficient to permit this foreign barge to ply its trade. I am glad to report that the governmental resources necessary to provide a full legal and economic analysis of this issue that would be fully sensitive to spirit and letter of the Jones Act was not undertaken, yet the barge was permitted to sail anyway. A number of lessons could be suggested from a fuller development of this regulatory episode, none of them encouraging optimism about the pros-

[1] This externality can also be expressed in reciprocal terms as a social cost of public provision of health insurance, which raises the question of whether it is socially preferable to move toward $\hat{Q}$ by regulation of health or by regulation of health insurance.

pects of achieving $\hat{Q}$ through the regulatory route. The point here, however, is that regulation can move us toward $\hat{Q}$ not only by undoing market failure but also by undoing legislative failure.

Analyzing the Consequences of Regulation

The analytical and informational expertise required for intelligent choice in regulatory matters is truly formidable. The necessary preliminary steps of quantifying social benefits, social costs, and even units of measurement for the output of the good or service in question, involve great difficulties in practice. The actual determination of $\hat{Q}$ for practical problems is more difficult still.[2]

Consider an example in which the economic analysis necessary for socially optimal regulation might be attainable without too many problems—the optimal carryover storage of grain. Stockpiling is a justifiable regulatory issue because of externalities and possible ill-functioning of markets that suggest governmental intervention to attain $\hat{Q}$ in this activity. There exists a good deal of econometric analysis that is pertinent to optimal stockpiling. But, even so, one finds sufficient uncertainty about future trends in supply and demand, the elasticities of supply and demand, and the costs of storage that a substantial range of recommendations about optimal stock levels results. $\hat{Q}$ cannot be estimated with precision. Moreover, the externalities that the private trade ignores are extremely difficult to quantify. There is even disagreement on exactly what kinds of things these externalities are.

The difficulties faced in determining $\hat{Q}$ are no less, and indeed are probably more formidable, in other areas of regulation of agriculture. In fact, the difficulties are so great as to give Figure 1 an appearance of pure pie-in-the-sky, as far as any hope of actually attaining Q is concerned.

Nonetheless, in regulatory decision making economists can be of real assistance in promoting rational social choice. First of all, we can search for evidence as to the costs imposed by unregulated markets as compared to ideally managed markets. Second, we can attempt to assess the consequences of alternative regulatory proposals. The remainder of this paper is devoted to discussion of how best agricultural economists can provide these useful services.

Estimating Effects on Producers

Two fine examples of positive economic analysis of regulatory activity are the USDA's study of the prohibition of subtherapeutic uses of animal drugs and the National Brucellosis Technical Commission's study of alternative schemes for brucellosis eradication. Both show what costly and time-consuming effort is needed to bring our best analytical tools to bear on issues of benefits and costs. Two problems exist with these studies and the problems are even more serious with less ambitious studies of benefits and costs. First, even our best econometrics often leaves much to be desired, especially when results involving cross-commodity effects and transitions from farm to retail are involved. Quantitative estimates often appear more solidly based than they really are. Second, econometric models tell us especially little about the issues policy makers are most interested in—who gains and who loses, and how much.

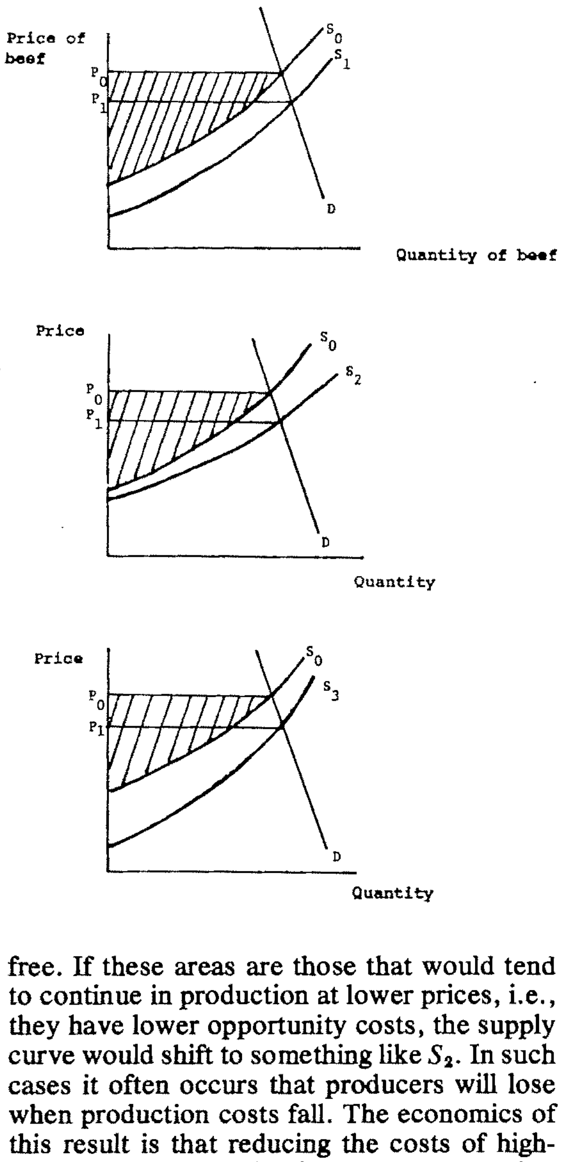
On the consumer side, the measurement of gains or losses is relatively straightforward. Lower prices reduce expenditures and increase consumers' surplus, and both can be estimated. On the producer side, however, the situation is more complicated. The reason is that regulation of production practices does not shift supply functions in easily specified ways, while the measurement of producer gains (producers' surplus or rents) depends on what happens along the whole length of the supply function, not just at the margin.

Figure 2 shows three possibilities in the context of brucellosis eradication. First, suppose that the supply function shifts downward by a constant amount from S_0 to S_1, i.e., production costs fall by a constant amount. Producers' rents then must increase, since output increases, and the fall in price is necessarily less than the vertical shift in supply (unless demand is perfectly inelastic or supply is perfectly elastic). Note that producers' rents increase even though total revenue will decrease if demand is inelastic.

A second possibility is that production costs are reduced to yield the same market price as S_1 does, but intramarginal production is not so greatly affected. Nonuniform effects are likely for brucellosis eradication because some areas of the United States are already brucellosis-

[2] Some potentially workable ideas for governmental management of analytically intractable regulatory problems are outlined in Bosworth's paper at this conference.

Figure 2. Alternatives for a Shifting Supply Function.



free. If these areas are those that would tend to continue in production at lower prices, i.e., they have lower opportunity costs, the supply curve would shift to something like S_2. In such cases it often occurs that producers will lose when production costs fall. The economics of this result is that reducing the costs of high-cost marginal production creates tougher competition for low-cost intramarginal production. For example, if we make it cheaper to grow corn in Texas, this makes Corn Belt producers worse off.

The third possibility is the converse of the second. A result of this kind is shown as S_3 in Figure 2. Price falls the same amount as under the S_0 to S_1 shift, but producers' rents increase even more than they did under the S_0 to S_1 shift.

Unfortunately, the standard econometric models and estimating procedures do not permit discrimination among these three alternatives. It is possible to compare arithmetic shifts of supply equation intercepts (the first case) with percentage shifts via logarithmic specification or changing-parameter models (a particular sort of S_0 to S_2 shift). In general, however, the analysis of producer benefits or costs from regulatory measures requires a more detailed structural investigation of the supply function than is typically undertaken for purposes of price forecasting or other standard uses of econometric models. For an example of empirical work with attention to the structure of supply shifts, see Scobie and Posada T.

Choosing Among Alternative Analytical Possibilities

In stating the results of investigations into the consequences of regulation—for example, in informing regulatory authorities about estimated benefit-cost ratios of program alternatives—consideration should be given to the ways in which regulators will decide what to believe. Consider these two propositions: it is altogether too easy to convince people of what they expected to hear anyway; and the researcher's ability to gain credibility as an "expert" is perhaps even more important than the evidence actually adduced.

For example, the U.S. government is perpetually considering the pros and cons of allowing more foreign sugar into the U.S. market. We have some econometrics to indicate price effects, consumer losses, and producer gains. But these estimates are limited by the relevance of the elasticity estimates and the models they come from. It is tempting to say that more sugar imports lower price in the short run as our model shows. However, in the long run maybe the shrinkage of U.S. sugar production would lead to higher prices. This is of course a possibility but there does not seem to be any evidence on the matter. Nonetheless, if we are not careful, we find ourselves saying that free trade in sugar is just as likely to make consumers worse off as better off. It is not surprising that industry representatives will accept such results, but it is somewhat dismaying how readily disinterested regulators can be induced to accept dubious results. This does suggest the importance of taking into account the process by which administrators reach their views on analytically uncertain questions, which is what most quantitative assessments of benefits and costs of regulatory options are.

Role of Conceptual Advances

In some regulatory issues, conceptual advances are perhaps at least as important as econometrics. Indeed, my own belief and experience is that significant progress in regulatory matters could be made by a serious and consistent recognition that demand curves slope downward and supply curves slope upward in both the short and long run.

Conceptual advances beyond this are rare. An outstanding example is available in the regulation of agriculture: namely, the analysis of classified pricing under marketing orders developed in Kessel; Kwoka; Ippolito and Masson; and Buxton. What they collectively provide is basically a model of a price-discriminating cartel with free entry. To review the basic ideas—classified pricing provides a way to sell a given quantity at a higher average (blend) price; namely, set a price differential which charges more for uses relatively inelastic in demand. A common reaction to the assertion that price enhancement results from classified pricing is that, after all, supply is not controlled, so production will tend to expand until expectations of profit are eliminated.[3] The service of the literature mentioned above is to show what the resulting zero-profit equilibrium looks like. The general result is that the higher blend price induces more than the unregulated market's output; and that, while there are zero profits, producers' rents are higher at the higher price. This model is basically similar to a Chamberlinian monopolistic competition model—a model which also can be used to depict a cartel with free entry. With not much further development such models could throw light on the economics of the flow-to-market regulations used by many associations of producers under marketing orders. The empirical implementation of such models will require sensitive and detailed work, but should eventually provide the appropriate positive economics for public decisions in this area.

Other marketing issues need a better conceptual basis for rational regulatory action. With respect to "yellow sheet" pricing of meat, there is need for a better theoretical framework for assessing the likely gains and costs of abolishing or restricting formula pricing. The issue here is not so much competitiveness per se, but the adaptability and efficiency of market institutions. Returning (it seems inevitable) to milk marketing, Earl Butz as Secretary of Agriculture had confidence in markets, but even he justified classified pricing of milk under federal market orders on the grounds that unregulated markets could not properly handle the geographical distribution and pricing of a randomly produced perishable commodity that can also be processed. Is there a coherent conceptual framework for this result?

Analyzing Intervention Approaches

In addition to measuring benefits and costs, economic research on environmental issues can explore fruitfully private market mechanisms for internalizing externalities and the consequences of alternative forms of intervention. There has been interesting work on the reciprocal external benefits resulting from the interdependence of beekeeping and orchard or other flowering crop enterprises (Cheung, Johnson). On the issue of alternative forms of intervention, one important area for research is the pros and cons of direct regulation versus performance standards. Should the government attempt to specify particular production practices or safety equipment to protect farm workers health and safety, or should there instead be penalties imposed for accidents or negligence with farmers left free to choose specific practices?

Another area of choice is who is to pay penalties or receive subsidies to best achieve $\hat{Q}$ when externalities exist; for example, the bill for environmental cleanup or damage prevention. The alternatives usually considered are taxes or other charges against polluters versus subsidy of environmentally desired procedures. To date there seems to have been a greater reluctance to impose charges or other costly adjustments on farmers than on industrial polluters. And when one rural enterprise imposes external costs upon another, there is a marked tendency not to impose regulatory costs on either party but to compensate environmental losers at the expense of the general taxpayer. The best example is the beekeeper indemnity program. The use of certain pesticides in crop production or orchards

[3] The USDA reaction to charges of price enhancement by cooperatives under marketing orders has typically been along the following lines: "A vague or inaccurate notion of what agricultural cooperatives do and of powers they have, and a lack of understanding of the complexity of the agricultural marketing system in this country and the uncertainty of agricultural production as a way of life everywhere in the world is the source from which most criticism stems" (Smith, pp. 8–9).

sometimes unintentionally kills honeybees. The traditional mechanism for handling such an externality would have been to establish liability on either the pesticide user or the beekeeper through court cases. This approach would be analogous to the approach to dealing with damages caused by wandering cattle, as discussed by Coase. But the beekeeper indemnity program effectively settles liability upon the general taxpayer, since injured beekeepers are paid for damages out of the U.S. Treasury, not from assessments on producers. One would suspect that this approach would not lead to socially optimal practices in either pesticide use or beekeeping.

Assessing Regulatory Choices

The economic behavior of regulatory authorities should be better understood in order to assess the chances of attaining $\hat{Q}$ through government. Economic analysis of legislative decisions is a time-honored field of study going back at least to Beard. The discussion of the Jones Act above suggested that legislation to redistribute wealth creates divergences from optimality that regulation in the executive branch can correct. However, maybe the executive and the independent regulatory agencies cannot be trusted to move us toward $\hat{Q}$. Stigler is representative of a school of thought that sees real problems arising from the interests and incentives of regulatory agencies as related to the interests of the industry regulated. My own view is that this emphasis in the "new theory of regulation" is misplaced when applied to the more recent areas of regulation in agriculture (although it is well placed as applied to commodity programs and marketing orders). More pertinent in the newer areas is the traditional complaint that the regulators too often literally do not know what they are doing.

Economists can make useful contributions to the topic of how to regulate when you do not know what you are doing. In grain stockpiling, for example, one can explore the sensitivity of $\hat{Q}$ to the range of uncertainty about the unknown parameters which determine optimal storage. And, regulatory steps which do not yield extremely undesirable results can be suggested even when the assumptions on which they are based turn out to be wrong. Such policies may be called "robust." In addition, it is possible to learn from the outcomes of regulatory activity. For example, the knowledge base accumulated from past acreage control programs is a real help in avoiding errors in proposed price support schemes. An interesting treatment of optimal learning is provided in Rausser.

Problems which are more difficult still arise when the conceptual apparatus of Figure 1 is of uncertain relevance. Consider the idea of regulation of diet or nutritional information in pursuit of better health in the population. Regulation here involves a determination that the regulatory authority has knowledge that consumers, or a substantial subset of them, do not. This is said to justify taking measures to induce people to behave differently in their market choices than they otherwise would have. The definition of $\hat{Q}$ in such circumstances involves *MSB*'s based on something other than an aggregation of individual utility functions, which creates real difficulties in saying what $\hat{Q}$ means. Similar difficulties arise when market participants try to influence one another's preferences and actions. Nonetheless, in a case like regulation intended to further the Senate Nutrition Committee's dietary goals, while the effects on producers of beef, sugar, and so on, are a matter of concern, the welfare effects on the consumer side are even more problematical.

Similar conceptual problems arise with reference to the "structure" of farming, which is appearing on the horizon as a major regulatory target. The criteria by which one judges whether one attains $\hat{Q}$ more satisfactorily with one million or three million farms are not readily available from the type of welfare economics that lies behind Figure 1.

Regulating Uncertain Markets

One of the special characteristics of regulation in agriculture is that it is often concerned with managing markets under uncertainty. Regulation here involves difficult valuational problems in assessing benefits and costs, and in forecasting the private market response to regulatory intervention. Areas in which research has been undertaken include: management of grain stockpiling, programs to help producers cope with production uncertainty, regulation in the areas of credit and insurance, governmental regulation of private price-discovery institutions (e.g. futures markets), and provision of market information and forecasts.

The issues in regulation under uncertainty

bring out a fact that becomes ever more apparent as one considers the problems discussed in this section: good regulatory research is on the frontiers of agricultural economics. It is not that the research has to be esoteric or requires a Ph.D. in mathematics, but that we have to go beyond our standard tools of commodity market analysis. By this, I do not mean that we ought to be throwing our textbooks in the trash can. But we do have to be reaching out for new sources of information and new techniques of analysis. It is noteworthy that much of the recent work that has promise for improving our ability to analyze regulatory alternatives in agriculture comes from outside agricultural economics. For example, in the area of regulation under uncertainty the *Bell Journal of Economics* has recently published three papers that may be extremely useful to agricultural economists (Bradford and Kelejian; Nichols and Zeckhauser; Yohe). Each of these papers treats agricultural market analysis, albeit sometimes only in passing, from a point of view arising from developments in general economics which strike one as having great potential for more detailed application. While keeping up with developments in general economics involves major investments of time and effort, the payoff in advancing the analysis of agricultural regulation should more than justify the costs.

A final point that pertains to all the research issues discussed is that the applied nature of the research is a key characteristic. The fundamental theoretical issues—for example, the meaning and measurement of consumer's surplus, or general theoretical or ideological discussion of the proper role of the State—are ignored. This omission reflects my own prejudice that the comparative advantage of agricultural economists does not lie in the study of these general topics.

Concluding Remarks

It is in principle possible to identify socially optimal activity levels like $\hat{Q}$ in Figure 1, but it is often not possible in practice. And while it may be expected on a priori grounds that unregulated markets will fail to attain $\hat{Q}$, it is extremely difficult to judge how to attain $\hat{Q}$ through regulation. This paper has discussed how economic analysis can contribute to improved regulation of agriculture. There are several respects in which regulatory research differs from the applied econometrics usually undertaken by agricultural economists: (*a*) More detailed knowledge of structural relationships is necessary to estimate the distribution of gains and losses from market intervention than is necessary for price forecasting; (*b*) Concentration on hypothesis-testing based on rejection or failure to reject a null hypothesis often does not help in regulatory matters where the issue is choice among two or more regulatory proposals; (*c*) The audience for regulatory research is often not composed of professional economists familiar with agriculture. Communication of results and the arts of persuasion play an even larger role than usual. One needs to avoid jargon like a plague and base results on self-contained reasoning, not on unstated theories or doubtful assumptions whose failure would negate the conclusions reached.

The discussion of the preceding and related issues in this paper has been more sketchy and impressionistic than one might prefer. This reflects not only the limitations of the author but also the state of flux in the subject. It is perhaps the most exciting and promising area of research in agricultural economics today, because there is a strong demand for economic analysis in the area and because a substantial supply of analytical techniques that hold promise have not yet been systematically applied. I would go so far as to say that in the coming years the standard core of material that goes under the label of agricultural economics will be substantially changed, and that economic research on regulation and political economy in general will be at the center of this change.

The Economics of Regulation: A Critique

Jane Campana

Not since the 1930s have we been involved so intensively with the manner in which regulation affects the economy; not since the New Deal have we had occasion to re-examine the scope and complexity of regulation as it affects our economic activities on every level.

I cannot begin to pinpoint the cause of the current concern about pervasive government regulation. Perhaps many of the regulatory institutions themselves have been rendered obsolete by changed economic conditions. Perhaps the social acceptance of economic regulation has spurred firms in specialized sectors of the economy to compete not in the actual marketplace, but in the regulatory marketplace, and government in general has been only too happy to respond to their interests. Certainly, during the last decade, recognition of the need for new social goals such as a cleaner environment, avoidance of an energy crisis, safer foods, drugs, and working conditions has left in its statutory wake a plethora of regulations that impinge on every kind of economic activity.

In any event, the public's recognition of the scope and complexity of economic regulation is growing daily. And common to both the public at large and to the "regulatory community" is the perception that the lawyers are responsible.

No self-respecting lawyer would decline the chance to assume major responsibility for the mechanics of a regulatory scheme, although he or she might decline to criticize some of the particulars on the grounds of professional courtesy. It is true that, in many areas of economic regulation, the policy behind the regulation, as well as the manner in which it is applied and its subsequent tests of validity in the courts, has been largely controlled by lawyers. Whether we should perceive this control as bringing a flow of benefits to lawyers to the detriment of society in general is a question that could be endlessly debated. Personally, I would not trust an economist to do that analysis.

However, economists are beginning to have an expanded role in current regulation. This does not mean just analyzing the nuances of established regulatory schemes, but also determining whether a regulation is necessary or beneficial in the first place. This is as it should be. Economists have a particular advantage in taking a direct role in the regulatory process since the task is extremely technical and becomes more so each year. Moreover, the economist's role is not and should not be limited either to cost-benefit analysis or to forecasting the many effects of a particular regulatory issue; rather, economists should be prepared to make substantial contributions to the ultimate issues of public policy.

As a lawyer who has had substantial professional contact with economists, I would not deprecate the importance of the increased role of economists either in assisting the regulatory process in a technical sense or in the formation of basic policy. In the former role, there is no question that, as Alfred Kahn has observed, lawyers who do not seek the cooperation of economists cannot understand what their opponents' witnesses are saying (p. 15). In the latter role, bearing in mind that value judgments are implicit in applied economic theory, there is no reason why economists are not at least as qualified to render judgment on issues of public policy as are lawyers, politicians, and other social scientists. Besides, most lawyers generously would make room for economists to share their role as the bearers of bad news.

The Role of the Economist versus the Role of the Lawyer

However, as a lawyer by training and an economist by marriage, I do have some observations which I would like to share with you today on the respective roles of lawyers and economists in the regulatory process.

For the purpose of a tidy analysis of those roles, it is tempting to try to distinguish between those situations in which economic re-

---

Jane Campana is an attorney, Office of the General Counsel, Council on Wage and Price Stability, Washington, D.C.

search is used to provide technical expertise, and those situations, increasingly frequent, where economic research and principles play a major role in policy formation. The fact that such a distinction cannot be drawn easily reveals two fundamentally different views of the economics of regulation; first, the lawyer's perspective of regulation as a process. And, second, the economist's perspective of all regulation as having economic consequences, if not economic purposes.

Lawyers are indoctrinated in process: its origins, its use, and somewhat peripherally, its ends. For the origins of the political process, a lawyer would look to the Constitution whose relevant interpretations are mostly in the realm of procedure.

The concept that economic regulation does not violate the due process clause of the Constitution, as long as it is properly delegated and reasonably related to a legitimate legislative purpose, is so firmly embedded in the constitutional law of the last seventy years that it needs no discussion here. Suffice it to say that a lawyer's view of regulation as a product of the political process is logistically grounded in constitutional law and that constitutional law provides no guidance about the substance of economic regulation. It dictates only the procedural safeguards without which that regulation would be found deficient on grounds of procedural due process.

Procedurally, regulation in the traditional sense is derived from statutes enacted by Congress. However, as anyone who has observed the workings of Washington can readily tell, regulation is a rather complex process in which particular legislative provisions are often not the results strictly of congressional initiative but are instead responses to the initiatives of regulated industries, public interest lobbies, agencies created to handle already-existing regulatory schemes, or the executive or judicial branches, all of whom may in turn derive their initiative from any of the others.

The political constraints on the use of economic research are part and parcel of the origins of economic regulation. Since that subject could occupy the entire career of a political scientist, I will not attempt to deal with it here.

However, it is obvious that the process of creating economic regulation is one in which economic principles can be and increasingly are applied freely. It is at this point that the economist's perception of all regulation as having economic consequences, if not economic motivation, can come into play most freely.

Until a regulatory scheme is enacted, its motives and its probable consequences can and should be closely scrutinized from every angle. And there is no reason for this process to stop once the regulation is enacted. The results of economic research can be applied fruitfully when legislation is designed neither to control a market nor to address itself directly to any particular economic goal, but to achieve instead a result whose economic consequences are unlikely to be perceived. I am speaking of legislation designed to achieve social goals, like clean air or safe food and drugs; to eliminate inequities, like civil rights legislation, and to set minimum standards, like that which regulates professional groups.

The Economist's Role in Developing Legislation

Using economic analysis in creating these types of legislation often has been ignored. Instead, this analysis has been treated either as an interesting but unnecessary perspective, or flatly rejected in favor of advancing an overriding legislative purpose. Even now, the procedural bias of lawyers and legislators is apparent and can condition or defeat the use of economic analysis.

Let us look first at the role of economic analysis in developing legislation to set minimum standards for professional services. One such statute, which I have had the bad luck to encounter, is a state statute requiring barbers to be licensed. I am sure this statute was enacted largely to enhance the status of barbers in the state. Legislators would claim that the purpose was to protect people from having their hair butchered by incompetents or touched by felons. Economists would say that the statute's purpose was to restrict entry to the profession and thus enhance the incomes of those already in it.

The statute says that barbers must receive licenses before they can practice their art, and that in applying for the license they must state that they have never been convicted of a felony. I am sure that no study of the supply of barbers in the state or the demand for their services was done when this legislation was enacted, nor, to my knowledge, has one been done since. Nevertheless, the state legislature, in its infinite wisdom, several years later decided that the state did not have enough

trained barbers and there were a lot of inmates in the state prison who should be taught a useful trade. Given this woeful clash between legislation restricting the supply of barbers and legislation designed to expand the supply of barbers, the inevitable happened.

My client was, of course, a convicted felon who had been trained as a barber in the state prison, but was unable to receive a license from the Board of Barbers. In this particular instance, as in so many others, procedure provided the solution. The Board of Barbers, for the first time in its history, convened to hear an appeal and, even though the rejected applicant originally got his felony conviction for robbing the house of the Chairman of the Board, the Board ultimately granted his license. The point of this story is that the legislature never understood the economic consequences of the law's enactment; legislatures routinely pass laws designed to set minimum standards for professional and other groups and rectify what they perceive to be inequities without perceiving that there are economic consequences.

Of course, economic theory also can be used to justify legislation enacted to correct inequities. For example, courts which were asked to decide whether the government could extend the mandate of the Civil Rights Act through the use of procurement power relied heavily on a purely economic argument. That argument was that, since the effect of applying the Civil Rights Act to government procurement would be to expand the number of qualified applicants in the labor market, such an application would promote economy and efficiency in government. This was not the stated purpose of the Civil Rights Act nor of the Executive Order that applied it to government procurement, but research elaborating on its economic effects was instrumental in the subsequent tests of its validity.

The use of economic research in legislation primarily designed to further social goals, particularly environmental goals, is currently an area of great concern. It is in this area that a purely procedural orientation interacts most strongly with the perception that economic consequences inevitably result both from the passage of such legislation and its subsequent implementation through agency regulations.

The first battleground is the creation of the legislation itself. In recent years Congress has exhibited two conflicting tendencies in enacting legislation, both of which have many implications for the application of economic research. On one hand, Congress has made sweeping policy assertions with little guidance to the agencies created to carry out the mandate about the actual application of the policies. Two examples of this kind of legislation are the National Environmental Policy Act and the Food Additives Amendment to the Food, Drug and Cosmetic Act. On the other hand, Congress more recently has enacted legislation which so minutely details the considerations to be applied by the agency interpreting the legislation that the agency is left with little or no discretion to introduce decisional elements, like cost-benefit analysis, which Congress may not have considered.

The effect of the failure or refusal to provide explicitly for the use of cost-benefit analysis in both congressional and regulatory decision making has been to emphasize the procedural elements of the decision-making process, sometimes at the expense of the factors on which the decision is based.

Through its own rules Congress is now providing economic impact analyses for each proposed piece of legislation. However, these analyses tend to be somewhat perfunctory and often serve to deflect the basic question of whether the legislation is even necessary or desirable in the first place.

The Economist's Role in Agency Rule Making

Nevertheless, once legislation delegating power to an agency to implement a congressional mandate has been passed, the question often becomes, not what factors can be considered in implementation, but at what point in the decision-making process economic considerations can be introduced, if at all.

It is useful at this point to reflect on the notion of procedural due process as the courts have applied it. As Justice Frankfurter has said, "The history of liberty has largely been the history of observance of procedural safeguards" (McNabb v. United States). The procedural safeguards applicable to administrative agencies are expressed both in the Administrative Procedures Act and in the Administrative Law decisions of the courts. I am sure that most of you are aware of the Administrative Procedures Act, which provides, among other things, that when agencies undertake regulatory action through rule making

they must first articulate the basis for such action and then respond to public comments about it.

Economic analysis of the proposed agency action assumes its greatest importance during the notice and comment period, and it is at this point in the process that the battles over the relative weight of economic criteria in environmental decision making are presently being waged. The agency decision must be made on the basis of the record, taking into account such factors as it is allowed to consider, as expressed by the statute or in agency policy.

If a decision departs substantially from agency policy, the agency can be shown not to have taken into consideration certain factors that it is required to consider; if a change in policy is not justified by a reasoned analysis indicating that prior policies and standards are being deliberately changed not casually ignored, then the decision is vulnerable to challenge in the courts on the grounds that it is both arbitrary and capricious and also an abuse of agency discretion.

The importance of a legislative mandate to consider the costs and benefits of regulatory decisions at this point in the decision-making process cannot be stated too strongly. Even narrowly drawn acts can usually be reconciled with sound economic positions. In the absence of a legislative mandate, when an act is silent on what factors must be considered, it can be argued that economic considerations can and should be taken into account.

The timing of the introduction of the results of economic research into the decision-making process can also be critical. Recent court decisions have suggested that in certain circumstances, the record upon which an agency decision is based must be fully open to public participation and comment. Studies introduced after the close of the public comment period, if used as the basis for an agency decision, may make the decision vulnerable to challenge in the courts on the grounds that the decision was not based on the record and that there was no opportunity to counter the information presented. No court has yet struck down an entire regulatory scheme solely because an economic research study presented to the agency after the close of the public comment period formed the basis for the agency decision. However, the issue has caused agencies to draw firm lines around the manner in which information is presented to them and to define explicitly the factors which constitute their decisions. Until the issue is fully litigated, the procedural boundaries will be even more narrowly drawn.

It is to be hoped that one side effect of these developments will be an improvement in the quality of economic research. As economic considerations play an increasingly important role in agency decisions, the research in which these considerations are expressed will become more important and be the subject of more public scrutiny.

This brings me to my final observation. So far I have talked about three kinds of regulation: regulation designed to set minimum standards, regulation designed to rectify inequities, and regulation whose purpose is to promote broadly-stated social goals. I have not yet mentioned regulation which is designed primarily to foster economic goals.

This area is, more than any other, the realm of the economist. The decision about whether or not to regulate is one founded on economic theory (albeit not without value judgments), and the fashioning of such regulation is dictated primarily by economic principles. However, the lawyer still plays a rôle.

The Lawyer's Role

A lawyer's perspective is necessary here for two reasons: first, to introduce and ensure the maintenance of those aspects of procedural due process that are common to all regulation and second, to translate economic concepts and regulations into words.

If the central feature of economic regulation per se is the influencing of behavior in the marketplace, then the central feature of the mechanics of any regulatory scheme, the notion of due process, is that much more important. Regulation which proscribes or constrains behavior should always be preceded by public notice and an opportunity to be heard. To the extent that advance notice would cause the very behavior that the economic regulation is trying to prevent, a conflict between the concept of due process and the purpose of the regulation is inevitable. How, for instance, can even a voluntary pay or price standard be announced to take effect prospectively, without causing anticipatory pay and price increases of the very sort that the standard is designed to discourage? And how, in general, can any comprehensive economic regulation be implemented without retroactive conse-

quences, rendering actions which people have already taken unprofitable, risky, or even illegal?

As Alfred Kahn has observed; ". . . in a society that profoundly respects the institution of private property, the initiative, operating control, and responsibility for economic performance continue, even under regulation, to rest primarily with private management. The role of the government remains essentially negative: setting maximum prices, supervising expenditures, specifying minimum standards (for products or services), in short, contravening the decisions of private persons only after the fact, only when their performance has been or would otherwise be obviously bad" (p. 18). In essence, the economist's desire for an efficient marketplace, for the preservation of freedom of choice in the marketplace, and for other economic goals can and often does conflict with the lawyer's desire for a fair and orderly process by which decisions are made and conflicts resolved.

The final point I would like to mention concerns the lawyers' role in translating economic concepts into economic regulations. There are some who have claimed that lawyers have never been very good at written English. However, it is also undoubtedly true, that words are the lawyer's stock in trade. A lawyer would rather face a page of fine print than a single algebraic formula. When it comes to the job of writing regulations, neither fine print nor algebraic formulae are entirely satisfactory. Even if a regulated industry can survive on the precise guidance that statistical tables, square root signs and other incantations can provide, in the final analysis economic regulation, its concepts, and the manner in which they are applied must be comprehensible to a judge and sometimes to a jury as well. Economic research, which forms the basis for decisions must be equally comprehensible, lest it be ignored by those unschooled in such things as the techniques of quantitative multivariate analysis.

In short, both professions come to the process of regulation armed with the respective jargon of their trades. It is the task of both professions, and it is not a small task, to demystify the theory and the application of economic regulation. While this partnership will not be without tension, it has every promise of being extremely fruitful.

Regulation and Economic Analysis in the U.S. Department of Agriculture

Howard W. Hjort

We in the Department of Agriculture (USDA) are proud to co-sponsor this conference with the Farm Foundation, the American Agricultural Economics Association and the Food System Research Group (NC-117).

I understand that the proceedings of this workshop will be presented as a special issue of the *American Journal of Agricultural Economics*. This is as it should be. The topic for discussion at this session is important. Given the policy setting, it is essential that we talk about the need for objective assessments of regulatory actions.

Your conference program reflects a broadened view of the regulatory process. It evidences a recognition of the legal and political aspects of policy decision making. It establishes a challenging research agenda—one that, as accomplished, will help to shape the regulatory process.

There was a time when food system research economists interested in regulation thought primarily of measuring the costs of rules that somehow interfered with market processes. The topics were narrowly defined. The increased costs associated with environmental protection and worker safety were routinely assessed. Less routine were studies to assess benefits. Until recently, commodity policy research was not considered as regulation research. But the policy setting today makes such a broadened view essential.

The Policy Setting

The past several years have been characterized as a time of opening of the public decision-making process. The broader involvement of interest groups in issues dealing with the environment, work conditions, health and safety and the extent of competition in industry is a reflection of this changed policy setting.

Howard W. Hjort is Director of Economics, Policy Analysis and Budget, U.S. Department of Agriculture.

For agriculture, this opening of the decision process has resulted in broadening the scope of the issues routinely considered. More and more, the focus of the policy problems we deal with is on food. The food policy we talked about developing just a few years ago is quickly evolving. The concerns of Congress are also more food oriented—and Congress increasingly relies on economic information in making decisions.

The Congressional Budget Office, the House and Senate Budget Committees, the General Accounting Office and the Congressional Research Service, to name a few, are all adding to the analytic process.

This evolution of the policy process is putting intense pressure on the traditional institutions. Regulatory agencies, once comfortable in working closely with those being regulated, are opening the process to others affected by their decisions. The system is beginning to recognize that all decisions imply gainers and losers, and that both parties need to be involved in the decision process.

The Department of Agriculture's Response

The USDA, as a cabinet-level department involved in regulatory decisions, is responding in a positive way to this changed involvement. We are shaping the day-to-day operating procedures in a way that helps us make better decisions by incorporating information from all affected parties.

Early on, we established a framework for obtaining and using input from the public. USDA's Office of Public Participation is housed in the Office of the Director of Economics, Policy Analysis and the Budget.

Public participation in government decisions serves two important purposes: (*a*) It is a source of information for decision makers on attitudes and alternative approaches to proposed programs; (*b*) It assures the public, by means of an open decision process, that government actions are properly conducted.

It is important that public participation be viewed as an integral part of the decision-making process. It is also constructive to state what public participation is not:

(*a*) It is not public relations or the publicizing or promotion of agency programs.

(*b*) It is not a one-sided process of seeking support for agency positions.

(*c*) It is not a ritual fulfilling of a requirement. Unless the public input is analyzed and used, the legal requirement is not truly met.

(*d*) It is not a poll on whether a statutory authority should be carried out. The quality, not the quantity, of the comments affects the decision to be made.

The decision calendar, which is now made public, also helps open up decision making. Those likely to be affected by our decisions are now informed as to when a decision will be rendered.

In addition, impact analysis now is required for all regulatory decisions. This analysis is reviewed and must be approved on all major regulations in the Office of the Director of Economics, Policy Analysis and Budget.

These impact statements are taken seriously—they are not simply perfunctory statements which meet some legal requirement. They are the record of how the decision was made. They show the alternatives considered and the projected impacts of the action.

Every decision by an executive agency constitutes a part of the record of the administration of the incumbent President. President Carter has extended his oversight to all government regulations, major and minor. He has established oversight mechanisms to focus on the number of regulations, their necessity, their burden, their clarity, and their impact on society and the economy (see Appendix).

The need for analysis as the documentation of the basis for decisions or programs is a more recent requirement than the established clearances for legal authority or budget authority. It has become necessary for two primary reasons: (*a*) because the volume of administrative rule making has become so large that restraints on arbitrariness are absolutely essential, and (*b*) because secondary impacts of federal actions can be as far-reaching as the primary benefits and both must be understood.

An adequate impact analysis forms the decision record. It provides the preamble for public notice, it responds to public comment, it documents environmental impact assessment and other required analyses and incorporates by reference other studies, consultant reports, transcripts or memo records of meetings.

Finally, in the Working Group on Food and Agricultural Policy, representatives from across the government are involved in discussions where options are considered. This way we are able to ensure that the broader national and international issues are considered before a decision is made.

Role of Economic Research

As should be obvious, such a process puts increased pressure on the product of our economists. They too are challenged to broaden their perspective—to consider the public good.

In a process such as I have described, the advocacy groups cannot be relied on for objective analyses—such analysis is often not in their best interest. Even if the research they do is objective, it is likely that those with opposing views will be successful in reducing its credibility.

Such a setting then gives rise to the need for more involvement from public sector analysts. Such analysts are in a unique position to improve the decision process.

Issues can be identified, and potential adjustment costs made explicit and public prior to the debate.

It is not our place to dictate social or political objectives—that is a task for the political system. However, once the goals and objectives have been voiced through that system, economists can identify and evaluate the economic consequences implied by the options for achieving those objectives.

We have a responsibility to influence the policy agenda by conducting good research and communicating the results in a way which brings significant economic issues to the public's attention. Innovation and creativity are vital in policy analysis.

ESCS Expands Research

To that end, we have redirected some of the resources in ESCS to research on topics dealing with contemporary regulatory issues. At the present time, we are involved in cooperative efforts with the Food Safety and Quality

Service (FSQS), the Food and Nutrition Service (FNS), and the Extension Service, to mention a few.

In each case, the research is designed to improve the public's understanding of USDA's regulatory actions and to help make the trade-offs clearer.

Presently, for example, we are:

(*a*) establishing a monitoring program to help the Secretary of Agriculture determine whether cooperatives are unduly enhancing prices;

(*b*) conducting the Department's study of the net weight labeling proposal;

(*c*) involved with FSQS in a task force effort to assess meat and poultry inspection issues;

(*d*) participating with the Land Grant Universities in the Food System Research Group (NC-117) effort; and

(*e*) evaluating the meat pricing system.

In addition, there is an increase in resources for food safety and quality research in the President's fiscal 1980 budget.

Studying the Cumulative Impact is Important

An important but often neglected aspect of regulatory research involves the identification of cumulative impacts from the entire set of policy actions.

The Carter Administration is now involved in a major effort to slow the rate of inflation in the general economy. Since regulatory actions are often designed to internalize costs, thus resulting in increasing the accounted-for costs of producing a unit of output, their effect is often to put upward pressure on prices.

It is essential therefore that the extent of the cost-increasing pressure for each issue be known prior to making the decision.

Perhaps more important, but often overlooked, is the cumulative impact of all such decisions. Given that we have an issue-specific political advocacy process, such analyses take on added significance.

Perhaps a good example is the structure of the farm sector. For many years, our farm programs have been justified on the basis of a policy desire to "save the family farm."

There is little disagreement with a national objective of encouraging a family farm system. But the cumulative effect of our farm programs may well have been to hasten the concentration of the farm sector: (*a*) Federal tax policies provide incentives to purchase land and hold it as a hedge against inflation. (*b*) Commodity programs, too, primarily because the benefits are based on the volume of production, may have provided relatively more support to the larger farms. (*c*) Even the benefits of our Land Grant University and Extension Service programs may have gone disproportionately to those we least intended to help.

The Secretary of Agriculture has identified the farm structure issue as one of the highest priority. Recently, he called for a "full scale national dialogue" on the issue.

The structure issue is a regulatory issue. I hope you will give it consideration as a high priority research problem.

Concluding Comments

About a year ago we sponsored a series of food policy seminars. The focus of those sessions was on the food assistance programs.

This conference addresses another of the important food policy issues. In most cases, regulation research is simply policy analysis. Many of you have been involved in policy work for years. You have the tools and the experience. We look forward to working with you.

Appendix

Evaluation Criteria for Executive Order 12044: Improving Government Regulations
Office of Management and Budget (OMB)
April 10, 1979

The President has directed OMB to report semiannually on the effectiveness of Executive Order 12044, "Improving Government Regulations," and agency compliance with its provisions. The evaluation plan outlined here will focus on the five essential goals of the Order:

I. Effective senior-level policy oversight
II. Increased public participation
III. Better and more useful analysis
IV. Periodic review of existing regulations
V. Increased simplicity and clarity of regulations (plain English)

The evaluation plans outlined here give agencies an opportunity to review and critically assess their own performance in these five areas and to provide OMB with documentation of their accomplishments and shortcomings.

In addition, OMB will conduct case studies, from time to time, of individual regulations to determine whether they were developed according to the letter and spirit of the Executive Order.

We will also seek comments from the public on specific agency practices and the effectiveness of the Order in general.

I. Effective Policy Oversight

The Order requires heads of agencies and policy officials to exercise effective oversight of the development and implementation of agency regulations. This requirement is intended to raise the level of regulatory decision making within agencies so that policy officials with broader perspectives and responsibilities can balance the other more parochial interests of technical staff. We believe that more effective policy oversight is the key to the implementation of many of the other provisions of the Executive Order, such as regulatory analysis, public involvement, and clarity. Without it, realization of the other objectives may be impossible.

There are three stages at which the Executive Order requires policy-level oversight for significant and existing regulations:

1. Approval of the semi-annual agenda of regulatory actions;
2. Review, before development begins, of the issues, the alternatives to be explored, plans for obtaining public comment, and target dates for completion of each step in the development process; and
3. Approval before final publication.

The most useful appraisal of agency compliance with this provision should come from case studies of selected regulations, from frank appraisals by the agency staff, and from information supplied by members of the public. Agencies are required to describe in detail several examples of how they carried out this provision of the Executive Order for their significant regulations. Agencies should also tell us, using examples, the effects of this provision of the Order: What major recommendations were disapproved at the policy level? What improvements, if any, were made as a result of better policy oversight? If delay was a problem, agencies should describe those cases in detail, including the reasons for delay and whether or not the quality of the regulation was affected.

OMB will conduct case studies of the development of selected new regulations and the review of existing ones as a supplement to these agency reports. These case studies will enable us to make objective, informed judgments on the effect of the Order and Individual agency performance.

II. Public Participation

The Executive Order requires that the public be offered an early and meaningful opportunity to participate in the development of agency regulations. In the past, regulatory proposals have not always reached the public in a timely, informative manner. The requirements of the Executive Order are intended to ensure that the people who are affected by the regulation—those who pay the costs or receive the benefits—have an opportunity to alert federal regulators to the effects and potential problems of the proposed regulation.

To give the public adequate notice, the Order requires agencies to publish at least semiannually, an agenda of significant regulations under development or review. In addition, the Executive Order encourages agencies to achieve greater public participation in several ways: (1) by publishing an advance notice of proposed rulemaking; (2) by holding open conferences or public hearings; (3) by sending notices of proposed regulations to publications likely to be read by those affected; and (4) by notifying parties directly. Agencies are to give the public at least 60 days to comment on proposed significant regulations, except in certain rare instances. This requirement is intended to improve agency decisions by giving the public more time to prepare informed comments.

In their progress reports, agencies will describe, using specific examples, what methods have been used to publicize proposed agency actions and to solicit public comments. Agencies should further describe: (1) which approaches (e.g., hearings, public notices, etc.) resulted in the most useful comments, (2) which were largely unsuccessful, and (3) why.

Agencies should also describe whether expanded opportunities for public participation were given as a general rule, only occasionally, or just in certain cases, such as for proposals with major economic effects. Have efforts to increase public participation resulted in a wider variety of respondents (e.g., more individuals, businesses, state and local governments)? If public comment has increased, has this helped or hindered the agency? How? Where possible, agencies should give examples of significant actions taken in response to public comments, such as withdrawal of a proposed regulation, major changes in the number of people or businesses affected, or significant reduction in cost.

III. Regulatory Analysis

Regulatory analysis is intended to focus agency attention on the economic consequences of regulatory decisions and to ensure that intended regulatory goals are achieved effectively at the least cost. The Executive Order requires agencies to prepare a regulatory analysis for significant regulations which are expected to have major economic consequences for the general economy, individual industries, geographic regions or levels of government. These analyses are to be made available to the public.

While we will be tracking the agencies' regulatory analyses, each agency should provide its own assessment of how this provision worked. Were the analyses, as a rule, completed early in the formulation stages of a regulation? Was the least burdensome of the acceptable alternatives chosen? If not, were reasons provided to the public? Agencies should discuss and provide examples of how the

analyses did or did not contribute to the formulation and design of the regulation. For example, where in the agency were the analyses prepared, by program people or by a special analytical staff? If this varied, which approach was most useful and why? Who in the agency found the analysis to be most useful—program managers? Management analysis staffs? Policy-level decisionmakers?

IV. Existing Regulations

Agencies are required to review periodically their existing regulations to see whether each is achieving the policy goals of the Order. Those reviews are subject to the same procedural steps outlined for proposed new regulations. They are intended to help weed out unnecessary regulations and to improve essential ones. Agencies should report how effective their reviews of existing regulations were. We would like to know what difference their reviews made. For example, were unnecessary paperwork requirements eliminated? Was the meaning of the regula tion clarified? Were better, less burdensome regulator approaches discovered and implemented? Were any regu lations recommended for outright elimination?

V. Plain English

So that individuals who must comply with regulation understand them, the President has directed agencies t write regulations as clearly and simply as possible. Al though this is an extremely important requirement of th Order, plain English is difficult to define and measure Some regulations must be written in technical language but at a minimum, the preamble should be clear and un derstandable to the lay reader. We would appreciate hel from the public and the agencies in identifying especiall good and especially poor regulations. We will report to th President which agencies continue to issue confusing reg ulations as well as identify those agencies that issue ex ceptionally clear and well-written regulations.

Politics and Regulation
(Richard King, North Carolina State University, Chairperson)

The Politics of Policy Analysis

Nina Cornell

What I would like to do today is to share a little bit of my experience in trying to influence policy, and to share with you some of the things that I have learned about trying to influence policy through using analysis.

Let me start by laying out explicitly a couple of my assumptions. I am assuming that by policy analysis we really mean economic analysis directed to policy issues. And, I am going to make clear that I am confining my remarks to the regulatory context. By that I do not mean the context in which we find out what legislation ought to be passed to set the framework for regulating in any particular area. I mean the context in which an agency starts to exercise its discretion to deal with any particular fault, problem or issue for which a regulation or a set of regulations is required by law.

Politics really seems to me to mean having some influence in making changes—in other words, communicating and winning. I am going to discuss both because maybe they do not mean the same things any longer to me that they mean to people outside of government.

I think we have to realize the facts of life. First of all, policy analysis can come either before or, unfortunately, after a decision has been made. If after, no politics really are involved. In that situation, the decisions on the policy and the regulation already have been made, and policy analysis is just window dressing to try to justify the decision after the fact.

I really want to address the rest of my comments to the case where policy analysis is truly coming before the decision or, more accurately, before each stage of the decision because there usually is not just one decision point. In the case of regulation, by which I mean rule making either formal or informal, you start with a notice of proposed rule making, and hearings are held at several stages along the way before final rules are issued. During this period, everyone has the opportunity to influence the final decision.

Nina W. Cornell is Chief of the Office of Plans and Policy, Federal Communications Commission, Washington, D.C.

Communicating

When I talk about communicating and having influence, they really mean the same thing. Effective communication enables you to influence somebody. There are some essential keys to effective communication.

First, no jargon. I cannot tell you how many people walk away the first time you say marginal costs. They do not know what it means and trying to define it after you have used the word marginal is far worse than never using the word at all. Start with what you say it equals and never mind the jargon. You can bring that in later. Second, in trying, at an early stage, to get a decision maker to start looking at what ought to be done and how the problem ought to be structured, keep it as brief as you possibly can. Third, make sure that what you tell the decisionmaker at that stage is relevant to the decision. It is not the stage for a long history of the affected industry. He or she does not have time.

Knowing the Law

The next thing about politics or influencing decision making is being conversant with one particular basic law. It is important to know not only the law that sets the regulatory framework, but also the Administrative Procedures Act, because every rule and regulation has to conform with it. Most important is to understand the standards set by that Act for judicial review of an agency's action.

Informal rule making involves putting out a notice of proposed rulemaking and asking for

comment. This is called notice and comment rule making. The standard of review for this kind of rule making requires that whatever decision is made must not be arbitrary or capricious based on the record available to the decisionmaker. I stress that because it brings us to the question of what the record is, how important it is, and how valuable it can be for the policy analyst to know how to use the record. With that knowledge, the analyst can push a decision in the direction he or she thinks the decision ought to go. The record is equal to everything filed in a docket, which is the way agencies usually refer to any formal or informal rule making. The record is everything filed by outsiders in response to a proposed rule making in the *Federal Register,* plus any in-house studies performed. People will send in comments by the deadline, there will be reply comments after another deadline, and maybe another round of answering each other's comments. Everything the agency has analyzed is made available to the decision maker up to the time the rule is promulgated; anything received after that cannot be used by the agency to justify a decision. The decision must be made on the basis of the record available to the decision maker at the time he or she finally says, "This is the rule I am going to put out."

Formal rule making has a higher standard. It has to be based on the *preponderance* of evidence in the record before a decision maker can make a decision. That is why we find that formal rule makings usually involve such things as adjudications or license grantings. We see a lot of that at the Federal Communications Commission (FCC). When you cannot tell clearly which of the two candidates is most qualified to get a single license, a formal adjudication can go on for years because the preponderance of evidence on the record must support your position or else you get taken to court. And the court will say that you did it wrong; you should go back and do it again. So it goes on forever. We have license cases that go on for seven or eight years because you are trying to count how many angels dance on the head of a pin—you have to have a preponderance of the record on your side.

Informal rule making applies to most of the major regulations—the ones which have major economic impact usually involve informal, not formal rule makings. One way to characterize these cases is that the decision must fall in the realm where reasonable men can reasonably disagree. The first rule for economists in dealing with lawyers is to come to understand somehow why it is that lawyers think that the word "reasonable" is very precise. They think that when I talk in economic context I am being very imprecise, but they will hold up a reasonable standard as something very concrete and rigid.

If you understand all this, if you really can put those pieces together, you can apply this to make a difference in the decision.

I am going to pick an agricultural example, though I have very little background per se in agriculture. Take an agency facing the question of whether to ban or curb the use of nitrates and nitrites in bacon. You want to be sure that the decision is economically based. My basic definition of economics is that, in a very fundamental, not necessarily quantifiable way, economics means looking at costs and benefits. Efficiency is achieved when the benefits exceed the costs. If you have more than one choice, you pick the one that has the largest excess of benefits over costs. Again, I do not mean that in a quantifiable way. I am not here to argue about what is the proper social rate of discount or any of those other quantifying problems that arise in numerical cost/benefit analysis. A decision like the nitrite/nitrate-in-bacon decision, however, should be based on a clear understanding of the costs and benefits: what will it cost if we take them out versus what will we gain if we take them out.

Suppose you, as an analyst, are starting that one from the beginning. The first thing to do is to lay out to the decision maker a brief jargon-free memo that tells him or her what this question really involves. The question is whether or not we continue to allow nitrates and nitrites in bacon, and the decision maker has some very real choices. It may be that the choice is no additives and no bacon versus bacon and additives. Or, the choice may be no additives and very high increases in the cost of bacon versus continued additives and continued low-cost bacon. Or, it may really be no additives at the cost of a one-time change in the way bacon is processed, a short-term rise in price, but maybe no long-term real rise in real terms in the price of bacon. In other words, it may mean only a temporary disruption to the industry.

You will have to be credible as you write that memo. If you predict how the public is going to react—the extremes from Ralph

Nader and the public interest law firms on the one hand, and from the bacon industry on the other—you may display how reasonable you have been in comparison to those extremes. You will have predicted accurately what is going to be said once the proposal becomes public.

Using the Record

This kind of regulation has to be done through a notice and comment rule making. After the decision on what is to be put out for public comment has been made, it is important to be conscious of what the record means to the decision. It is now time to do a detailed analysis of the costs and benefits, particularly the future costs and the future benefits, and to make sure it gets into the record. Put it out for public comment. A lot of economists really do not want their analyses out for public comment. They are concerned that every detail in their analysis may not be correct. You can always put it out with caveats—that it is a draft, noting that all the numbers have not yet been checked and that indeed there is further work to be done.

At this point, it may not get you an "A" as a term paper, but it can have an impact. If you put it out for comment, even as a draft, and people comment on it, you then multiply the amount of the record that deals with the set of issues that you believe ought to face the decision maker. You have taken that record and made it focus on the set of issues that you, as a policy analyst, think are the important issues. As a result, the decision maker will have to focus on the issues and the kind of cost/benefit approach that you are trying to introduce in the process of doing policy analysis. You are making the record work for you.

There is another point I want to make. Speaking as the economic historian I once was, I can say very forthrightly that this still is not the time to do an accurate economic history of hog production since 1900. It will have little role in the decision process. It may be excellent economic analysis, but it is not policy analysis. That goes back to my comment about the future costs and future benefits. It may be that a policy analyst will find an accurate detailed economic history of hog production since 1900 to be very useful. It will tell the policy analyst what options are viable or not viable based on past experience. And it will also help the analyst to figure out some of the costs and benefits that he or she may not have thought about. But it is not policy analysis. It may be the raw material, but it is not policy analysis.

Burden of Proof

In addition to using the record and the Administrative Procedures Act and the standards of judicial review, you should be aware of the importance of where the burden of proof lies. The person who has to prove something is always at a disadvantage compared to the person who can sit back and wait for it to be proven. Therefore, the way the decision choices are structured, both for the decision maker and in a notice and comment period, makes a big difference to the outcome.

To go back to the blatant example of the nitrites and nitrates in bacon: if the burden of proof were on proving nitrates and nitrites safe, we would have seen bacon without nitrates and nitrites on the shelf at the first mention of possible risk. Whether that is good or bad is something I am not addressing here. The point is that it is very tough to prove safety beyond a shadow of a doubt. Even to prove something harmful beyond a shadow of a doubt is quite difficult and takes quite a long time, although it is easier. If you had to prove nitrates and nitrites safe they would be removed immediately and they probably would be out for a long period of time even if ultimately they were proven safe and let back in. Our system, however, leaves them in until proven harmful, so they have stayed in for a long time since the questions were first raised.

For a more subtle example, I will turn to the field of communications. The Federal Communications Commission has issued a Notice of Inquiry, which is something like an Advanced Notice of Proposed Rule Making in which the Commission, because of court decisions, is looking at the question of whether there should be open entry or restricted entry in the provision of simple long-distance telephone service. It is an either/or situation. You have open entry or you have restricted entry. Restricted entry is what we had until the U.S. Court of Appeals of the District of Columbia ruled that the FCC did not have the right to prevent entry unless we made a public interest finding that monopoly was in the public interest.

If the court had made the other finding, there would still be restricted entry, and it would go on for years while interested parties tried to make the case that competition was more beneficial. In the total absence of data—because the available market data is past data based upon restricted entry and upon obsolete technology—we would be trying to argue something that cannot be proven. And it would be litigated. If we tried to do it, we would get litigated and litigated, and maybe we would finally win and finally be able to open entry.

But the court reversed that by saying that the FCC had to permit open entry unless we made a finding that monopoly was in the public interest. Suddenly the burden was on the other shoulder. It was up to those who wanted restricted entry to prove that it was in the public interest and beneficial. Now they find themselves with stacks of past data based on obsolete technology. So it is not going to be very useful for them to talk about what it would be like in the future if we restricted entry and allowed only one provider of long distance telephone service.

Notice how different the outcome is now likely to be. It will still get litigated unless Congress succeeds in settling it legislatively by amending the Communications Act this year, and it may get litigated even so. In the meantime, there is going to be open entry while those who want restricted entry continue to litigate. If the burden of proof were still on those who want competition, restricted entry would stay in effect until the litigation ended. You should not underestimate the power of putting the burden of proof in one place or another. It may be one of the most important factors in determining what decisions get made.

Strangely enough, one of the most important factors in making policy analysis influence decisions has to do with bureaucratic structure—in particular, the bureaucratic relationship of the analyst to the decision maker. An economist or a policy analyst wants to have an impact on the decision. It is most important that the decision maker has a stake in the work that the analyst does. The best way for that to happen is for the analyst to work for the decision maker. Because, then, as that analysis becomes public, the decision maker, as the boss, has to stand up for the work his or her staff has done. The decision maker has a stake in it; it is important. The worst bureaucratic relationship is for the analyst and the decision maker to be co-equals reporting to separate bosses. Then the decision maker has no accountability—no stake in that analysis. Therefore, there is no real reason that he or she has to take it into account, stand up for it, defend it, answer to it. Earlier I heard a speaker talking about analysis, bureaucratic structures and so on. They are important and they do make a difference to the decisions that are made.

Winning

At this point, I would like to talk a little bit about what winning means around Washington. The first rule of Washington is that nobody gets everything they want all the time. And, in many cases, getting the decision in a regulatory context based on a full cost/benefit analysis is a massive victory. More of them are happening in Washington every day, but it still amounts to a massive victory. A full analysis means including the costs to society not just to one industry or one part of an industry. It looks into the future not just the present and the past. It looks at all the benefits to society, again not just to one small group or one small class. It has to deal with who wins and who loses all across the board.

The second thing about winning is attitude on the part of the analyst. To keep one's mental health in Washington, one has to be able to see glasses as half full rather than half empty. I hope I have outlined ways in which to make glasses slightly more than half full.

Economists, Regulation, and Public Policy

R. James Hildreth

A number of laws establish regulations that apply to the food and agricultural industry. These regulations reflect public policy regarding the physical, social, and economic environment within which the industry operates. As Jim Shaffer has stated: "Economic regulation results from the attempt of citizens to articulate preferences about the physical and social environment they share. There are many problems in the articulation of preferences by both market and political processes. Economics supposedly deals with the mechanism for expressing preferences as guides to production of goods and services . . . There are no simple solutions to the problems associated with the enactment, design, implementation and evaluation of economic regulation. But it is possible to provide understanding which can lead to improvements in the regulatory system and performance of the political economy" (p. 5).

This paper explores the role the economist should play in the process of establishing public policy that regulates the food and agricultural industry.

The Changing Regulatory Process

Until the past few years, it was fitting that many students of regulation described the political relationships between the regulated industry, the regulatory agency, and the congressional subcommittees with jurisdiction over the agency as an "iron triangle." The dominant position was held by business, but it had to operate within the discipline and constraint of the "iron triangle." It was agreed that the regulatory agencies often did not serve the public interest, but promoted special interest at the expense of the public. While businessmen would complain about regulations, they did not strongly oppose them.

While most economists agreed that the purpose of government regulation of business was to cure competitive imperfections in the marketplace, some argued that regulation was a technique firms used to escape the competitive forces of the marketplace. Most scholars recognized a comfortable and cooperative relationship between the regulator and the regulated. The congressional acts creating the regulatory agencies were general statements giving those agencies extremely broad powers, and they provided little specific policy guidance except to tell the agency to act in the public interest. Most of the agencies were organized on an industry-by-industry basis—for instance, the Interstate Commerce Commission, the Civil Aeronautics Board, and the Federal Communications Commission.

But things have changed on the regulation scene, and horror stories of regulation abound. An example was given at the 1976 Public Policy Education Conference by William Allewelt, president of a cooperative canning enterprise in California. A mold named geotrichum exists wherever summer fruits are grown, and it is impossible to avoid the mold in commercial canning operations, as well as in household kitchens. The mold is viewed as totally harmless by the industry. However, under the applicable regulations of the Food and Drug Administration (FDA), there was no tolerance for this mold. This meant that when FDA decided to be concerned about the mold, they had to enforce a zero tolerance. The cooperative was forced to move from three seven-hour shifts to two shifts working nine to ten hours each in order to allow cleaning operations to reduce the level of the mold. The estimated loss was 1,800 seasonal jobs in the communities where the fruit canning plants were located. Allewelt estimated the total cost to the cooperative for the entire incident was at least $2,000,000, eventually resulting in a loss of $500,000 for the fiscal year.

The conventional wisdom about regulation a few years ago would not have allowed for the cry of anguish contained in Allewelt's story. Weaver argues that the reason for anguish is that there is a "new regulation" which is quite different from the "old regulation."

The "new regulation" agencies were estab-

R. James Hildreth is managing director, Farm Foundation, Oak Brook, Illinois.

Many of the ideas in this paper were contained in the author's paper, "Public Policy and Regulation," presented at the Northeast Agricultural Economics Council Annual Meeting, June 1978.

lished to operate as adversaries of the interests they regulate, according to Weaver, rather than in the comfortable, cooperative relationship between past regulatory agencies and the regulated. The laws under the "old regulation" establishing the agencies were short and provided little specific policy guidance. The "new regulation" legislation is very lengthy and very specific. The possibility of capture by the regulated is minimized, since the "new regulation" agencies are organized along functional lines with their jurisdictions cutting across industry boundaries. The "new regulation" laws often give nearly any interested person a standing to sue the agency for failure to do precisely what the law tells it to do. Weaver reports that the new agencies lose most of the court cases. Further, Weaver holds that the "new regulation" agencies operate with little or no concern for the cost or consequences of their pursuit. "The EPA [Environmental Protection Agency] for instance, is explicitly forbidden by law to pay attention to the cost in setting and enforcing the nation's primary ambient air quality standards" (p. 52).

The traditional "iron triangle" is no longer at work. Many of the advocates of the "new regulation" are strong in their opposition to the "iron triangle" of the "old regulation." Should an agency appear to be operating in the mode of the traditional "iron triangle," the public interest groups will bring court suit to put the agencies back on the straight and narrow. Supporters of the "new regulation" often argue for deregulation of the airline industry, as well as of the trucking and communications industries.

The opponents of change have even learned to use the courts and the "new regulation" to achieve their ends—witness the opponents to enforcement of the 160 acre limitation on irrigated land successfully bringing suit to require an environmental impact statement on the effect of enforcing the 160 acre limitation.

The Economist's Role

Under the "new regulation," open conflict exists. The established business interest groups are screaming at the public interest groups, and the public interest groups scream back. Suits are brought in court. Charges and counter-charges between the agencies and firms are put forward.

Weaver points out that, from the point of view of political scientists and journalists, regulation is a part of the battleground for the ongoing conflict between private interest groups and the public interest. He suggests the "new regulation" may be more a social policy than an economic policy.

Under the neat economic arguments of the "old regulation," one could use data and logic to determine if the competitive market structure was flawed and then initiate regulation to modify performance. But under the "new regulation," the arguments are much less straightforward. And very little useful information goes to Congress, which could trigger changes in the laws that started the entire process.

The optimum amount of regulation is difficult to define. An attempt to internalize the external costs placed on society by the actors in the marketplace is the rationale for much of the "new regulation." Determining the optimum amount of internalization and accompanying regulation is most difficult. Internalization usually involves major changes in the property rights of individuals, as well as placing value on items that are not exchanged in the marketplace.

Is there a role for the economist in such a regulatory setting? I think there is an important role, and I will give you my views on what that role is and how it might best be performed.

The traditional public policy research and education mode provides economists with a useful approach to regulation. This mode involves defining the policy issues, developing alternatives to deal with the issues, and then predicting the consequences of the various alternatives. Economists have made major contributions to public policy developments within this framework for years. Regulation policy research under this framework can make significant contributions to the debate and dialogue. Economists can play an important role in helping to identify the critical issues, prescribing alternative approaches for handling the issues, predicting the impacts of the approaches, and assessing the degree to which regulations achieve their original objectives.

Policy research and education is often viewed as problem solving by the social science community. Much of the frustration of both social scientists and politicians is explained by this view. The question of how policy research can help policy formulation

has been examined by Rein and White. They state: "The long-standing problem-solving model is in large part a myth. Research may solve problems, but it also has three other important functions: 1) identifying problems as a step toward putting issues on the agenda, 2) mobilizing government action, and 3) confronting and settling dilemmas and trade-offs" (p. 130). They also hold that the search for an issue is the lifeblood of politics; that policy dilemmas involve a conflict of values; and that politics is quite different from science. Their ideas are cited to illustrate the validity of the agricultural policy research and education mode, which has been used effectively for decades.

Four kinds of research studies were suggested by Dale Dahl, University of Minnesota, at this conference: (*a*) Pre-legislation research—the study of the predicted consequences of alternative "rules" or methods to achieve policy goals; (*b*) Post-legislation research—the study of effects of the regulations implemented in terms of meeting the policy goals; (*c*) Administrative agency research—the study of the ability of an agency to administer "properly" a set of regulations to achieve their charge, in other words, the economics of bureaucracy; and (*d*) Cumulative effect research—the study of the cumulative effect of a mix of regulations on a sector or sub-sector of the economy. The issues, alternatives, and consequences mode is useful for each kind of research study suggested by Dahl. However, the issues are different for each kind of research—the issues for pre-legislation research are not the same as administrative agency research.

Identifying Issues

The "old regulation" issues seemed much simpler, since they focused primarily on obtaining sufficient competition. Much of the "new regulation" legislation passed in the late 1960s and early 1970s focuses on concerns for the environment, health, and safety. The rise of the consumer movement and the reduction in legitimacy of science and the political process played a role in obtaining that legislation. The current concern about inflation has raised issues of price effects, costs, and effectiveness of regulation, as well as the impact on capital investment and jobs. But the identification of significant and fundamental issues in current regulation policy is difficult.

Much of the "new regulation" deals with safety: food safety, worker safety, and environmental safety. The current policy debate about risks appears unsatisfactory. In the past, the usual process to resolve risk issues was to rely on expert opinion. Today, no useful process for generating a consensus of experts accepted by citizens, scientists, and government exists.

Further, the term "safety" is often ill-defined for use in determining regulatory policy. Lowance defines a thing to be safe "if its risks are judged to be acceptable" (p. 7). Under this definition, safety is always relative and judgmental. Lowance holds that two activities are necessary to determine safety: "*measuring risk,* an objective but probabilistic pursuit; and *judging the acceptability of that risk (judging safety),* a matter of personal and social value judgement" (p. 7). It appears more useful to define safety as Lowance does than to define it as the achievement of zero risk. The policy debate would be greatly improved if citizens had some idea of the probability of a "bad" event, and a way to make social judgments about the acceptability of levels of risk.

Clear statements of specific issues will lead to useful and effective regulation policy research and education. The most difficult part of policy research and education has always been definition of issues. Understanding and insight of production and marketing processes, as well as political and governmental processes as they apply to the problem under consideration are required. Economists are surely in a position to aid in this process.

Prescribing Alternatives

Charles Schultze, in his book, *The Public Use of Private Interest,* raises two specific and separate questions: (*a*) whether government should intervene, and (*b*) how? He states: "The basic theme of this book is that there is a growing need for collective influence over individual and business behavior that was once the domain of purely private decisions. But as a society we are going about the job in a systematically bad way that will not be mended simply by electing and appointing more competent officials or doing a better analysis of public programs" (p. 5).

The alternatives for dealing with regulatory public policy issues may be grouped under the two categories given by Schultze: to intervene

or not, and how. Little attention has been given to the how. Schultze says: " . . . we usually tend to see only one way of intervening—namely, removing a set of decisions from the decentralized and incentive-oriented private market and transferring them to the command-and-control techniques of government bureaucracy. With some exceptions, modifying the incentives of the private market is not considered a relevant alternative . . . Instead of creating incentives so that public goals become private interests, private interests are left unchanged and obedience to the public goals is commanded" (p. 6).

The contrast between the method dictated by the basic legislation of the Environmental Protection Agency and the legislation dealing with conservation of agricultural land in the 1930s is interesting and instructive. For EPA, reduction of erosion is a means of obtaining clean water; for the legislators of the 1930s, reduction of erosion was a means for assuring the long-term productivity of land. Both programs have the reduction of erosion as a significant objective. EPA was guided toward heavy use of the setting of standards and issuance of regulations, that is, "command-and-control." The 1930s legislation guided the USDA toward the use of technical information and education, as well as provision for cost-sharing of conservation practices.

The methods for obtaining performance are alternatives in the issues, alternatives, consequences framework. Seldom does the political debate include the implementation methods. Consideration of alternative implementation methods and the consequences of alternative methods would greatly improve the quality of the debate. The usual policy alternatives of whether or not to intervene are not sufficient.

A paper by Seitz and Spitze which analyzes alternative policies to achieve control of nonpoint sources of water pollution is one example of the economist's contribution to improving the policy debate. They proposed a system for policy development of state plans including component steps and ways to achieve each step. The alternatives presented are persuasion (education), state investment, economic incentives for the farmers and mandated performances. This kind of thought and analysis should lead to more efficient and effective determination of society's preferences.

Alternatives to standards and inspections to improve occupational safety and health are presented by Nichols and Zeckhauser. The first alternative is provision of information. Current government efforts do include provision of information, but the resources devoted to information are tiny relative to those used in setting standards and enforcement. The authors state: "Better information should increase the efficiency of private markets, and will increase equity to the extent that it increases the workers' awareness of the risks they face and enables them to demand compensation or protection" (p. 63).

Incentive mechanisms—for example, the levying of taxes for injuries—is the second alternative identified by Nichols and Zeckhauser. An injury tax would create incentives for the employer to improve safety programs and control a whole range of factors which contribute to accidents, including safety training, rather than just correcting the limited number of physical conditions directly regulated. Safety could be made to pay for the employer and the employee by modification of workmen's compensation. While incentive mechanisms are less promising for occupational health, ways can be found to tax the employer for providing the kind of poor environment which leads to poor health in the workers.

As every policy worker knows, there is always the alternative of a combination of other alternatives. A combination of information, incentive mechanisms, and standards may be a much more attractive alternative than the use of only one method in achieving the goals of the Occupational Safety and Health Act (OSHA).

Predicting Impacts and Evaluating Effectiveness

The economist can play a very important role in predicting the impacts or consequences of implementing the alternatives. And, after the regulations have operated for a time, the economist can evaluate their effectiveness in achieving the original objectives. This evaluation could lead to recommendations for scrapping the regulations, changing them, or adopting alternative approaches. Such information could improve the regulation policy process significantly.

Little information on consequences has been included in the political debate during the passage of recent regulation legislation. The

consequences of not reducing pollution, increasing worker safety, and limiting or eliminating certain substances in food were discussed, but not the consequences for productivity or effectiveness of the regulation. Horror stories unfold relating to consequences of implementing approaches which were not analyzed thoroughly enough before legislation was passed and regulations established.

The consequences of government costs can be measured. The *Wall Street Journal* for March 14, 1978 reported an interview with Murray Weidenbaum of Washington University on the cost of regulation. He stated that the forty-one regulatory agencies in the federal government had a combined budget of $4.82 billion for fiscal 1978; consumer health and safety regulatory agencies had a budget of $2.67 billion; environment and energy agencies had $1.12 billion, and regulatory agencies in the USDA had a budget of $830 million.

Wildausky argues that the collectivization of risk leads to "market socialism," that is, all costs of risk reduction do not appear in government budgets, but they are passed on to society by higher prices and reduced investment to create future jobs. He also suggests that the burdens of regulation to achieve risk reduction are distributed uniformly throughout society and makes the statement: "The very people who are supposed to benefit from collectivization of risk will turn out to be the losers" (p. 35). The measurement of all the costs and benefits of a policy, and their distribution would be useful in regulation research, though by no means easy.

The policy debate leading to the passage of OSHA legislation did not appear to include much discussion of alternatives to standards, and it only included a small amount of discussion of the impacts of the standards and enforcement method. Nichols and Zeckhauser present some post-legislation information on consequences. "The post-OSHA injury rate data fail to reveal any clear trends or dramatic improvements" (p. 52). They also point out the costs have been high: OSHA estimates the cost of complying with the standard for coke-oven emissions is between $11,000 and $58,000 per worker for the entire United States. Even now, little information is available on the effect of economic incentives or provision of information on occupational health and safety, although the costs to producers would likely be lower than the standards and enforcement method.

Summary

In conclusion, economists should be active in developing and refining the public policy of regulation. The political debate on regulation has generally been rather incomplete. It has not been cast in the issues, alternatives, and consequences framework. Regulation policy needs careful empirical analysis of sharply defined issues, considering all feasible alternatives, and predicting impacts of the alternative approaches to obtaining desired behavior and action. Finally, the effectiveness with which regulations achieve their objectives must be evaluated.

Agricultural economists, with their long, rich, and useful experience in agricultural policy, can make a significant contribution to improving the quality of the political debate on regulation.

Research Needs of the Regulated

Timothy M. Hammonds and Doyle A. Eiler

As analysts peering back from the receiving end of the regulatory funnel, we are struck by the number of factors of major importance which typically are omitted or treated only superficially in contemporary regulatory analysis. The companion feature, equally striking in light of these omissions, is the degree of certainty with which many members of our own profession present their policy recommendations.

To be sure, a balance has to be struck between complexity and capacity in any analytic model. Our point is that important considerations are being neglected for reasons completely unrelated to capacity considerations.

We will focus our attention on three specific areas which are sorely in need of greater research attention. They are: consumer input in the regulatory process, jurisdictional overlap of regulatory agencies, and the current use of industrial organizational analysis as a source of normative regulatory policy recommendations.

Consumer Input in the Regulatory Process

Most analysts accept the premise that government regulations introduce inefficiencies and distortions into the marketplace, either intentionally or as a consequence of substituting social for economic processes (for example, Samuels, p. 100). Indeed the very purpose of regulation is to alter the performance of the economic system for the benefit of an identifiable or imagined constituency. Thus, the regulatory debate is inherently political.

The primary purpose of this political process is the reconciliation of the interests of the beneficiary constituency with the interests of those who must bear the cost. For food industry regulations, the general consuming public is typically identified as the beneficiary constituency. But, how do regulatory agencies discern the interest of the general consuming public they are trying to satisfy?

The two sources most frequently used are input from professional consumer groups and the public hearing process. Although one must not a priori reject the notion that professional consumer groups reflect general consumer attitudes, the compatibility of their views with those of the public at large deserves verification. While regulatory and legislative bodies provide opportunity for public comment through the hearing process, it is disturbing to see the government proceed as if the views expressed at public hearings are representative of consumers in general with no independent verification. The group of witnesses appearing at hearings must not be thought of as representing or even approaching a random sample of the population. They provide valuable input, certainly, but this input is not by itself sufficient.

The limitations implicit in the reliance on professional advocates and the hearing process can be overcome through the use of well-designed consumer research. Consumer research can provide the broad scale representative expression of consumer attitudes needed by regulators. Unfortunately, regulatory agencies have been reluctant to commission these studies. Two recent examples illustrate the productive role consumer research can play in the policy process.

The Federal Trade Commission (FTC) has expended considerable effort in order to create an elaborate inspection and enforcement program in an attempt to ensure the availability of items appearing in retailer ads. Recently the FTC, at the urging of its own staff, undertook an attitude survey to determine whether shoppers really suffered from the lack of availability of advertised items.

Although the final report has not yet been issued, the survey has found that only a minority of shoppers are concerned about lack of availability, that those customers who are most concerned are well aware which stores are unreliable and do not shop there, and that "the market is taking care of the problem" (Bureau of National Affairs, p. A7).

A great deal of agency effort and public expense could have been saved if the research

---

Timothy M. Hammonds is senior vice president and Doyle A. Eiler is director of research, Food Marketing Institute, Washington, D.C.

project had taken place before this particular regulation was put into place. It remains to be seen what impact this information actually will have, but it should play a major role in enforcement policy.

Food labeling provides another example of the role consumer research might play. The Food and Drug Administration (FDA), the Department of Agriculture (USDA), and the Federal Trade Commission (FTC) now are considering jointly a revision of food labeling regulations touching specifically on ingredient labeling, nutrition labeling, open date labeling, "imitation foods" designations, food fortification, and information presentation formats. As part of this reassessment process, five cooperatively sponsored regional hearings were held to solicit public opinion and reaction. The agencies were trying to solicit input from groups not normally heard. This was a worthy effort which served their purpose. However, it did not supply a random or even stratified random sample of public opinion.

Although label revision is designed almost exclusively to have impact on the purchase decision, these three agencies undertook no research to explore consumer use of alternative information presentations prior to the hearing process. In fact, there was a great deal of discussion on the desirability of graphic labeling and the need for some system of nutrition scoring without direct testing of these concepts.

To our knowledge, the only currently available consumer research bearing directly on these issues was conducted by Food Marketing Institute. A representative sample of the shopping public was polled with a standardized questionnaire supplemented with a series of focus groups to explore attitudes in depth. The research findings indicate that the list of ingredients is much more important than nutrition labeling, that a more organized form of the current label would be more effective than a totally new graphic format, and that the public has a major concern about regulatory agencies which "editorialize" rather than inform (Hammonds).

It is now time to look again at what constituency groups we really serve with each of our regulations. If it is truly the general public, consumer research must play a larger role in the decision-making process. This is not to say that the public should be polled with specific alternatives of regulatory language. But, basic attitudes, needs, and priorities must be explored. Regulatory researchers have much to learn from their colleagues in consumer market research.

This is not a call for judging the desirability of specific regulations solely on the grounds of public opinion. Neither is it a denial of the existence of non-use benefits which flow from some regulations. It is merely to say that consumer research is an extremely valuable input to the decision-making process which is almost totally neglected at present.

Jurisdictional Overlap

Along with regulatory legitimacy, we must address consistency of application. The single ingredient most certain to render any regulation unworkable is inconsistency of application. The single most effective way to guarantee inconsistency of application is to allow jurisdictional overlap among separate agencies. The food industry faces this problem regularly.

Consider, for example, jurisdiction over food labeling and advertising, which is shared by the USDA, the FDA, and the FTC. Responsibility for assuring the accuracy of statements appearing on food labels and in advertisements for food products resides primarily in these three agencies. From time to time, additional inroads may be made by the Environmental Protection Agency (for pesticide residue), the Consumer Product Safety Commission (for packaging hazards), the National Oceanic and Atmospheric Administration (covering fish products), and the U.S. Postal Service (covering mail order sales). There is currently no systematic, clearly defined mechanism for resolving the regulatory duplication and inconsistencies which are caused by these overlapping jurisdictions.

Conflict between these agencies is furthered by court interpretations of what comprises a food label. In layman's language, FDA authority extends to labeling while FTC authority covers advertising. However, several court cases suggest the FDA jurisdiction in food extends to many materials commonly thought to be advertisements. In reality, many forms of advertising fall under the purview of both agencies. This often exposes a company to conflicting standards and procedures.

Many in this audience will play a role in the President's regulatory reform program—if not this President's program, then some other

President's program. The discussion of this issue need not be prolonged because a comprehensive treatment is available elsewhere (Rill and Frank) and because the point to be made is simple. Jurisdictional overlap must be eliminated. At the very least, a formal mechanism for timely resolution of interagency conflict should be established. Businessmen have a right to know exactly whom they must satisfy. Less invites chaos. In the name of regulatory reform, let us lay this issue to rest. This is a topic which should not be left as an afterthought for agency clerks to resolve. It deserves professional attention.

Industrial Organization Analysis

Finally we come to an area of inquiry which cycles into public fashion whenever inflation intensifies. Since the Food System Research Group (NC-117) is a cosponsor of this conference, industrial organization analysis needs to be addressed. We will look at economic analysis as interpreted by laymen, the dynamic nature of competition, the need for validation of new techniques, group interaction in the marketplace, capital market imperfections, and the public policy response to "excess" power.

Analysis and the Layman

Industrial organization analysis and its policy implications are emotional public issues. Therefore, the danger of oversimplification is great. This is one topic in our profession which frequently finds its way into newspaper editorials, popularized talk shows, and platform speeches. We need to be conscious of the fact that in many cases our writing will be read not by other economists, but by laymen.

Marion and Sporleder have an important observation on this topic in an early draft of a paper they prepared for the 1976 American Agricultural Economics Association annual meeting. That is, that in the hands of noneconomists, the tools of analysis become "unbending standards of evaluation."

As an illustration, consider the Neal Report prepared by the White House Task Force on Antitrust Policy, 1968: "The term 'oligopoly industry' shall mean a market in which (1) any four or fewer firms had an aggregate market share of 70% or more during the last seven of the ten and four of the most recent five base years. . . ." (*Congressional Record* 1969, p. S5645). The Hart bill followed in 1973: ". . . monopoly power is possessed by any corporation if the average rate of return on net worth after taxes is in excess of 15 percentum over the period of five consecutive years . . . or . . . if any four or fewer corporations account for 50 percentum or more sales . . . in any year out of the most recent three years preceding in filing of the complaint" (*Congressional Record* 1973, p. S4362). Oligopoly becomes monopoly, 70% becomes 50%, and the time period for analysis shortens. Many noneconomists have picked up this theme with four-firm concentration ratios the sole criterion for judgment and 50% the sole cutoff point for monopoly power.

Carl Kaysen wrote in 1955: "It seems vain . . . to hope for more from concentration measures than that they should provide a preliminary basis on which resources for further study should be allocated" (p. 118). It is time for us to include similar cautions in our own public pronouncements. The difference between analytic techniques and policy standards deserves clarification.

The Dynamic Nature of Competition

The second and related major industrial organization topic is the persistence of market power over time. Contemporary industrial organization analysis has tended to abstract from a modeling of the dynamic competitive process to a reliance purely on structural indicators. This is a serious error.

Recent models used in Congressional testimony have been constructed to identify markets as "noncompetitive" once the sales of the largest four firms reach a norm variously identified at 70, 60, 50 or even 40% of the relevant total market. This fuels the notion just discussed that the complexity of competitive behavior may be reduced to a simple formula utilizing a single standard. It also implicitly conveys the impression that once obtained, market power persists.

There is substantial evidence that this is not the case, at least in food distribution. Folsom points out in a recent *American Journal of Agricultural Economics* (AJAE) article: "If for example, one examines the ten largest food retailing firms of 1962, he will find that three of them are not among the ten largest of 1976. Additionally the largest firm of 1962 experienced a real sales decline after adjustment for

inflation. Four of the ten largest firms in 1962 made less than 3% return on stockholders equity in 1976, with two of them actually losing money'' (p. 186–7).

Joan Robinson observes the need for considering the dynamics of the competitive process in a recent paper: '' . . . it seems to me that the research for a single generalization is a hangover from the equilibrium model. There is no simple theory to cover the multifarious evolution of a private enterprise economy . . . this knowledge cannot be well organized if it is squeezed into formulae that smooth over distinction between the future and the past'' (p. 1326).

Our primary focus should be on the dynamics of market power. Simple cross-section analysis is relatively inexpensive and readily lends itself to ad hoc policy analysis. But it is not relevant to the real competitive process. It is no more than a starting point. We must model competition as a dynamic process looking beyond simple numbers to the behavioral dimensions.

Validation of New Techniques

The introduction of a time dimension brings us to the third major issue, the validation of new techniques. An active core among our profession is developing new industrial organization theoretical constructs and measurement techniques. Since the intent is to address regulatory action and structural remedy with significant private and social cost, the need for careful validation is compelling.

In the development of any new analytical technique, there is a critical need for independent data sets for model development and for validation. The literature of econometrics addresses the severe consequences which flow from the failure to address this issue. That literature should be reviewed in an industrial organization theoretic context.

By the nature of our marketplace, the number of independent data sets is severely limited. Even portions of the early writings of Bain have been questioned by authors applying his models to the same industries with data drawn from subsequent time periods. More recent examples of the neglect of independent validation are available. There is a tendency in industrial organization analysis to use a data set to identify a competitive market norm, then to apply that norm back to the same data set to estimate market ''overcharges.'' The establishment of any market norm should be subject to independent validation.

One solution is to allow a validation period which provides additional, if not totally independent, data sets through the passage of time. There are, no doubt, other techniques which would be even more effective. Given the public policy issues at stake, careful validation of any new analytic techniques is essential.

Group Interaction

Our fourth major issue is group interaction within the marketplace. The time has long since passed when we can treat managerial discretion as if it operated in a vacuum. The popular assumption is that management behavior need be the only focus of analysis. If operating costs are high the assumption is that management has grown lax as size has increased.

We must abandon this fiction. There are many critical relationships within any major marketplace, but the most critical is that between management and organized labor. In our reassessment of industrial organization theory we must face the most glaring omission from models in current fashion: the role of organized labor.

Our profession has never adequately addressed the role of organized labor and its impact on market structure. The common models assume labor to be an operating cost, therefore, under management control, and thus, in no need of inclusion as a separate variable.

The truth is that it has been politically unpopular and occasionally personally uncomfortable to throw a realistic light on the role of organized labor. Until we have the theoretic framework and analytic tools to address this facet of our marketplace, our models cannot lead to meaningful public policy conclusions. This is the single topic which is most in need of attention in industrial organization analysis.

To be sure, the topic is complex. John Hicks points out: ''It is quite wrong to think of the labor market as being similar to the primary product market, in which price is set by demand and supply. The pursuit of fairness in labor relations has many difficult aspects; but one of the clearest and least controversial of the demands which it makes is continuity in standard of living'' (p. 102).

It would appear that our analytic heritage in the primary commodity markets is an incomplete guide. But this issue must be addressed if our analyses are to build credibility. Management is certainly not the helpless pawn of organized labor. However, the reality of the interaction should not be denied. This issue must not be sidestepped, and it must not be oversimplified. It is here that the tools of industrial organization analysis will ultimately prove their worth or their irrelevance.

Capital Market Imperfections

Our fifth topic is the presumption that advantages to size lie primarily or exclusively in the product market. As a consequence of this implicit assumption, price levels have been the focus of most models applied to the food distribution sector. In fact, there is substantial evidence, in other industrial sectors at least, that advantages to size may well lie in the input factor markets.

This concept deserves careful examination by agricultural economists. There has been work in this area, but none to our knowledge includes food production or distribution in the analytic set.

In particular, one important recent work examining the industrial sector has never received adequate discussion in our literature. In 1975, Dr. Daryl Winn published a study from the Graduate School of Business Administration at the University of Michigan. He examined 736 firms in 70 industries adjusting for risk, depreciation, and current versus historical cost reporting. He states: "Weighing the accumulated evidence from the many tests of the several hypotheses in this study, I must conclude that there is considerable doubt as to the validity of the fundamental hypothesis . . . that after the independent influences of size, capital intensity, growth, risk, and the distortions arising from historical cost accounting are accounted for, firms in concentrated industries are found to earn above-average rates of return." He goes on to say: "Clearly, if our concern is with 'excess' returns, then the cause of that concern appears to rest largely with imperfect capital markets and not imperfect production-selling markets. . . . Though monopoly power may lead to restricted output and artificially high prices, as indicated by above-average rate-of-return measures, the misallocative effects are probably not nearly so critical as those which result from imperfect competition in the money capital markets" (pp. 137–138).

This is not the last word on the subject by any means. It does suggest, however, a major policy departure from recent suggestions as to structural remedies.

The Public Policy Response

Finally, we come to the sixth major issue, the nature of public policy response. Suppose that "excess" market power is eventually identified, if not in food distribution then in some other sector. Then we face the question of what remedy or remedies should be employed.

Few would deny the terrible problems created by direct government intervention in the marketplace, even when the primary goal is widely accepted. Typically, we have thought in terms of new business regulations, structural alterations, or in the ultimate, deconcentration. Now that we have a new consumer consciousness in this country, it is time to rethink how we might use this force to impact the marketplace where previously we have looked only to direct intervention.

Our consumer research at Food Marketing Institute shows a remarkable confidence on the part of the public in their ability to make intelligent decisions given the proper information. Might it not be that improving consumer information flows in key decision-making input variables would lead to corrective behavior which would erode any "excess" market power? What better way to improve consumer welfare than to impact consumer behavior directly? We started this paper with a call to explore consumer attitudes, needs, and priorities. It is fitting that we now come full circle ending with an exploration of the consumer's contribution to corrective action.

Conclusion

We have talked about the need for consumer input into the regulatory process through well-designed consumer research, the need to address jurisdictional overlap in the name of regulatory reform, and the need to rethink the directions of industrial organization analysis.

Regulatory reform and the trend toward cost-effectiveness analysis on the heels of our tax revolt have produced the rare confluence of good politics and good economics. The profession of agricultural economics is in perhaps

the best position of any discipline to shape the direction of hard economic analysis as part of policy assessment.

Food is at the forefront of our inflation news, and, as a result, it is an unavoidable candidate for regulatory and legislative reassessment. It is equally obvious that agricultural economists are well grounded in this sector of our economy. The analytic foundation we lay must be realistic, comprehensive, and carefully communicated, for the precedents set here will have a major impact on other sectors of the economy soon to go through a similar reassessment.

Public policy is, of necessity, a process of debate, of balancing efficiency with social issues. But, if public decision making is to be effective, it should be grounded on a solid foundation of research. We now have an opportunity to bring this goal closer to reality. If we seize the opportunity without overreaching our capabilities to deliver, without substituting judgment for analysis, without ignoring the realities and complexities of the marketplace, we can make a major contribution to the public debate.

Regulation Analysis as a Research Focus in Agricultural Economics

Dale C. Dahl

Economics is the study of the behavior of man and his institutions as they engage in the allocation of scarce resources. Its intellectual objective is to understand the nature of this conduct and its underlying rationale. But the pragmatic reasons why economists undertake their investigations are two: (*a*) to predict future behavior and its social consequences, and (*b*) to alter (or regulate) that conduct or its effects in accord with given or perceived performance standards.

These reasons are also central to the distinction between positive and normative economic analysis (Buse, pp. 23–24); the "positivist" perceiving his role as describing, rationalizing and predicting within a given institutional framework, the "normativist" extending his study to consideration of alternative institutional mechanisms used to achieve stated public or private goals.

Economists have a long history of debating which analytical role is professionally appropriate (Bronfenbrenner, p. 7–8). While any serious study of the history of economic thought suggests that normative considerations have been fundamental to most new developments in economic theory and method, an early and lingering insistence by many practitioners on striving for a form of "scientific objectivity" (presumably devoid of value judgments) has tended to place economists into either positive or normative "camps."

The discipline of agricultural economics is both an outgrowth of the agricultural sciences and an extension of economic analysis to agricultural problems (Taylor). From its beginnings, and into the present day, agricultural economics has been distinguished as an "applied" discipline—one that initially addressed a range of social problems encountered as farmers, agribusinessmen, consumers and public bodies allocated their scarce resources to achieve various levels of food and fiber production, distribution and consumption. Now it has been broadened to include community and regional development, public decision making, and the application of economic analysis to the study of the use of other basic resources.

As the scope of agricultural economics has expanded, it has retained a real world "problem" orientation. To the extent that the problems analyzed have a "what-ought-to-be" component, agricultural economic studies are implicitly or explicitly value-laden and take on a normative character. This conclusion (or assertion) does not simplistically suggest that all agricultural economic analysis is normative in nature, but it does emphasize that various types of normative economic analysis have been a leading hallmark of our discipline.

Principally during the past two decades, an extensive literature on the subject of the economics of regulation has come into existence (Grant, 1979). While some authors have identified the 1962 and 1971 articles by Stigler as groundbreaking (Peltzman), there appears to be a consensus that these and subsequent studies are "an attempt to join neoclassical theory with 'institutional economics,' " (Kahn p. VII) and that this type of work represents a rigorous and potentially valuable example of normative economic analysis.

The purpose of this article is to explore the potential of regulation analysis—this develop-

ing subdiscipline of economics—as a research focus in agricultural economics. It will be asserted that most current-day agricultural economic analysis is normative in character; that the gap between orthodox and institutional economics is being bridged or closed; and that future research must pay increased attention to legal aspects of economic questions and the economic analysis of the law.

First, it is argued here that the U.S. food system, conceived to include business activity from the manufacture of agricultural inputs, through farming, to the assembly, storage, processing and distribution of food products, is one of the most regulated of industrial groupings. It is further argued that the mere mass of statutory, common, and administrative law relating to this sector has served to discourage academic agricultural economists from expanding their research horizons much beyond the study of traditional price and income strategies, and that an educational effort is needed.

Second, it is argued that traditional normative economic analysis is only a part of an emerging methodological paradigm that can be used to address a series of significant current research problems in the food sector. This paradigm essentially extends the structure-conduct-performance interrelationship to include the analysis of alternative policy remedies and to reorder the analytical sequencing of this and other approaches.

Third, it is argued that a demonstrated range of analytical conceptions and tools that can be employed in food regulation analysis now exist. Further, research opportunities for the study of regulatory questions may be considered in terms of before-and-after regulatory enactments, in terms of the regulatory agency, charged with administrative functions, or in terms of the cumulative impact of a group of regulations on vertically-defined industrial subsectors, horizontally-defined industries and markets, or in terms of more broadly defined macroeconomic variables.

Regulation in the Food System: An Overview

Regulation economics, though heralded as a newly-developing branch of economics, is difficult to define because of an apparent lack of agreement on what is meant by the term "regulation."[1] A review of the literature reveals a spectrum of definitions ranging from broad to narrow in conceptual scope.

At the broadest extreme, regulation refers to the "full pattern of government intervention in the market" and includes "taxes and subsidies of all sorts as well as to explicit legislative and administrative controls over rates, entry and other facets of economic activity" (Posner).[2] The narrowest definition encountered states that regulation refers to the process by which administrative rules are promulgated, applied and adjudicated in an effort to articulate and enforce legislative enactments (Russell).

The definition used in this article is implied by Kahn and is composed of three types of government involvement in the economic system: (a) those political activities that cause government entities to be co-participants with business and consumers as producers and users of economic resources; (b) governmental control or direction of certain economic decisions by selected industries (e.g., public utilities); and (c) that range of statutory, administrative and common law that attempts to encourage, constrain or facilitate operational aspects of the private market economy. Within this definitional framework it is clear that regulation permeates the organization and operation of the U.S. food system to a considerable degree.

U.S. Food System Regulation

The U.S. food system has a unique organizational structure. A concentrated array of input manufacturers sell to a less-concentrated distribution level, and they provide production supplies to a relatively atomistic structure of farmers. In terms of vertical input-output flow, commodities produced by hundreds of thousands of farmers enter into an increasingly concentrated series of markets, finally to reach millions of highly-decentralized consumers.

---

[1] This lack of agreement is amply demonstrated by a comparison of the articles by Shaffer and by Gardner in this special issue of the *American Journal of Agricultural Economics*.

[2] Presumably, this broad definition of the term would encompass the entire set of economic functions of government as presented in principles texts: "(1) providing the legal foundation and social environment conducive to the effective operation of the price system, (2) maintaining competition, (3) redistributing income and wealth, (4) adjusting the allocation of resources so as to alter the composition of the national output, and (5) stabilizing the economy, that is, controlling unemployment and inflation caused by the business cycle and promoting economic growth" (McConnell, p. 102).

Within this economic subsystem are not only millions of business firms and consumers, but governmental units (federal, state and local), which play participatory roles as holders of vast quantities of natural resources and as buyers and sellers of raw farm products and foodstuffs. Data from 1974 (USDA) show that 40% of the total U.S. land area was under federal, state, and other public ownership. This public land holding was not merely in the use form of parks and forests, but included, in addition to forests, 1% of the cropland, 33% of the pasture and rangeland, and 84% of special use and unclassified lands, such as tundra, swamps and that used for military bases. Largely through the Commodity Credit Corporation, the federal government is a major purchaser of raw farm products, not merely for the purpose of farm price stabilization but as an input to domestic and foreign assistance programs. Federal, state and local governments also purchase processed and packaged foodstuffs to satisfy several domestic and foreign assistance programs.

While the term "public utility regulation" is rarely applied to agriculture, it is clear that the U.S. food system has most of the attributes of a public utility and the several price and income policies of the federal government have become increasingly directed not only to such common variables as rate making (prices) and entry, but to the quality and quantity of food available for nutritional needs (Houthakker). The public utility character of the U.S. food system is put in bold relief by consideration of the collective bargaining alternative for farmers (Geyer). Can farmers, through collective action, be permitted to produce and sell any quantity and quality of food at prices advantageous to them, without the welfare of consumers being protected by government?

More than in most industry groupings, the U.S. food system is monitored, constrained and facilitated in its organization and operation by a highly complex set of statutes, administrative rules and common law pronouncements at all levels of government (Grant, 1978). At the federal level, land and water use constraints, environmental laws, farm labor policies, and agricultural finance programs stand out as intervention examples directed to the regulation of agricultural resource use. Policies that limit business organization alternatives, and those that foster and constrain agricultural cooperation as well as other forms of collective bargaining exemplify governmental influences on U.S. food system organization. Special tax policies and a range of programs designed to expand the demand for farm products, assist disadvantaged consumer groups, and foster international trade are regarded as central to U.S. farm policy. Beyond this, a substantial set of rules administered by several federal agencies attempts to foster competition and protect consumers, farmers and agribusinessmen in the name of health, contractual justice and economic protection (Burke).

The conclusion is clear. Regulation of the U.S. food system represents all of the aspects of regulation economics set forth earlier: government participation, public utility direction, and operational rules. From a review of the literature it is clear that the words "agricultural policy" have not meant the full range of regulations espoused here.

From Agricultural to Food Policy

During the past two decades the phrase "agricultural policy" has been changed to "agricultural and food policy" and that set of statutory, administrative and common law relating to agricultural policy has expanded to include a wide range of issues stretching from the problems of rural proverty and environmental pollution to international trade and development, to antitrust and market regulation, to the protection of the consumer from misinformation about food products and from unsafe or poor quality food. This broader view of the regulation of the U.S. food system has encouraged agricultural economists to expand their analyses away from the mere consideration of how to enhance the income and welfare position of the American farmer, and to consider the external effects and interrelationships of those policies in terms of other segments of the economy. This broader view also has brought forth an increased number of demands by policy analysts that agricultural economists develop a comprehensive and internally consistent food policy in the years ahead. Those agricultural economists who wish to respond to this plea increasingly have faced the realization that the regulation of the food system is so extensive that it almost requires specialized legal training and study to begin to comprehend the magnitude and interrelationships of the pertinent law.

Food Regulation Education

No single document, set of volumes or journal permits the interested agricultural economist access to that full subset of the law that pertains to the regulation of the U.S. food system. Because of this, agricultural economists not only continue to approach economic problems in a piecemeal fashion; they are also limited in their vision as to possible legal solutions.

Economic analysts, like others, have become increasingly specialized, not only in terms of the problems addressed, but also with regard to the methodology employed.

Academic agricultural economists have long been methodologically oriented rather than problem oriented in their studies, and they have been particularly noted for using fashionable approaches. A successful analytical method that gains academic respectability is frequently replicated to the point of intellectual exhaustion while social problems are left unaddressed or under-addressed. We are fast approaching a real world of problems that can no longer be left to lawyers and other professionals to resolve without the aid of economic analysis.

A Regulatory Paradigm

Nearly 20 years ago a research approach which would serve as an orientation for studies of the marketing and pricing of food products was suggested to agricultural economists (Clodius). This paradigm of analysis was captured by the phrase "market structure analysis," which professed to study the relationships among a group of variables classified under the headings of structure, conduct, and performance. This analytical approach had a history of uses in industry, legal analysis and economics. It achieved a level of academic respectability and offered potential as an approach to a wide range of significant economic questions. Numerous studies were made by agricultural economists using this approach (Dahl). Unfortunately the research that resulted came under attack as being essentially descriptive, lacking in analytical content, and having limited social impact (Farris).

In my view these assessments did not lessen the power of the investigative approach but rather demonstrated that it had been sorely misused. Most of the market structure studies completed did little more than describe the number and size distribution of firms engaged in various market activities, and they appeared to be conducted without respect to a problem focus. In addition, economists encountered substantial difficulties in conceptualizing and quantifying conduct and performance variables. Following the attacks against the studies by respected agricultural economists, researchers tended to abandon this approach in favor of more fashionable methodologies. Accordingly, most of the recent developments in market structure analysis have come from industrial organizational economists and those involved with antitrust problems (Helmberger).

Normative Market Structure Analysis

Even if the market structure approach had succeeded it could have been argued that the sequencing of the trilogy was reversed and lacking in terms of problem identification. Rather than descriptively seeking the structure of markets or industries so that conduct and performance hypotheses can be positivistically tested, the research method might well have yielded more acceptable results if the analysis had been more normative in nature from the start.

A normative market structure analysis would presumably begin by identification of a performance problem, leading to a study of structure and behavior as an explanation for the existence of the problem. For example, a normative market structure study might begin with the observation that industry profits are high relative to other industries and would proceed in the development of hypotheses that included structure and conduct variables (as well as others) that would help explain this disparity.

Such a normative market structure analysis, however, would be lacking unless attention were paid to how a disparate profit situation could be corrected. Unlike legal scholars, economists (especially those in the academic world) tend to limit their normative studies to the mere identification of explanatory forces rather than to continue seriously in their research by offering analyses of alternative remedies that might be used to resolve the perceived problem.

Regulatory Remedies

As might be expected, legal scholars pay considerable attention to the remedy of conflict or problem situations. These remedies may be pecuniary, punitive or equitable in character but they are designed to resolve immediate and long-range problem situations by economic and political sanctions.

While the law of remedies usually is studied in terms of micro-decision making situations, a corollary (and analogous) set of remedies exists with respect to macro-legal problem situations. These remedies are principally economic and political in character and represent alternative means by which problems can be resolved. A number of regulatory alternatives were set forth in a recent Senate report devoted to the study of federal regulation (U.S. Congress). They included such options as deregulation, establishment of performance standards, regulation of information, economic incentives, and various subsidies. There are other regulatory alternatives as well.

Regulation economics, in terms of the previous discussion, is a form of normative economic analysis that includes an analytical consideration of policy remedies of problem situations. It is not limited to the use of expanded or reordered market structure analysis, but has as its distinctive character its orientation to macro-legal remedies of perceived problems.

In terms of the market structure analysis illustration, a paradigm for regulation economics would include four sets of variables: performance, structure, conduct, and regulation. The sequencing of the analysis might take on several forms but would always include a problem statement as well as a study of alternative regulatory options to aid in problem solution. If, for example, the problem was perceived as relatively high profits in an industry, the analysis would not only be directed to why these profits exist and to whether or not they are justified, but also would extend to consideration of regulatory alternatives that could be employed in an effort to reduce profits to more acceptable levels.

Government and Academic Research

In the categories of economic inquiry attributed to regulation economics it is easy to recognize a significant portion of the work of food research economists in the federal establishment and especially in the U.S. Department of Agriculture.

While we may recognize regulatory economics as something that we practice as government researchers, it appears from my review of the literature as something not often practiced by academic agricultural economists. Part of the reason for this, clearly, is that government economists perform their research within the milieu of the law and its administration, while academic economists are free to study questions and methods without being so fettered. It goes without saying, perhaps, that agricultural economists at academic institutions frequently have been admonished for not dealing with the most pressing agricultural issues addressed in governmental circles. In some ways this separation has reaped conceptual and methodological benefits. But in other ways it has produced a set of research results that are sometimes trivial or redundant.

Increased efforts of academic agricultural economists to engage in regulatory economic analysis may help not only to bolster a sagging research image, but also to provide a merging of concerns between academic and governmental economists. This can only be achieved through a concerted effort to educate academic economists as to the regulations that pertain to the food system. For this effort to have an impact, a willingness on the part of government agencies to accept advice and criticism is needed. Perhaps even more important than education and administrative openness is knowledge of the analytical techniques and theoretical analyses that might be employed in addressing regulatory questions.

Methods of Regulatory Analysis

Consideration of the role of the economist in the regulatory matters of government involves recognition that "public economic policies are not, and cannot be framed on the basis of 'purely economic' considerations alone" (Kahn, p.14).

We are, at once, confronted by the practical question: What guidance can economics provide legislators, administrators and judges in framing, applying, and enforcing policies involving government participation, direction and facilitation of private sector competition? Consider the answers provided by Kahn.

The answer to this question combines the two quite distinct purposes of economics—science and prescription. There is nothing unusual about this double motivation; it involves ambivalence only when we fail to keep clearly in mind which of the two purposes we are at any time serving, and in which of our two roles, physician or scientist, we are acting. As for the first, there must be very few professional economists who were not moved to enter that gloomy profession (no matter how far they may later have gone astray) by a belief that economic problems bulk large among the many vexations of human existence in society, and by a hope that the application of goodwill, intelligence, and professional expertise to the formulation of public policy could make an important contribution to the improvement of the human condition.

But if such an inquiry is to be conscientious, its scope and method must be rigidly scientific as well. The economist who asks a politician "Won't you let me advise you on your legislative program?" deserves only another question in response: "What do you *know*?" And only the economist who can answer "Well, I can tell you that if you pass a law that says such-and-such, these are the things that will probably happen," or "If you do nothing about such-and-such, this is what will probably happen," deserves to have his offer taken seriously.

This is not to argue that economists have no other function in government than to serve as technical assistants to politicians. As we have already suggested, formulating public policy can never be a job for the scientist alone. In the last analysis, deciding what *should* be done can never be accomplished only with the help of the type of information that says "If you do A, then B will follow." And if it follows from this truth that economists cannot, *as scientists*, presume to settle the ultimate issues of public policy, it also follows that there are no *other* scientists who can presume to do so either. If framing public policy requires in the last analysis the *art* of the politician or philosopher, this is an art that the economist may be better equipped than anyone else to acquire and to practice within his own domain: who can have given more thought than he to the ultimate ethical and political implications of alternative public economic policies?

Economists have a particular advantage when it comes to taking a direct role in the regulatory process. The job is an extremely technical one and becomes more so each year. It used to be done almost exclusively by lawyers and politicians, with accountants and engineers as assistants. But for decades there has been great and increasing dissatisfaction with their performance. One important criticism has been that they were behaving too much like lawyers and bookkeepers—excessively concerned with proper administrative procedures, the balancing of equities, and the measurement and covering of accounting costs—and too little like economists—paying practically no attention to things such as marginal cost, elasticities of demand, or to the dynamic conditions of innovation and growth. For these and other reasons that will appear later, economists have been drawn more and more into the process, bringing with them their own esoteric terminology and tools; the lawyers that have failed to seek their direct cooperation find they cannot understand what their opponents' witnesses are saying (pp. 14–15).

Economic Decisions by Government

It was argued earlier that U.S. local, state and federal governments have functions of resource management and product purchasing and selling similar to those of other food economic sector participants. The major difference presented by government participation is the oft-noted variation in its objective functions as compared to businesses and consumers. Presumably, government engages in economic activities not to maximize short- or long-run profits, but to enhance public welfare, to assure economic stability, and to otherwise conduct its foreign and domestic policies.

There is a notable lack of published economic modelling and analysis as to this type of public decision making. But it has been addressed in legal literature under the rubric of "economic theories of regulation."

> Two main theories of economic regulation have been proposed. One is the "public interest" theory, bequeathed by a previous generation of economists to the present generation of lawyers. This theory holds that regulation is supplied in response to the demand of the public for the correction of inefficient or inequitable market practices. It has a number of deficiencies that we shall discuss. The second theory is the "capture" theory. This theory holds that regulation is suppled in response to the demands of interest groups struggling among themselves to maximize the incomes of their members (Posner, pp. 335–336).

Much of the rationale for government resource management and the trading of agricultural and food products is part of the public Congressional Record, but agricultural economists need to do systematic studies of administrative decision making. A series of studies by the American Enterprise Institute relating to nonagricultural industries and other economic activities illustrate the type of analysis needed for the food system.[3]

[3] American Enterprise Institute (Selected Series), Washington, D.C.: Campbell, Rita Ricardo, "Food Safety Regulation," AEI-Hoover Study 12, Aug. 1974. Helms, Robert B., "The Economics of Environmental Quality," National Energy Study 2, July 1974. Hite, James C., Hugh H. Macaulay, James M. Stepp, and Bruce

Public Utility Regulation

Federal price programs for agriculture represent the key type of rate-making regulation so central to public utility economics. With target prices associated with average cost of farm production, the issues of marginal versus average cost pricing are muted by the existence of an atomistic farm structure. But the economic price-discrimination basis for certain market orders opens up the rate-making issue in terms of producer and consumer costs and benefits. Some of the recent work by Buxton exemplifies the type of regulatory analysis that can and should be undertaken by agricultural economists in the years ahead (Buxton).[4]

Market Regulation Analyses

The substantial array of agricultural and food statutes, administrative rules, and court decisions require systematic analysis by agricultural economists. At least four types of studies can be undertaken, most of which employ traditional microeconomic models and quantitative methods: (a) pre-legislation research; (b) post-legislation research; (c) administrative agency studies; and (d) cumulative impact investigations.

Economists should and do make important contributions to the development of rule making by legislative and administrative bodies. Stigler, in a plea to scholars, emphasizes the importance of this type of research:

> Let us pause for a moment to discuss the difficulty of disentangling and measuring the effects of an economic policy. Many lawyers and some economists will deny that it is possible, for example, to separate the effects of the S.E.C. [Securities and Exchange Commission] review of stock prospectuses from the effects of higher taxes, more stable national growth, accelerating innovation, and a thousand other circumstances that distinguished the 1960s from the 1920s. I would remind these doubters that if we cannot measure the effects of policies, the society is incapable of rational behavior—rational behavior is behavior appropriate to the ends in view, and means cannot be appropriate if their effects are unknown. The fundamental reply to the doubters, however, is that we can isolate the effects of policies with substantial and improving precision. My study of the S.E.C. review of stock prospectuses, which reached the conclusion that the review had not improved the experience of purchasers of new stock issues, was much criticized by the S.E.C. defenders. Even the critics, however, accepted my general line of economic analysis, and almost all disinterested students accept the conclusion that the S.E.C. review has not made a large difference. With further study the conclusions can be made more definite and more reliable, but techniques of economic analysis are already available to form a useful estimate of the effects of most economic policies (Stigler, 1973, pp. 7).

No single or simple methodology is employed regularly to conduct pre-legislation economic research. Clearly, among the most popular techniques are various uses of cost-benefit analysis, a set of concepts and techniques that have become a regular part of the "tool-kit" of the agricultural economist (Westfield). Another obvious methodology employed is the use of forms of input-output analysis, especially where the tracing of external impacts of proposed policies is important (Rose). In general, the particular method of analysis must be tailored to the rule proposed and the interests perceived (Petersen).

Post-legislation research involves a "post-mortem" consideration of the effects of a rule once it is in effect. In essence, it could be regarded as a follow-up analysis of what actually happened as a result of a new rule in contrast to the pre-legislation study of what might happen. This hindsight study is or should be a crucial part of continued legislative and administrative efforts to assess the original action. Unfortunately, less published work illustrating this research approach is available than its importance implies. Part of the reason for this, or course, is the difficulty of sorting out the effect of a policy as part of an array of influencing factors over time.

It seems reasonable to suggest that pre- and post-legislative studies should be viewed by economists together as a complete analysis so that methods might better be devised to isolate policy effects. This represents a challenge not only to government economists, but also to administrators who need to become aware of the need for this more comprehensive approach.

The study of administrative agency behav-

ior now is a more important part of economic and legal literature than ever before (Russell and Sheldon). This type of analysis includes attempting to specify the utility functions of administrators for insight into their decision making. Aspects of this function include (but are not limited to) assurance of the administrator's post-regulatory agency future retention of a political coalition, his or her own views of what is right and wrong, and reputation with peers and associates.

While the subject of "what makes the USDA tick" is frequently encountered in "coffee" talk or popular (and sensational) articles and books, relatively little scholarly effort has been expended to understand the political pressures and internal workings of the agencies that administer food and agriculture policy.

Recently, interest has developed in the final category of market regulation research, the cumulative impact of a group of rules that impact upon various dimensions of the food economy. This type of analysis is illustrated by various attempts to answer the question of what is the dollar cost of regulating a segment of the economy. The problem with this type of research, as with cost-benefit analysis generally, is the appropriate specification of the direct and indirect costs involved and whether a meaningful quantitative appraisal of the benefits can be obtained. This kind of research also suffers from the difficulties encountered by the analyst in determining the causal relationships and levels of influence they represent. Also of substantial significance is the issue of whether stated rules are, in fact, enforced.

Conclusion

Agricultural economists, because of their rich history in applied, normative economic analysis, have the opportunity to make substantial intellectual contributions to regulation economics in the years ahead. In so doing, they also have the chance to be much more influential than they have been in policy-making processes by government at all levels.

> There are known aspects of our society which most of us wish to improve, and new and different imperfections will continue to appear. If we seek to correct these various deficiencies without knowing how legal systems work and what effects they actually achieve, we shall achieve improvements only by sheer chance. We shall often embark upon programs to aid paupers that further impoverish them. The law and economics of public policy now poorly serve, but can surely be brought to serve powerfully, our social conscience (Stigler, 1973, p. 2).

Pre-Regulation Research: The Triumph of Policy Analysis

Thomas P. Grumbly

Washington has a way of taking simple, even elegant truths and transmuting them into intellectual mush. In their moment of triumph, ideas are quickly sucked into the maw of the executive branch and never heard from again. When I saw the title of this paper in the conference brochure, I knew two things: first, policy analysis had finally triumphed in domestic agencies; second, its transformation into ''pre-regulation research'' indicated that analysis was about to be turned into an endangered species.

I want to talk today partly about the triumph of analysis in regulation, but mostly about the danger signals that could threaten its existence—signals that are more serious than unfortunate terminology. I want to do this against a brief historical backdrop of analysis that may help you understand the urgency with which I deliver my message.

Policy analysis is the reincarnation, in my view, of the old discipline of political economy. It attempts to amalgamate political science, economics and other disciplines to make the whole more than the sum of the parts. In doing this, it represents the best of the Enlightenment tradition that commands us to take hold of our futures and mould them by our reason. It is not clear, however, that analysis is in an equilibrium situation. The drive for specialization and the conflict of world [illegible]

For the moment, however, analysis has clearly triumphed. The evidence is abundant: Executive Orders demand that analysis be done; policy study groups spring up all over town; legislation is introduced to ensure that analysis is enshrined in statute. The questions now are: how do we make it work and how can we make it stick?

I think these questions are best addressed by looking at some emerging problems. Some are endogenous to the various policy analysis systems—we can see them happening as analysis is installed as a result of either Executive Orders or agency fiat. Others are, not surprisingly, exogenous, and have more to do with the intrinsic nature of the federal system. Solutions to both sets of problems must be reached before analysis can be said to be more than a fleeting event on the public stage.

Problems Inherent in Policy Analysis

The analytical systems currently being installed in regulatory agencies bring at least four difficulties with them: (*a*) analysis, believe it or not, is not easy to explain; it is not intuitively obvious to the casual observer; (*b*) the method of implementation threatens to glorify process over substance; (*c*) the modes of policy analysis—particularly cost/benefit anal-

informed decisions is lacking; documentation often does not exist. The temptation of the analyst to be nonanalytical can become unbearably strong.

In the same way that one cannot tell people how to do analysis, neither can one legislate it without running the risk of trivializing an important subject. If the reasons for analysis are not carefully explained and digested—and, more importantly, if incentives are not extant to produce good analysis—the executive branch will produce a blizzard of paper and not much else. This is the harsh lesson of Programming, Planning and Budgeting (PPB) of the mid-1960s. If you will recall, President Johnson ordered this particular brand of analysis in all domestic agencies (not just regulatory agencies). It fell of its own weight. Analysis survived that fiasco, if only barely, and we must take care to nurture and to push only as fast as the bureaucracy can bear.

This brings me to perhaps the most important internal conflict within impact, preregulation, or policy analysis: the philosophical battle that pits, in essence, proponents of marginal utility theory on one side and principled activists on the other. I suspect that most of us here resolved the problem for ourselves after we took Economics I. The concepts of marginal utility, opportunity cost and the like teach that we have choices in the world for our scarce resources and that nothing is absolute (except perhaps the concept of balance inherent in the teachings themselves). For various reasons, other intellectual and social traditions in this country view this economic man as unprincipled man—as man willing, for example, to sell his neighbor's health in return for a few cents less on his utility bill. This conflict becomes increasingly intense as always scarce resources become scarcer because of inflation or other reasons.

I believe that this battle between balance and principles will be the hallmark of the last twenty years of this century, as Americans are forced to adjust to a world in which they control fewer of the means of production. As an analyst, I am convinced that we must find some way to reconcile the two camps, lest analysis be charged (perhaps justifiably) with sacrificing the democratic values that distinguish America from the world's tyrannies in the name of rationality. On the other hand, we must remember Alexander Hamilton's admonition in the first *Federalist Paper:*

> It will be forgotten, on one hand, that jealousy is the usual concomitant of violent love, and that the noble enthusiasm of liberty is too apt to be infected with a spirit of narrow and illiberal distrust. On the other hand, it will be equally forgotten, that the vigour of government is essential to the security of liberty; that in the contemplation of a sound and well-informed judgment, their interest can never be separated; and that a dangerous ambition more often lurks behind the specious mask of zeal for the rights of the people than under the forbidding appearance of zeal for the firmness and efficiency of government. History will teach us that the former has been found a much more certain road to the introduction of despotism than the latter, and that of those men who have overturned the liberties of republics, the greatest number have begun their career, by paying an obsequious court to the people, commencing Demogogues and ending Tyrants (Hamilton, pp. 5–6).

Efficiency, then is no vice; my concern is that it not become the principle used by demogogues to exploit a people that is losing its wealth. In other words, analysts must choose their patrons carefully.

A final, and very practical, endogenous problem for analysis is the need for staff analysts—bureaucrats—to do analysis. Despite the nearly level nature of full-time federal employment over the last ten years, most Americans outside Washington perceive the federal government as bloated. They are, of course, at least half right. We obviously have numbers of people who really have outlived their professional usefulness. This should not obscure our need, however, for more first-rate people to do the kind of analytical work that line managers often do not have the time for or the interest in. I was reading the *Washington Post* recently and spotted a comment by a man in a little town in Missouri, who, when asked by the reporter what he thought of the problems that confronted the world said, "There's plenty of people to worry about them things, so I just go about my business and hope they do a good job." So say we all, but where are those people in my agency who have the time to think and write?

Other Problems Facing Policy Analysis

Earlier, I promised to discuss some other problems within the federal system that will present obstacles to the implementation triumph (as opposed to conceptual) of analysis, particularly in regulatory agencies. In the main, I think these are three: (*a*) the fear, even

by bureaucrats, of increasing complexity that further dilutes personal responsibility; (*b*) the trend in government to make more decisions at upper levels coloring an already difficult situation with class overtones; and (*c*) the evident split in health regulatory agencies between policy and science.

As we approach 1984, the spectre of George Orwell looms ever more threatening on the horizon, and people fight to keep the society simple and resist the kinds of perversities that Orwell predicted. Policy analysis is seen by many people as merely another new vocabulary "complexifying" an already-mysterious world. People are wary of the cold-eyed analyst; they conjure up pictures of a future dominated by a reason that seems to exclude passion and politics from consideration. More particularly, the growth of policy studies staffs in both cabinet agencies and the Executive Office of the President multiplies the number of veto points in an already-burdened system. This further depersonalizes decision making and can, if not carefully watched, produce an *ennui* in the operating arms of government that will defeat the purposes of doing analysis in the first place.

Related to this first problem, but perhaps more significant, is the increasing tendency of policy officials to make more and more decisions—often based on the analysis presented to them. This is fine in principle, resting on a widely accepted, and, I think, legitimate notion that career officials fundamentally should recommend, but not unilaterally initiate, new policy. However, by permitting policy officials to exercise greater independence, analysis can exacerbate the "only I know" elitism that many new officials enter the government with. Instead of fostering trust, analysis can erode it and introduce a new kind of authoritarian attitude into government that may be just as bad as the helplessness heretofore induced by being at the mercy of career officials.

Finally, and most parochially, policy analysis is being introduced in regulatory agencies at the same time that the scientific community (and here I am thinking mostly of the National Academy of Sciences) is beginning to question the connections between science and policy. Should the two be disconnected? Should scientific testing, particularly chronic toxicology, be carried out by institutions that do not need to bear the policy responsibility for decisions? In the current system, policy analysis and science are clearly in a symbiotic relationship, as economics and politics attempt to define questions for study, press for alternative solutions, and so on. The scientist cannot be disconnected now from policy officials, although each must have a clearly-defined role. This causes tension, but it is often useful in guiding scientific inquiry along paths that create useful near-term knowledge. Any departure from this system might thoroughly change the environment within which analysis is carried out and consequently alter the requirements.

The Search for Solutions

Solutions to these problems are not easy to generate. I am not going to try to solve each and every problem, but merely to suggest a range of things that could be done to improve the climate for analysis.

First, we must apply the principles of economics to our choice of analyses. We can neither work our good people to death, nor use them on issues that are minor. The urge to require analysis on all decisions is great, but we must resist it. Rule one then is that more analysis on fewer issues guarantees the best use of resources.

Second, we must somehow strike a *detente* between the policy and career officials of this government. Analysis must not be used as a weapon by policy officials to raise decisions higher than their importance deserves. If analysis is seen to represent and symbolize mistrust, it will die. Rule two might then be stated: Make policy analysis a cooperative intellectual endeavor between short-timers and long-timers.

Third, we must remember that analysis is a means to an end, and not an end in itself. If analysis is perceived to symbolize delay, it will be attacked and, I believe, ultimately demolished from both the right and the left. Rule three then is only to do analysis on issues that you are prepared to make decisions on.

Finally, rule four is that we must only promise what we can deliver. We cannot say that policy analysis by itself will make regulation more efficient, or government less intrusive. These problems are too heavy a load for any single system. What we can say is what scholars have been telling us for many a year: Analysis can clarify objectives and help us move

Post-Regulation Research: Milk Marketing Order Regulations

Boyd M. Buxton

The dairy industry represents a major part of the U.S. food system. In 1977 consumer expenditures for fluid milk and manufacturing dairy products reached $27.4 billion and represented 12.6% of the consumers' total food dollar.

Questions are being raised about the impact of the federal milk marketing order program which directly regulates the handling and farm-level pricing of about 65% of all milk produced in the United States. The program has been in existence for over forty years and has played an integral and pervasive part in shaping the U.S. dairy industry.[1] Before any changes are made in the program, it is important to untangle and understand the complex economic relationships involved in order to evaluate the continued need for all or part of these regulations. This paper is an example of post-legislative research designed to help evaluate a long-standing set of regulations.

Generally, the milk order program is not well understood. Some research results have been very controversial, and points of view on the program vary widely.[2] Some argue that the program does not meet the stated goals outlined by Congress (Masson and Eisenstat) while others argue that the goals have been achieved and the public interest served with a minimum amount of government regulation (Forest). Some studies have attempted to measure the social costs of the program (Ippolito and Masson, MacAvoy) or alternative pricing policy modifications of the program (Buxton 1977, Dobson and Buxton). Other studies have considered the economic impact of alternative pricing policies under milk orders (Hallberg, Fallert and Buxton).

This paper is divided into three parts. The first part reviews the major regulatory procedures and goals of the federal milk marketing order program. It further develops the economic rationale on how the regulations achieve those goals and reviews the major benefits usually ascribed to milk orders. The second part of the paper contains a discussion of the major economic impacts of milk orders while the third part contains some conclusions and policy implications.

Federal Milk Marketing Orders

On 1 January 1979, there were forty-seven federal milk marketing orders in the United States. These orders only regulate Grade A milk, which is produced under more stringent sanitary conditions than Grade B milk. Milk must be Grade A in order to be used as a fluid beverage (fluid milk) while manufactured dairy products can be made from either Grade A or B milk.

There are two major regulations used in all federal milk marketing orders: (*a*) classified pricing whereby milk dealers (handlers) are required to pay different prices for the Grade A milk they buy depending on how they use the milk; and (*b*) pooling all revenue from the sale of Grade A milk at the different use prices from which a uniform (blend) price to be paid Grade A farmers is calculated.

Classified Pricing

Federal order regulations require handlers who buy Grade A milk from dairy farmers or associations of dairy farmers and who distribute it in the specified market area to pay at least minimum prices set under the order for the milk according to how the milk is used. If the milk is used in fluid products such as whole

---

The author acknowledges the comments and suggestions of Jerome Hammond, Martin Christiansen, Richard Fallert, James Miller and David Banker. The views expressed in this paper do not necessarily reflect the official views of the USDA or ESCS.

[1] The Agricultural Marketing Agreement Act of 1937, as amended, provides the legal basis for the federal milk marketing order program (Ward).

[2] For example, see the exchange of ideas between the U.S. Justice Department and the U.S. Department of Agriculture resulting from the original report entitled "The U.S. Justice Department Report on Milk Marketing" (U.S. Department of Justice, 1977, 1978/USDA, 1977).

milk, skim milk, low-fat milk, and milk drinks, it is designated as Class I and receives a Class I price.

If the milk is used in manufactured dairy products such as butter, dry milk, and nonfat dry milk, it is designated Class III milk and receives a Class III price.[3]

The same Class III price is used in most federal orders and is set equal to the average price that manufacturing plants pay per 100 pounds of Grade B milk (f.o.b. plant) in the Minnesota-Wisconsin area (often referred to as the M-W price). This price is determined by supply and demand conditions in the manufacturing milk market and moves up and down as supply and demand conditions in the market vary. A floor is effectively placed under this price by the operation of the price support program as the government stands ready to purchase dairy products in amounts needed to keep it from falling below the support price.[4]

A minimum Class I price is separately determined for each federal order by adding a Class I differential to the M-W (Class III) milk price. Under present pricing policy, the minimum Class I price in federal orders east of the Rocky Mountains can be approximated by adding to the M-W price 90¢ plus 0.15¢ for each mile the specific order area is located from Eau Claire, Wisconsin. For example, the minimum Class I price in Southeastern Florida market order is set at $3.15 above the M-W price (90¢ plus 0.15¢ times the approximately 1,500 miles the order is from Eau Claire, Wisconsin).

Pooling Returns

A second major regulation of federal orders requires that all payments for regulated Grade A milk in the different use classes be pooled. A uniform (blend) price representing the average value of all Grade A milk sales in the order is calculated and used as a basis for paying dairy farmers or their cooperative associations. In order to qualify for the pool, dairy farmers or their cooperative association must ship designated proportions of their milk to the fluid market for Class I use. The pooling regulation is a mechanism that allows all dairy farmers producing Grade A milk in a given market to receive a comparable price regardless of how their milk is used. Before federal orders were established in 1937, milk cooperatives had instituted similar pricing and pooling programs. However, the depression conditions made such programs difficult to operate without formal government regulation.

Goals of Federal Milk Orders

The major goals commonly ascribed to federal milk marketing orders as presently administered are reflected in the following list:[5] (*a*) to promote orderly marketing conditions for milk produced by Grade A farmers; (*b*) to set minimum prices consistent with supply and demand conditions and to assure consumers an adequate supply of fluid milk year-round; (*c*) to administer and supervise the terms of trade in deficit milk markets in such a manner as to equalize the market power of buyers and sellers and promote constructive competition; (*d*) to improve the income situation for Grade A dairy farmers.

An overriding objective is that milk orders are to be administered so as to be in the public interest. The above goals lack clarity in meaning by using terms such as "orderly marketing" and "adequate supply." These terms must be more precisely defined in order to provide a better understanding of what milk orders are to accomplish.

The term "orderly marketing" usually is associated with stabilizing fluid milk prices, providing secure and dependable markets for individual Grade A dairy farmers producing milk primarily for the fluid market, and promoting constructive competition by improving the balance of market power between farmers and handlers. "Adequate supply" is usually associated with maintaining a reserve of Grade A milk on a seasonal, weekly, and daily basis that can be drawn from when the Grade A milk supply is tight relative to fluid demand. Such a reserve would eliminate unusually high prices and possible shortages.

[3] Milk used in certain soft manufactured products is designated Class II and receives a Class II price about 10¢ above the Class III price. Conceptually, these two use class designations can be treated as one.

[4] The government presently supports the U.S. manufacturing milk price, which is normally about 10¢ below the M-W price but moves up and down with it.

[5] Sections 601, 602, and 698c(18) of the Agricultural Agreement Act of 1937, as amended (USDA 1971), contain the specific statements on the objectives of the orders as stated by Congress. Also, a 1962 report to the Secretary of Agriculture by the Federal Milk Order Study Committee (USDA 1962, pp. 12–13) outlined the Committee's views on what were the major objectives of milk orders. See also Ward.

The economic rationale on how the classified pricing and pooling regulations of milk orders serve to achieve the goals of milk orders is discussed in the following sections.

Stabilize fluid milk prices. Classified pricing provides an economic incentive for farmers in the aggregate to produce more Grade A milk than is actually needed for fluid use plus an adequate reserve. The impact of Class I differentials being consistently above cost-justified levels is to encourage Grade A dairy farmers sharing in these higher-valued sales to increase their milk production and for some Grade B dairy farmers to convert to Grade A milk production (Buxton 1978). Higher fluid milk prices also discourage fluid milk consumption. The net result is a Grade A milk reserve that either can be used as fluid when needed or diverted into manufacturing when not needed. This eliminates the probable wide fluctuations in the fluid milk price relative to the M-W price due to seasonal and other unsynchronized variations in supply of Grade A milk and fluid demand.

This approach to stabilizing fluid milk prices works only if a secondary market exists for the Grade A milk not needed to meet fluid demand.

Market security. Pooling the returns from the sale of all Grade A milk reduces the concern of farmers as to whether their specific milk is used in fluid products at the higher Class I price or in manufactured products at the lower Class III price. Farmers are paid on the basis of a market average price regardless of how their specific milk is used. Without pooling, an individual farmer or his cooperative association would be under economic pressure to sell as much of his or their own milk as possible in the higher-valued fluid market. Strong competition for the fluid market likely would develop as long as farmers could realize a higher price in that market. Some Grade A farmers probably would be dropped from the Grade A milk market during the season of highest milk production when Grade A milk supply exceeded fluid use. This would leave the farmer seeking an alternative manufacturing market outlet for the extremely perishable milk. Switching back and forth from the fluid to manufacturing market may be difficult and at times results in distressed milk prices and even uncertainty as to whether an outlet exists.

The classified pricing and pooling regulations of milk orders, then, reduce the need for "switching" outlets and provide Grade A dairy farmers with more secure markets.

Balancing market power. For a long time the dairy industry was characterized by many small dairy farmers selling milk to a relatively few large handlers. Minimum Class I prices under milk orders protect dairy farmers from the effects of possible price wars or other price-cutting activities by handlers. Such supervision of the terms of trade is more likely to promote constructive competition for a commodity as perishable as milk.

Increase farm income. Classified pricing that charges a higher price for the relatively more inelastic demand for fluid milk is a form of price discrimination. Returns to Grade A dairy farmers are increased by charging a higher price for milk used in the relatively inelastic fluid market than in the manufacturing market.

To summarize, there is a logical rationale by which classified pricing and pooling provisions of federal milk marketing orders can be used to achieve "orderly" marketing and "adequate" supplies of milk and to improve incomes of Grade A dairy farmers. Fluid milk prices have not been more unstable relative to manufacturing milk prices, and fluid beverage milk is available year-round in essentially every grocery store across the United States. Also, Grade A dairy farmers are assured of a stable outlet for their milk even when large quantities of Grade A milk are diverted into manufacturing. These aspects of milk marketing are held by many as benefits of the federal milk marketing order program.

Other benefits of milk orders include the collection and dissemination of timely and accurate market information, unbiased audits, and verification of weights and tests of farmers' milk.

Our inability to measure quantitatively some of the benefits complicates any attempt to measure public interest specifically. It requires that policymakers must consider the trade-offs and then make decisions on selected provisions of federal milk orders and on the federal milk order program itself.

Although the federal milk marketing order program has generally achieved its goals, two relevant questions remain: (*a*) Can the same benefits and goals be achieved at a lower so-

cial cost? (*b*) Are there alternative approaches to serving the needs of the fluid milk market? To probe these questions in more detail, the next part of this paper considers some basic economic implications of milk orders.

Economic Implications of Milk Orders

Well-developed economic principles of milk marketing provide a framework from which many of the economic implications of milk orders are derived. Particularly useful studies for analyzing the implications of milk orders are provided by Bressler, Harris, and Kessel.

Seven major implications are identified in the following sections. They are not mutually exclusive, nor are they all-encompassing, but they are considered separately for discussion purposes.

Excess Reserves of Grade A Milk

Grade A milk production has increased dramatically despite relatively small increases in the amount of milk used as a fluid beverage. Grade A milk not used for fluid but diverted into manufacturing uses increased from about 24.3 billion pounds in 1967 to over 42 billion pounds in 1977. This increase has come about as a result of both expanded milk production by existing Grade A farmers and conversion by other farmers from Grade B to Grade A milk production. The conversion has been especially dramatic in Minnesota and Wisconsin where a large proportion of the remaining Grade B milk is produced. In 1977, 66% of the milk produced in Wisconsin was Grade A, compared with only 44% in 1967. In Minnesota, the proportion of Grade A milk increased from 19% in 1967 to 49% in 1977. All milk in the United States will become eligible for fluid use if these trends continue despite the fact that less than half of the milk will likely be used for fluid.

Why are farmers converting from Grade B to Grade A milk production when essentially all the additional Grade A milk is diverted and used in the lower-priced manufacturing market?[6] There are many contributing factors, but one essential factor is that a farmer can get a higher price for Grade A than for Grade B milk.[7] A logical assumption is that unless a farmer receives or expects to receive a higher price for Grade A than for Grade B milk, he will not be willing to incur the added cost or inconvenience of the higher farm sanitary standards of Grade A milk production. Because a dairy farmer must produce Grade A milk to participate in a milk order pool, the blend price advantage over the manufacturing milk price can provide the economic incentive for a farmer to convert from Grade B to Grade A production. This is how classified pricing and pooling generate a reserve of Grade A milk and therefore contribute to orderly marketing. If Class I price differentials in milk orders can be set at levels to provide a necessary reserve it would be possible to set them at still higher levels, which would result in excess reserves. An important implication of the rapid and likely nearly total conversion to Grade A milk is that Class I prices have been set higher than can be justified for stabilizing fluid milk prices, providing market security, providing adequate quantities of Grade A milk for the fluid market, and otherwise achieving orderly marketing conditions. Harris recognized this by pointing out that if classified pricing were used to achieve only market stability and security, that "there would be no tendency toward expansion of supplies beyond the effective demand requirement of the market" (pp. 66–67).

Geographical Price Distortions

Setting minimum Class I differentials in order markets east of the Rocky Mountains according to how far the market is located from Eau Claire, Wisconsin, ignores supply and demand conditions for fluid milk in those markets. Why should the Class I price in any market reflect transportation costs for fluid whole milk from Eau Claire when that market has more than enough Grade A milk plus a reserve to meet its own fluid demand and no milk is actually transported? For example, in 1977 the New England milk market, where essentially all milk is Grade A, utilized only 59% of its milk as fluid while 41% was used for manufacturing. This is more reserve than is needed to meet fluid demand by most standards and is

[6] At present, there appears to be no public health concern over the consumption of manufactured dairy products made from Grade B rather than Grade A milk. Therefore, converting from Grade B to Grade A milk is not nor has it been explicitly stated as a goal of classified pricing.

[7] The economic relationship between classified pricing and excess Grade A milk is explained in Buxton 1978.

evidenced by the fact that no fluid milk is shipped from Eau Claire, Wisconsin, into New England. Yet, in 1977 the average minimum Class I price was $11.46 in New England compared to $9.74 in the Chicago regional market (USDA 1978, pp. 44 and 52). In the absence of regulation and assuming a reasonable degree of competition, competitive forces would be expected to cause the Class I price to fall in New England.

The present policy of using a single-price basing point in Eau Claire ignores possible multi-basing points in other surplus areas such as New England. The implication of geographically distorted prices is to encourage milk production in relatively inefficient production areas.

Preliminary research indicates that the distortion favors milk production in the Northeast, South, and West over the Lake States, Corn Belt, and Plains (Fallert and Buxton). However, additional research is needed on evaluating the exact magnitude of the distortion and the implications of following a policy to reduce this distortion.

Expanded Milk Production

Classified pricing and pooling creates a divergence between the price a farmer receives for his milk and the value of that milk in the marketplace. An additional amount of milk produced will be worth the blend price to the farmer but worth only the Class III price in the market because it must be diverted into manufacturing. The divergence, giving inaccurate price signals to Grade A dairy farmers, would be expected to result in the farmers producing more milk individually and in the aggregate than they would if they received the market value rather than the calculated blend price.

The average price received for fluid eligible milk in 1978 was $10.79 per hundredweight while about 40% of that milk was sold at the manufacturing milk price of $9.68 (USDA 1979, p. 28).

Depressed Manufacturing Milk Market

Increasing Class I differentials encourages milk production, as described above. It also discourages fluid milk consumption by increasing fluid milk prices. The combined impact is to increase the amount of milk that must be used to make additional manufactured products to be sold in the manufactured dairy product market. These additional manufactured dairy products tend to depress the manufacturing milk market. The actual impact on the manufacturing milk price (Class III price) depends on whether the market price is at or above the manufacturing milk support price. If the market price is the same as the support price, the government will purchase, under the price support program, the added dairy products resulting from the higher Class I differentials. If the market price is above the manufacturing support price, then the added dairy products would depress manufacturing milk prices. In both cases, classified pricing and pooling provisions under federal milk orders tend to keep the manufacturing milk market depressed.

Only Grade A Farmers Benefited

Only Grade A dairy farmers receive higher milk prices as a result of classified pricing and pooling under milk orders. Because relatively high Class I differentials under milk orders tend to depress the manufacturing milk market, Grade B farmers are worse off, or at best no better off, as a result of them. It is true, however, that many Grade B farmers, by converting to Grade A milk production, can also benefit. However, this is a forced situation because the only alternatives to converting to Grade A milk are to accept the Class III price for their milk or quit dairy farming altogether.

Because milk markets do not benefit Grade B farmers, pursuing the goal of classified pricing to increase the income of Grade A farmers raises a major equity question: Can classified pricing legitimately be used to improve farm income when all farmers do not benefit?

Inefficient Movement of Milk

Once a cooperative which is manufacturing dairy products principally in plants located relatively close to a fluid market ships enough milk to qualify for the pool, the incentive to ship additional Grade A milk to the fluid market is greatly diminished. If it does ship additional milk to the fluid market, it will not pay its producers any more for their milk. There is an actual disadvantage in shipping milk to the fluid market since the cooperatives that have manufacturing facilities would want the largest volume of milk possible to lower unit costs in their own manufacturing operations. Negotiated Class I prices above federal order min-

imums help provide the incentive for such cooperatives to "give up" the milk in their own manufacturing operations and ship it to the fluid market. This means that increased Class I differentials still may not get the milk needed for fluid use.

This situation creates a need to go further distances from the central market to obtain enough milk for fluid demand even though closer supplies exist. To the extent that this phenomenon exists, fluid handlers need to bring milk for fluid use from more distant areas than likely would be the case without regulation. Many factors influence the manner in which cooperatives serve the fluid market; only general forces and implications are pointed out here.

Restrictions on Reconstituted Milk

The present order program assumes that fluid milk demand must be met with fresh whole milk. As discussed, a reserve of Grade A milk would be needed under this assumption to balance seasonal and day-to-day variations in supply and demand and thereby stabilize prices.

However, it has been technically possible for some time to commercially recombine nonfat dry milk, milkfat, and water into a fluid beverage milk. This reconstituted product could then be blended with fresh whole milk to meet fluid demand. In effect, this would provide a storable reserve rather than a fresh fluid milk reserve. Presently, there are provisions in federal milk marketing orders that effectively raise the cost of reconstituted milk so as to make it an uneconomic alternative.[8]

A recent report has taken a preliminary look at the effects of reconstitution on regional prices, utilization, and production (Hammond, Buxton, and Thraen). Results indicate that the maximum Class I differential would be less than the actual Class I differentials that now prevail under federal and state marketing orders. Generally, the Class I differentials based on fluid transportation costs from Eau Claire, Wisconsin, could no longer hold.

Another implication of this alternative would be that Class I differentials high enough to create a necessary fluid reserve could no longer be justified on the basis of stabilizing fluid milk prices. The storable reserve could achieve the same orderly marketing objectives as previously attributed to the fresh fluid reserve.

More research is needed on the potential of other possible alternatives. For example, about 2 pounds of nonfat dry milk and 21.3 pounds of water may be blended with 100 pounds of fresh whole milk of 3.7% fat to yield 123.3 pounds of fluid milk with 3% fat. The average fat test of all fluid beverage milk is now 3% fat. Also, frozen concentrated milk, like frozen concentrated orange juice, would reduce transportation costs, increase shelf life, and could open new markets for fluid milk domestically and overseas.

A major implication of the present milk order regulations is that they distort the economic feasibility of possible innovations for serving the fluid milk market more efficiently without sacrificing orderliness or adequate supply objectives.

This raises an interesting question: What kind of fluid milk industry would evolve if the only economic use of milk was as a fluid beverage? Clearly a reverse, much of which would need to be dumped, would be costly. A great deal of innovation would be expected to avoid waste. Storing fluid milk as nonfat dry and milkfat ingredients or in other forms to be recombined probably would be an integral part of such a dairy industry.

Conclusions

The economic principles of milk marketing and current research methodology contribute a great deal to evaluating the impact of milk marketing order regulations. However, all the questions have not been answered. There is presently no methodology that can predict with a high degree of confidence what the real world would look like without the federal milk marketing order program. The competitive model may not accurately reflect the conduct of cooperatives and handlers. Would or could cooperatives step in and impose the same results as are achieved under market order regulations? Are some regulations needed to create a healthy competitive environment?

At the present time, no model or methodology exists that can predict whether disorderly and chaotic conditions definitely would appear in the absence of regulation. Could the technological changes in handling and transporting

[8] Seven states have outright prohibitions on the production and/or sale of reconstituted milk while 9 states have Grade A standards that effectively prohibit the sale or manufacture of reconstituted products (Hammond, Buxton, and Thraen, pp. 18–19).

milk and the ability to store fluid milk in ingredient form result in orderly marketing of milk without the present regulations? Even if the answer were yes, would such a change in policy be in the public interest by increasing social welfare? Which groups would benefit and which would lose? What kinds of resource adjustments would be required? These questions require additional research even though considerable work has been done. The research must be a broadly focused, no-holds-barred approach. There is a tendency for a "conventional wisdom" on why things cannot be done differently to appear in connection with long-established regulations.

The economics of milk marketing and research methodology are sufficiently well-developed to identify some of the major economic impacts of milk marketing regulations. A major conclusion is that the goal of increasing returns to Grade A dairy farmers has been explicitly or implicitly pursued beyond that needed to stabilize fluid milk prices and provide market security. Reducing Class I differentials from the present levels, therefore, would be possible without risking the market stability, security, or adequate supply objectives. The decrease would need to be made over time in small incremental amounts since present research methodology is not able to identify the exact cost-justified Class I differentials in all federal order markets with a high level of confidence.

Although the relevance of welfare theory is still a matter of debate, it represents the best methodology available for evaluating whether lowering Class I differentials would be in the public interest.[9] The results of the previously mentioned studies indicate that lower Class I differentials would increase social welfare while raising Class I differentials would do the opposite. This would be the conclusion as long as the Class I differentials were not lowered below the level needed to provide a necessary reserve and thereby to stabilize fluid milk prices.

Another significant conclusion based on the economics of milk marketing is that a geographical distortion exists in the Class I price. This distortion results from implicitly assuming only one surplus fluid milk area from which Class I prices in all other markets are aligned according to distance. This ignores supply and demand conditions in various regions of the United States. In addition, welfare theory seems adequate to conclude that reducing the distortion is in the public interest. However, the impact will be quite different among regions. The adjustments imposed on dairy farmers in the regions where price would be most affected (Southeast) would be considerable. Perhaps compensating those most affected would reduce the impact while still moving toward a more efficient system.

A real limitation in analyzing milk orders is a lack of good estimates on how dairy farmers in selected regions and consumers would respond to significant price changes. Better supply and demand estimates are needed. If obtained, they would, in combination with conventional economic theory, provide a great deal of useful analysis for policy decisions regarding milk marketing regulations.

[9] After review of welfare theory, Currie, Murphy and Schmitz concluded that it was the most useful tool available for many kinds of policy questions despite some limitations.

A Regulator's Perspective On Regulatory Research

Gary L. Seevers

There is no question that government regulation, viewed in the aggregate, has become a major influence on the performance of the economy in general and the food system in particular. As a result, it is essential that economists devote more of their own resources to developing a better understanding of the costs as well as the benefits of regulation. This will enable the political system to formulate regulatory policy more responsibly and it will help regulatory agencies implement that policy most efficiently. I am pleased to be invited to participate in this conference as I firmly believe that the application of economic analysis to this relatively new area of public policy has the potential for high social returns compared with other areas of work.

When I came to Washington from Oregon State University nine years ago, I had little interest in regulation and no teaching or research experience. I soon learned that regulation was a priority area of work at the Council of Economic Advisers. The Council was active in advocating less regulation of surface freight transportation, commercial airlines and natural gas production. The Council was also conducting analysis of the newly-emerging environmental regulations.

I first was exposed to the Council's regulatory analysis while I was on the staff. After I became a member, a major part of my responsibility was to coordinate the Council's regulatory analysis and represent the Council inside and outside government. Unfortunately, the amount of work which was needed greatly exceeded the capacity of the Council's small staff of two professionals in this area. This was especially true since new regulatory programs and requirements were proliferating rapidly in the early 1970s.

During the past four years I have been deeply involved in establishing a new regulatory agency which oversees commodity futures trading. My remarks today, therefore, will be from my experience as a regulator—from the inside, so to speak. The Commodity Futures Trading Commission (CFTC) was created by Congress in 1974 when commodity markets were exceptionally turbulent. In addition, establishing new federal regulatory programs was fashionable during this period. Even though Congress is more skeptical about starting new regulatory programs today, I believe they would have to establish the CFTC now if they had not already done so. I know Congress considers effective regulation of futures trading to be desirable and essential for the protection of the hedging and pricing functions of futures markets as well as for the protection of those who use the markets.

Let me make four general observations based upon my experience as a CFTC Commissioner. I hope my perspective will help you determine how to get a handle on regulatory research, which is not an easy task.

A Limited Role for Economists

The role of economists in most regulatory agencies has been small in the past. If I may take the liberty of comparing their role with that of lawyers, for instance, far more commissioners and agency heads are lawyers than all other professionals combined. Perhaps even more significant, lawyers dominate the makeup of most agency staffs and they have been more effective within the agencies than economists. Regulation has been primarily legal and adversarial and, of course, lawyers are trained to be advocates. What economists have to contribute is by nature more conceptual and conjectural, rather than concrete and decisive.

Legal work is also very labor-intensive. One fairly minor case can tie up several lawyers for months. The first chairman of the CFTC and I reached an understanding about the role of lawyers and economists. We used to have friendly but real debates about how many positions should be allocated to economic pro-

---

Gary L. Seevers is a former commissioner, Commodity Futures Trading Commission, Washington, D.C.

grams, and how many should be allocated to legal and enforcement programs. He would say that committing resources to research is like investing in an "ethereal cloud"—it might pay off way down the road. And I would say that hiring more lawyers to work on cases is a "bottomless pit" which could consume everyone in the agency.

Enforcement cases are easy to get your teeth into. There is a strong tendency for such "visible and specific" activities involving the righting of individual wrongs to crowd out activities like market-wide surveillance, economic studies and research that have a broad, long-term payoff. Regulation is a long, deliberative process and most regulators are reluctant to wait for research results. Economists can serve a useful function in regulatory agencies but it will not happen without a determined effort by the economics profession.

The CFTC has a higher proportion of economists among its professional staff than any other regulatory agency. Futures markets are economic institutions which require close monitoring and, as a result, we simply must have a large number of market analysts and economists. Nevertheless, it is a constant challenge to keep a reasonable balance of lawyers, economists and other professionals. One important factor is that new attorneys can be employed quite easily (as Schedule A employees) whereas employing new staff in other professional positions is always time-consuming and sometimes impractical due to civil service procedures.

Growing Demand for Economic Analysis

Fortunately, the role of economists in regulatory agencies is improving. There is more appreciation of the need to include economic analysis in the design of specific rules and regulations, and in the development of overall policy. Concern about the economic costs of regulation is increasingly evident in the Congress and has been recognized for some time in the executive branch, especially among those responsible for dealing with inflation. The consequence is pressure on regulatory agencies to include more economic analysis in their work.

Agencies have a choice between an economic approach to regulation and a purely legalistic approach. Public opinion and political concern definitely are creating the opportunity for agencies to pursue the economic approach. As this occurs there will be more opportunities for economists to be decision-makers, policy advisers and analysts, and to conduct studies and research.

The economic approach to regulation involves an attitude that leads to asking the right questions. Certain questions will be asked if an agency is following the economic approach. These will vary depending on the type of agency, but some useful questions are:

(*a*) Is a regulation really necessary, or will competition provide satisfactory performance?

(*b*) If a regulation is justified, would it be better done by industry self-regulation?

(*c*) How much burden will the regulation impose on those being regulated?

(*d*) Is the regulation enforceable, and at what cost?

(*e*) Does it provide economic incentives to achieve the desired objective?

(*f*) Does it provide useful information to the buyer or beneficiary of the regulation?

(*g*) Will it actually contribute to the objective being sought, or does it only give the appearance of contributing?

(*h*) How will it affect industry structure and competitive incentives among firms?

Obstacles to the Economic Approach

My third observation is that there are serious obstacles to stressing economic analysis in the regulatory process.

An administrator of a regulatory agency needs plenty of information and research when he follows the economic approach. It is difficult to have the pertinent information when it is needed, and administrators are often faced with the pressure to make decisions based on insufficient information. A new agency usually has statutory deadlines, insufficient resources and inexperienced personnel. An established agency usually has an enormous backlog of decisions to make. The CFTC Commissioners were constantly asked to adopt regulations without factual back-up in our early days. On many occasions I recall saying, "let's get the facts before we start regulating."

There are several reasons why there is so much regulation without first getting the facts.

One reason is a procedural pitfall in the regulatory process. Regulations are first proposed

in the Federal Register. It is easy to reason that a draft regulation prepared by your staff is only a proposal and agree to go ahead and solicit public comment on it even though the proposal may not have as much supporting documentation as you would like, and is only one of several alternatives. Unfortunately, this process may lock the regulator into that particular approach. This is why exploring alternative approaches is so essential as a first step. The CFTC now makes it a practice to have a general policy discussion where alternatives are examined before we consider a concrete staff proposal.

Another problem is that the Advisory Committee Act, along with a general concern about industry representatives having too much say in formulating regulations, precludes much informal solicitation of views prior to publication in the Federal Register. As a result, when regulations are first published, they often are not practical or thoroughly thought out. Once in the Federal Register, however, they enter a formal adversarial process which has numerous deficiencies.

A third problem is that regulatory agencies simply try to do too much. They fail to set priorities. An agency's budget is always tight and, in the short-run (six to twelve months) it is fixed. For most agencies the chances of "real" increases in their budgets are not good even over a longer period. Faced with fixed resources, it is important to set priorities and avoid taking on too many activities. Otherwise, each activity will be constrained to "stage one" of its production function.

I think there are significant diseconomies of size which are not well understood or appreciated in many government activities. To say it another way, agencies try to do too much and they end up not doing the important and possible things well. This problem certainly existed at the CFTC in our early years. Setting priorities is not only essential to good allocation of resources, it is also important if agencies are to follow the economic approach. The reason is that the economic approach has higher up-front costs; it requires more information, more research and more critical examination when regulations are being adopted.

If new agencies undertake too much rule making, they spread resources too thin and will be driven toward the legalistic approach. Over time this does not really save resources, however, because the higher up-front costs for the economic approach are more than offset by higher costs of administering and enforcing regulations.

Useful Regulatory Research

While the demand for regulatory research is there, the supply response is a real challenge. For one thing, it is difficult to undertake meaningful research when you are based at a university or research institution away from the agency. The CFTC has had little success with contract research. Timeliness and relevance are both problems as well as supervision to make sure the researcher follows the project's objectives.

The CFTC has had better success with in-house studies of particular regulatory problems. We also have a good record of applying economic analysis to many aspects of our regulations. But this happens when specific regulatory needs arise and the staff is directed to work on a problem. When in-house research is undertaken outside the context of specific needs of the Commission, it has not been very productive either.

This presents a dilemma for the academic researcher and for us. A definable regulatory problem seems to be needed to focus research, but by that time it is too late to solicit outside research.

We are now in the process of reviewing our entire research strategy. My conclusion is that the CFTC should devote most of its discretionary research funds over the next four years to descriptive research about the structure of the futures industry and about basic information such as who uses futures markets. One of our most valuable projects was a survey study of what types of firms and individuals are making use of the new financial futures markets in interest rates and foreign currencies. Little is known about many basic aspects of the markets and the futures industry, and the CFTC is in an advantageous position to generate and assemble such data and information.

The supply side of regulatory analysis is something that has to be worked on by economists if they expect to be heard, and to make a contribution. How does someone who is interested in regulatory research proceed?

I think it is important to make a strong commitment to an area for at least five years—probably to a particular agency or program. Be willing to familiarize yourself with the industry that is being regulated. Monitor

what the agency is doing, read articles on the legislative background and legal side of the agency. Get to know its staff as well as its programs. Expect to stray beyond conventional economic problems because regulatory analysis seldom, if ever, comes in clear and easy forms.

The potential for social payoff is large, however, judging by the successful research studies done in recent years that have contributed directly to regulatory reform efforts. Today, more than ever before, there is a market for economic analysis in the formulation and implementation of regulatory policy.

Cumulative Impacts of Regulation

Barry P. Bosworth

This paper discusses some of the cumulative impacts and aggregate effects of regulation, particularly as they relate to inflation. To provide some framework for the discussion, I want to give a perspective on the issue of inflation and the way regulation is part of that problem.

Without getting into all the complicated causes of inflation, I think there is one approach which provides something of a framework for looking at the issue. Inflation problems can be separated into three rather broad areas. It is necessary to keep them separate to keep them in perspective.

Momentum Inflation

The first is momentum inflation. Momentum inflation has very little to do with regulation. It simply has developed in this economy after over a decade of continuing inflation and the expectation that inflation is going to continue. Therefore, we probably have in the range of 7 to 8% a year of continuing inflation that is not of the classical economic type which says that inflation is due to excess demand—too much money chasing too few goods. It is more like a merry-go-round—a defensive posture.

I think it is interesting, for example, to look at the Teamster negotiations that were completed this year. In spite of all the newspaper articles that were written about those negotiations and whether or not they complied with the guidelines, there was one issue that never came up. That was whether anybody thought that there was a surplus of truckers or a shortage of truckers in this country. Those questions, it was thought, had absolutely nothing to do with the issue of what was the appropriate increase in wages. Instead, we have this momentum inflation. It is a situation where people believe that their own wage increases are justified because of past price increases. Each group is trying to match the wage increases of coal miners and Teamsters and others they read about in newspapers. Then, they want to add a little bit on top of that because they expect the whole process to continue and they have to keep up until the next time they get a wage increase.

On the business side, I think you see much of the same thing. Businessmen, for the most part, are raising prices to levels they think are justified in order to recover the cost increases for past wage increases and the increased cost of materials. And, perhaps, they are adding a little bit on because they expect the whole process to continue. The momentum has built up over a long period of time and now runs at fairly high and steady levels.

Most Americans have come to realize that they are not really benefiting from that inflationary momentum. They are beginning to realize that no one is making any appreciable gains. They are learning that their wage increases are simply being matched by others and followed by price increases. Most Americans now feel that they would like to get off that merry-go-round, if possible. But they hesitate to do so because they have absolutely no faith that anybody else will do the same thing. As long as everybody feels that no one else will show restraint, no one can afford to show restraint, and so the whole process simply continues. Momentum inflation has little to do with excess demand pressures in the economy or a shortage of labor or a shortage of capacity in most of the basic materials industries. It has everything to do with psychology.

Shocks to the Economy

The second part of that process, which intensifies inflation and makes it worse, is the fact that shocks are occurring constantly in the economic system.

For instance, bad weather drives up prices in the agricultural sector suddenly. As a result, beef producers liquidate the herd. A few years later beef prices increase and then people say, "I know there is a shortage of it. I know that the country has to cut back on beef consumption because we cannot raise more cattle in the short run but, I do not want to bear the bur-

---

Barry P. Bosworth is former Director, Council on Wage and Price Stability, Washington, D.C.

den." Pressure intensifies for wage increases that keep up with the beef price increase or gasoline price increase or what have you.

Another effect of those shocks is a growing awareness that the United States is no longer in a position to dictate world economic conditions. The disruptions that occur in other countries, including the economic policies they follow, upset the pattern of wage and price changes in this country and, therefore, touch off further rounds of wage and price increases domestically. One of the best examples was the Iranian oil crisis.

Our own people and policies aggravate the situation. We resist changing our institutions to buffer ourselves against the impacts of these external shocks and then, to make matters worse, we do not accept the consequences. We are used to thinking that if food prices go up, somebody is responsible, and the government will do something about it. Many Americans believe it is not necessary for us to learn to live with changed relative prices.

Five years after the big increase in oil prices, Japan and the European countries have accepted the fact of life that energy is going to be more expensive. They understand the need to adjust to that situation and go on. In the United States, on the other hand, five years later, we are still fighting over who is going to pay for those higher energy prices. Everybody feels that somewhere in the process it will be possible once again to find cheap energy.

Drop in Productivity Growth

The third area—which does bear directly on regulation—is related to the fact that the federal government and, to a lesser extent, state and local governments, constantly are taking actions that tend to exacerbate the price pressures. They either initiate a price increase in one sector or a wage increase in another or they take some other regulatory action that has the same result.

These actions divide themselves into two areas: One we would refer to as regulation, or changes in the rules of the game under which the system operates. The second, closely related because it also involves changes in the rules, is special interest legislation.

Both relate to the third area and the third problem that we face in the current inflation, the major decline in the rate of growth of productivity in this country. This country had a rate of productivity growth from the 1950s through most of the 1960s of about 3% a year. A period of price stability in the early 1960s up to about 1965 was accompanied by rates of improvement in productivity of 4 to 5% a year. In the last decade, however, productivity growth in this country has been less than 2% a year.

Many economists and individuals argued that the decline in productivity growth was simply cyclical and related to the fact that in that decade we had two severe recessions. They said that if we just had an expansion of the economy, productivity growth would recover and the rate of inflation would moderate. However, the last two years have been years of strong economic growth, major reductions in unemployment and what, if you only looked at the real side of the ledger, most people would say was an abnormally well-balanced strong economic expansion. Yet, the rate of growth of productivity has been less than 1%. It has become clear to everyone that this country is facing a somewhat permanent and major reduction in the rate of growth of productivity.

The question is how do we account for it? Most businessmen blame a capital shortage. But, it is important to remember that the rate of productivity growth in this country declined not just in recent years but from 1967 to 1973 as well. That was a period when the rate of growth of capital formation was stronger than it has been at any time in the post-war period. Yet, productivity growth declined. The period of decline in productivity coincident with the decline in capital formation has been only since 1973. Economists' efforts to identify the contribution of capital formation to productivity growth are always rather nebulous and difficult to pin down with precision. It seems clear that the slowdown in the rate of growth of capital formation only can account for a small proportion of the total decline in productivity.

Some people point to the fact that there has been a shift in the age and sex mix of the labor force. This period, they say, has been one of very rapid labor force growth and, therefore, the United States has an abnormally inexperienced labor force. Because so many women and young teenagers have come into the work force with relatively limited previous work experience, some claim the average efficiency level of that labor force is less than it was in

the past—and that has contributed to the slowdown in productivity.

If that were a reasonable explanation for the slowdown in productivity, the country could look forward in the 1980s to a very rapid growth of productivity because those young and inexperienced workers will be middle-aged and very experienced by then and the rate of growth of the labor force will slow down during that period. Empirical attempts to identify that contribution to productivity slowdown, however, have indicated that, particularly in the last five years, its contribution is extremely limited and cannot explain the major slowdown in productivity.

Capital formation could account for something between three-tenths and four-tenths and the shift in the labor force may account for something like one-third of the slowdown.

People also have pointed to such factors as the shift in the industrial mix of output. But all the empirical studies attempting to identify that factor have shown that the industrial shift, the so-called move to services away from goods, has not in fact occurred. Secondly, it is not true that the service sector of the economy has a lower level of productivity than the rest of the economy. Therefore, unless you want to count the move out of agriculture being offset by the growth in government, there has been no impact or shift in the industrial mix of output. In the private, nonfarm sector of the economy, there has been a major slowdown in productivity and, within that sector, you can find no contribution being made by the shift in industrial mix of employment.

That still leaves us essentially with the problem of trying to explain what has happened to productivity growth. People have pointed to research and development, but again empirical estimates to determine the extent of its impact have been very limited.

Impact of Regulation

One area that has had a significant impact on the rate of growth of productivity—has been the growing role of federal regulation and special interest legislation. The impacts of regulation typically do not show up as a higher profit margin and they do not show up as a higher wage rate. They show up instead as a decline in the measure of the rate of growth of productivity formation in the country. Attempts to estimate the impacts of regulation in individual industries and to aggregate those impacts suggest that, while it would be a gross exaggeration to say that regulation is the major cause of the slowdown in productivity growth, it has been an important contributor. The electrical utility industry, for example, used to show a very rapid growth in productivity and, for the last five years, has shown almost none. The construction industry has experienced major declines in the rate of growth of productivity. The mining industry used to experience between 3 and 5% growth in productivity a year but, since 1971, productivity has actually declined 40%. In surface mining, productivity is down about 20%.

Putting those facts together shows that there are important, significant aggregate effects on productivity growth from rapid growth in regulation. At the same time, it is very important to keep in mind that those regulations brought with them both benefits and costs and the two have to be balanced off against each other. In many ways, you are dealing with regulation in areas where the benefits are not precisely economic and, therefore, cannot be measured simply by looking at productivity. For instance, you have to make adjustments for the environment. But even if that is true, I think that, while there might be general agreement that the goals of regulation have been desirable and meaningful, it is extremely important for people to keep in mind that regulations are not free. Too much of the present attitude indicates that people believe that they are free. They want to improve the environment, to improve worker health and safety, but, the costs of regulation to achieve these goals, unlike most government activities, do not show up in the federal budget. Instead, they show up as increased costs and, therefore, higher prices in the private sector. At that point, everybody calls it inflation and they argue for a wage increase to compensate.

One of the problems has been that regulation has no automatic mechanism by which people agree to pay the cost. There is no direct way to demonstrate that they must be willing to reduce the demands they place on the economy to compensate for improvement in the environment or in health and safety. One of the problems is that there is not a general public acceptance of the effects of regulation nor a willingness to pay for them, except for a willingness to have everyone else pay for them.

There are a couple of other difficulties with

regulation. First of all, social regulation as opposed to economic regulation is relatively new. Like any other new industry, particularly when that industry is run by government, it is done poorly. In the regulatory area, one of the major gains that we can make is to try to distinguish between the goals and the means by which we try to achieve those goals. Too often much of the debate is about the goals. Business will say that it is not worth following because the needed regulations will increase costs. But they also bring benefits and those have to be recognized. When agencies like the Council on Wage and Price Stability (CWPS) and the Council of Economic Advisers (CEA) try to take an interest in some of these regulations and indicate that there may be a cheaper means of achieving the same goal, then usually the newspapers headline that the CEA or CWPS is at it again; that these agencies do not care about the value of a human life or that they want to destroy the environment. Yet, if you look at most of the regulatory proceedings, it is not the goals that are questioned. In most of the regulatory proceedings, you will find that the issues relate to the means by which the goals are to be achieved.

Approaches to Regulation

One of the largest areas of waste has been the insistence of regulatory agencies on specifying the design standards, the method by which compliance with the law is achieved. Almost never is the focus on performance standards. Performance standards set targets and let the industry determine how to achieve them. As a result of setting design standards we have inhibited incentives for private business or other groups to find ways to improve the efficiency of efforts to clean up the environment and to achieve other regulatory goals. In the current regulatory framework, if you are a businessman and know of a way to reduce pollution from your plant, you should keep it a secret because the moment you mention it, the regulatory agency will find out about it and order you and everybody else in industry to do it. It can only end up costing the firm money with no incentive to find a cheaper way to do it.

CEA and CWPS are trying to get the government to focus on the target, the objective they want to achieve and then leave it up to the industry to determine the cheapest way to accomplish the objective. The moment that pollution costs business something, business will have the same incentive it does with other cost factors. The effort will be to minimize those costs and find a more efficient way of reducing pollution.

A Structure for Regulation

The broader problem that this Administration has tried to address relates to the rule-making procedures. The Administration is concerned about the whole institutional structure by which we undertake regulation. Most of what government is doing today lies outside the budget. If regulatory agencies were spending tax money, everybody would understand that tax funds are limited, that there are many uses for them and that we have to make choices about how we spend money in order to maximize the benefits. We would have to equalize incrementally society's value of money spent on national defense versus money spent for health and welfare. We would have to debate those issues and decide which are legitimate issues for the public to participate in.

We have a budgetary policy by which we recognize that the Department of Health, Education and Welfare (HEW) always will want a bigger budget and the Defense Department always will want a bigger budget because what they care about is pursuing their own department's objectives. It is the task of the Office of Management and Budget (OMB) to balance those choices, and to present them to the President in a logical framework so that he can make some choices about priorities. If there is a limited amount of money available, the President wants to make sure we spend it so that at the margin in every area we are getting the same incremental benefits.

Many of the budgetary concepts that are applied to the use of tax dollars can be applied in the area of regulation. Regulation uses society's resources, but by a method different from collecting tax revenues and making the cost explicit. Regulation orders people in the private sector to do something and the cost shows up in the private sector. Society still ends up paying for the regulation. But, in the regulatory area, there is absolutely no budgetary framework. The Environmental Protection Agency (EPA), for example, has 20,000 employees interested in minimizing the damage done to the environment because that is the task EPA has been given. The Occupational

Safety and Health Administration (OSHA) wants to improve worker health and safety. Everyone in these regulatory agencies is dedicated to pursuing their agency's objectives, but there is no counterbalance. There is no attempt to make sure that the amount of money that goes to EPA and the benefits that are derived from it at the margin equal the benefits we would receive if we spent another dollar for OSHA or another dollar for HEW welfare programs.

But this is not a new problem. If you read the public newspapers from the time the White House Bureau of the Budget was formed you will find that the same thing went on. The argument then was that the President had no right to tell the Defense Department or any other Department what its budget proposals should be. The first effort was to see whether or not the President could get the agencies to send over their budget proposals at the same time. The process started out with the departments simply sending their budgets to the White House where they were bundled together and sent to the Congress. Gradually, a concept of Presidential review evolved and there came to be an Office of Management and Budget and a budgetary process that tried to ensure that the demands of the various agencies were constrained within limits.

Congress has realized that it has the same need to balance the demands to achieve various social goals and recently it has set up a congressional budgetary process. I think most people who look at the current federal budgetary process believe it has led to far more rational policy decisions with respect to where we ought to spend the tax money.

The only problem with all the reforms is that, while the reforms were taking place, most of the actions of the federal government shifted outside the budget. Now the budget process is largely irrelevant to the economic effects and, to a major extent, social effects of government because the federal government is involved extensively not only in regulation, but also in the whole area of off-budget financing and all the other ways by which government achieves various national goals without having the costs show directly in the budget. Therefore, one of the problems we face is trying to develop some sort of budgetary framework within which we can evaluate the conflicting interests of different regulatory agencies. In order to do that, we need some way to measure the benefits and costs of regulations. That is the challenge to economic analysis. This does not mean that regulation has to be reduced to a Corps of Engineers cost-benefit memo. One of the nice things about most human beings is that they are able to think in several dimensions. It is enough to be able to list the costs in dollar terms where the costs are in dollars and in other terms where the costs are in other terms. And, similarly with the benefits, we do not have to value a human life and put a dollar amount on it. Instead we can talk about the number of human lives that this policy would save.

In the budgetary process we make exactly the same decisions we are currently being asked to make in the regulatory process. In order to have a rational budget, first of all, we have to arrive at a way of trying to list the costs and benefits and evaluate them. I think that is the direction we should take.

Currently, the regulatory agencies do not want to demonstrate what the benefits of proposed regulations are because once the benefits are quantified they provide a basis for applying the budgetary framework. It seems to me far better to go the way we have in the general budget. Give the regulatory agencies a budget—a total amount of economic impact that they are able to exert on the economy with the cost of the regulations. At that point, they will try to measure the benefits of their regulations and account for them because they will want a bigger budget. Agencies then will be very interested in finding cheaper ways to regulate. If costs can be reduced, that will leave more regulatory funds for use in other areas.

I know somebody will come back and say that you cannot measure these things with precision. If you go back ten years ago and look up the budget projections for the costs of the food stamp program you will find out that those costs were not measured with precision either. We make lots of mistakes in projecting the costs of programs. The real question that should be relevant is whether or not we can give an order of magnitude within which to evaluate a regulation. I would suggest today that, for most regulations, improvements in analysis have got us to the point where you can give an order of magnitude measure of the effects. In particular, although you do not know precisely the value of a regulation, you do know the value of a change in the regulation with much more precision. You can tell whether or not Approach A would be more

effective than Approach B, even though you are not too sure of the exact cost of either one. You can figure out the differences between the two. Many of the elements that are required for the purpose of budgetary policy are there. All that is important is that the regulatory agencies be given a resource allotment for planning.

I think the current regulatory framework is headed in that direction. There is an attempt now to try to get every regulatory agency to write down the benefits of a proposed regulation, the cost of that regulation and, most important, the implications of some alternative approaches for achieving the same goals. This information must be prepared and put in a public document at the time the regulation is first proposed. Then that information is available for the public to comment on in an open proceeding where other government agencies also can comment.

The original agency is supposed to improve the analysis based on the comments received, and then use it as a basis for making the regulatory decision. That begins to look very much like a budgetary process except that the agencies are not held to any sort of total budget at the present time. Experience with doing economic impact analyses of regulation has shown that the analysis can come up with orders of magnitude effects for most regulations and that has been a useful process for trying to evaluate the implications of alternatives.

Implementing a New Regulatory Framework

Adoption of this process obviously is not the total solution to inflation, but it would make a contribution toward reaching that goal: first, because it is important that we find a way to stimulate the rate of growth of productivity in terms of a long-run improvement in living standards, and secondly, because the waste inherent in some regulations is a waste of society's resources. We probably could achieve a cleaner environment than we now have if we did it more efficiently. And we could save more lives than we do now. The current estimates suggest that regulation of a social type today is probably reducing productivity somewhere between five-tenths to three-quarters of a percentage point a year. An improved framework within which those social regulations are developed probably could cut that cost in half.

The Council on Wage and Price Stability, about a year ago, tried to provide a scorecard for evaluating special interest regulatory measures, such as those participated in by the U.S. Department of Agriculture (USDA) when it fixes a minimum price or restricts trade or other such measures. CWPS found that such measures are adding somewhere between one-half and a full percentage point to the current rate of inflation. In other words just these two areas of regulation, both of the social type, and both regulations designed to protect one individual group or another add somewhere between one and one-and-a-half percentage points to the overall inflation rate. An improved framework for doing that regulation would reduce the inflation rate directly. In addition, because of the multiplier effects of regulation—price increases generate further demands for wage increases—the aggregate reduction of the overall inflation rate would probably be roughly in a magnitude of about twice that.

The basic problem we always have with changing the framework is that every time you raise a specific situation, somebody is going to stand up and say that that particular item has a miniscule effect on the Consumer Price Index (CPI). I think CWPS probably has lost patience because of the number of times USDA has said some proposal would not increase the CPI by more than 0.001%. There is almost nothing that government can do in a $2.5 trillion economy that will raise the CPI by more than 0.001%. What we forget is that government is doing hundreds of those things in any given year and, when you add them up, they have a very considerable impact on the current inflation.

Some people say that we should leave this kind of concern up to the Congress and that, once a law is passed, Congress has spoken. Anyone looking at the history of these arguments will find 90% of the congressmen did not have the foggiest idea of what they were voting for. The issues that have come up in these areas are so complicated that most congressmen simply cannot understand all the issues and, therefore, the decisionmakers are not able to evaluate the issues technically.

A second problem that has come up is that the whole political process in this country has changed so much. A politician is tempted always to vote for the special interest group. I will use the sugar legislation as an example because it has involved a lot of regulatory

agencies including USDA. There are 15,000 sugar producers in this country. There are 220 million sugar consumers. You would think the outcome of a bill to more than double the current price of sugar would be obvious. We could get sugar for about 7¢ on world markets, the President offered 15¢ to domestic producers, they are asking for around 19 or 20¢. Why is it that those bills get as far as they do? Because there are 15,000 sugar producers who do not care about any other issue short of war. If their congressman votes for that sugar bill they will vote for him. If he votes against it, they will vote against him. Those 220 million sugar consumers will never know what hit them. Nobody is going to change his vote for his congressman depending on how he voted on the sugar legislation. They will wait for the special interest legislation that comes down the pike that affects them because sooner or later everyone belongs to a special interest group—whether it be sugar producers, steel industry, environmentalists or whatever. These are people who have a single interest in life and, therefore, will vote for or against a congressman depending upon whether or not he votes for their issue.

Congressmen have learned, it seems to me, that there is a good chance of getting elected today by forming a coalition of special interest groups. And, therefore, they vote for every piece of special interest legislation or regulation that comes down the pike. That creates a very difficult problem for stopping inflation. In most of these decisions, the special interest point of view will raise the costs and prices, and the general interest point of view will lower the costs and prices. But there is no way the general interest gets reflected because these are all small actions that, in isolation, will have almost no impact on the overall rate of inflation.

Regulation Research Issues
(Dale C. Dahl, University of Minnesota, Chairperson)

Food Industry Structure and Performance

Willard F. Mueller

The reason for concern with the structure of the food system is the belief—based on theory and experience—that the competitive structure of an industry impacts significantly on its performance. This is not to say we are concerned with structure alone. On the contrary, the ultimate purpose for examining industrial organization is concern with industry performance. In a capitalistic economy operated within a system of democratic institutions, citizens have a right to establish the rules governing private enterprise to insure that it serves the public interest. It is therefore inevitable and appropriate that public policies evolve to control those with private economic power.

Types of Regulation

The American system has developed two general forms of regulation of private power: (*a*) direct regulation of performance and (*b*) indirect regulation of performance by placing restraints on certain types of conduct and structure.

When substantial private economic power is held by business, the basic threshold question is not whether to regulate, but which method of regulation to use. Historically we have used both the direct and indirect approaches to regulation. It is important to understand pros and cons of each approach.

Direct Regulation

Direct regulation has the virtue of dealing directly with performance, a task easier said than done. Consider what is required for effective direct regulation. First, the regulator must know what kind of performance is desired and possible. Each of these require enormous amounts of knowledge. Even regulation of the railroads—the first explicit effort in direct regulation via the regulatory commission (Interstate Commerce Commission—ICC) approach—has proven beyond the ability of regulators. The ICC which traditionally was concerned mainly with rate setting, and so on, required a massive amount of paperwork and a bureacracy larger than those engaged in antitrust matters—the Justice Department and the Federal Trade Commission—and, by virtually unanimous agreement, it has done an inadequate job.

More recent examples are the various laws dealing with safety, pollution and even wages and prices.

The Indirect Regulatory Approach

This approach is best epitomized by the various antitrust laws. The basic premise of these laws is that business performance is determined in large part by the competitive structure of markets and the conduct of business firms. The approach rests in the heroic assumption that a causal relationship exists between structure, conduct and performance, and that we know what it is.

Problems of Two Approaches

Each approach has its virtues and vices. Because the direct regulatory approach requires detailed knowledge to determine some desired performance and how to achieve it, the approach necessarily requires enormous bureaucratic resources. Even under the best of circumstances—which seldom are found in America—the approach is cumbersome, bureaucratic, and places strains on our political processes.

The indirect approach has the great virtue of requiring relatively few resources, since it need not get involved in the difficult problem of specifying performance and determining how best to achieve it. But this virtue of

---

Willard F. Mueller is William F. Vilas Research Professor in the Departments of Agricultural Economics, Economics, and the Law School, University of Wisconsin—Madison.

simplicity is also its greatest weakness, making it vulnerable to criticism that may paralyze the process. Because we do not know precisely how market structure and conduct impact on performance, nearly every action taken can be criticized. Contrary to the criticism of this approach, this lack of knowledge has not lead to excessive antitrust action; on the contrary, imperfect knowledge is used as an excuse for bureaucratic timidity and inaction.

I have emphasized the difference between these two approaches because they are fundamentally different though there is need for research in each area. In the past decade, the trend has been toward more direct regulation of business. This partly reflects a growing feeling that (*a*) indirect regulation has failed to maintain competition and/or that modern technological imperatives have made the antitrust approach obsolete and (*b*) the most recently perceived problems requiring regulation, e.g., protection of safety and health, can only be achieved by specification of performance. The latter occurs when the performance to be regulated is not causally related to the state of competition in any event.

Research Needs

The ultimate purpose of research into the structure and performance of the food system is to provide reliable knowledge for public policy. Of course, there is a growing body of "Chicago School" economists who believe that the world of Adam Smith has been reborn, making unnecessary any form of indirect regulation, and that public efforts to control performance directly are likely to be so wretched as to justify a virtual hands-off approach here as well. Although these views are generating much public debate, they still represent a minority view.

Research in Direct Regulation

The growing technological and economic complexity of our environment makes inevitable the growth of direct regulation. Examples of research that needs to be done relating to the food system (not in order of priority) include the following: (*a*) Cost-benefit analyses of alternative regulatory schemes relating to virtually all programs regulating performance of the food system; (*b*) Impact of alternative price and wage control systems on farmers, food manufacturers, distributors and consumers; and (*c*) Deceptive advertising and an entire array of issues relating to the advertising of food products.

Agricultural economists also can make contributions into areas primarily in the domain of applied sciences. Multidisciplinary evaluation teams such as those of the National Academy of Sciences frequently should include economists.

Research in Indirect Regulation

Research in indirect regulation requires continuing review of factors influencing the structure and conduct of industry and a better understanding of how structure and conduct impact on performance. New work needs to be done to broaden our concept of performance, as well as to examine the playback impact of conduct on structure. More attention should be given to the distributive effects of market power rather than to the economist's traditional preoccupation with efficiency. Examples of issues requiring current examination include the following: (*a*) Significance of conglomerate mergers on structure, conduct and performance; (*b*) Evaluation of the significance of existing anti-trust treatment of agricultural cooperatives; (*c*) Examination of alternative strategies of indirect regulation, e.g., the relative efficiency of case law, rule making, guidelines and new legislation requiring presumptive illegality of certain conduct; (*d*) Evaluation of past enforcement efforts to determine their effectiveness. Finally, the ultimate thrust of much legal-economic research should be aimed at determining what the law should be, not merely what it is.

Panel Discussion

During the panel discussion following this paper, a number of other issues relating to structure and performance were raised. They included the following:

(*a*) What should be done about high profits in food manufacturing?

(*b*) What is responsible for high levels of concentration in food manufacturing and why is it increasing?

(*c*) Should limits be placed on the market

share of firms to prevent the emergence of shared monopolies?

(*d*) If policy makers want to deal with the problem of growing concentration do they have the necessary legal authority? Do they have the necessary information?

(*e*) Do consumers want the kind of product differentiation which may result in market power?

(*f*) What "norm" should be used in discussing the food system?

(*g*) Do consumers benefit from food manufacturing monopolies in ways that balance some of the costs?

Food Protection: A Research Agenda

William T. Boehm

Regulatory issues have become relatively more important as agricultural policy concerns. The still-evolving role of nontraditional food and agricultural clientele is at least a contributing factor. Increasingly, concerns about the quality of life, rather than just the quantity of goods and services produced, affect the emergence of food issues and influence the ultimate decisions. Often it is felt that regulation, obtained through the political process, is the most direct route to conflict resolution.

On the other hand, there is increasing public concern regarding the direct regulation of behavior by government. Most everyone agrees that there are "too many regulations." There is little agreement, however, on which regulations should be abolished. Deregulation is sought by those who do not have a personal interest in the industry to be deregulated or the social concern that prompted the original regulation.

The conflict embodied in the present policy settling has resulted in increased public scrutiny of regulatory actions whose purpose is to achieve private or social goals. Regulatory bodies, including those dealing with food and agriculture, are now required by presidential order to make decisions only after a thorough analysis of all the evidence, including comments from the public.

Without question, such rules have influenced the economic research and policy analysis agenda. Agency administrators throughout the federal government are now allocating resources to policy analysis staffs. The challenge they face, however, is to integrate fully the insight of the economic analyst into the decision-making process.

This paper relies heavily on the recent experiences of the Economics, Statistics and Cooperatives Service (ESCS) of the U.S. Department of Agriculture (USDA) in the area of regulation research. The focus of the paper is on food protection issues, but the experiences in that area provide a framework for additional research on other domestic food and agricultural issues. Clearly, the ESCS program of regulation research is still evolving. So far, we have been responding to the research needs of the department's decision makers, but the longer-term research program needed to support this effort is not yet well thought out. Nor is it integrated with work being done on land grant and other university campuses. The hope, of course, is that meetings like this one will help to sharpen the focus of the ESCS research program and to encourage the initiation of such research at other locations.

In the time available, I will review briefly the policy setting, discuss the legal framework providing the broad guidelines for research in this area, and present a research agenda drawing from some recent work done in USDA.

The Policy Setting

Economic research is typically not conducted in a vacuum. Most often, the studies are addressed to the resolution of particular private or social problems. In that sense, economics is only one of a number of disciplines that contributes to the body of information ultimately resulting in a decision. Economists, as social scientists, thus are acutely aware of the role played by that collection of forces commonly known as the policy setting.

The contemporary concern about adequate economic research and policy analysis in the area of food protection finds its basis in the wider concern for implementation of a broad-based food policy. The changed institutional setting was summarized earlier by Howard Hjort so I will not repeat it here. However, the point to be emphasized is that public institutions are now more open in their decision making. And, like it or not, they receive comments from interested parties on almost every issue.

The setting places a strain on the bureaucracy—decisions taken must be defensible or they will not be allowed to stand. In particular, a reasonable consensus regarding

---

William T. Boehm is Acting Chief, Food Economics Branch, Economics, Statistics and Cooperatives Service, U.S. Department of Agriculture. The views expressed in this paper do not necessarily reflect the official views of the USDA or ESCS.

the likely economic impacts of a proposed rule change is needed. All the parties affected by the decision being discussed do not have to agree on the assessment, but glaring holes in the impact analyses will not be allowed to stand unchallenged.

This opening up of the public decision process has resulted in a somewhat changed role for ESCS. Once primarily involved in research related to concerns of the farm sector, ESCS is now being asked to provide assessments of policy issues spanning all of food and agriculture. The department's "food agencies"—the Food and Nutrition Service (FNS) and the Food Safety and Quality Service (FSQS)—have become important ESCS clients in recent years.

My view is that the ESCS perception of the agency's own role has changed as well. There is more concern for service, for developing a research and analysis program that contributes to better decisions on matters of importance within USDA. Certainly, other areas of work are not being aborted, but there appears to be an honest searching for an allocation of the agency's resources that will allow it to contribute more effectively as USDA's economic research and policy analysis agency.

The Food Protection Issue

The specific topic of this paper is economic research on food protection. The boundaries of that research are established, in a sense, by one's view of the word "protection." Also important is the perspective one brings to regulatory research. I argue, at the outset, for a broad-view interpretation of both.

Food protection appropriately encompasses both food safety and food quality issues. Too often, the tendency is to narrow the interpretation such that only problems dealing with immediate or short-run protections from injury or death are considered as legitimate. In such cases, many social problem areas are dismissed as unimportant or as rhetoric because the immediate health or safety aspects are not obvious. The problem with that approach is, of course, that safety itself is a relative concept.

If, for example, some foods have the potential to affect health throughout the life cycle, then perhaps nutrition education should be considered as a legitimate food protection issue. The same concept holds for product labeling, the use and revision of grades and standards, and for policy decisions on the use of food and feed additives.

In the same vein, it is moot to argue that there is "too much regulation." All organized societies operate within the confines of a generally agreed upon set of rules and regulations—some more explicit than others. The more complex a society becomes, the more explicit the rules tend to become and, simultaneously, the more pressure there is to change the rules in order to alter the present distribution of income or the flow of other benefits. Thus, deregulation is not the absence of rules, it is simply a change in the way behavior is regulated.

Such a perspective is important for conducting meaningful economic research in the area of food protection. It forces a focus on the resource adjustment implications of changes in the food protection rules—a research mold familiar to most policy analysts.

The alternative to this rather broad interpretation of the research agenda is to narrow the focus such that only economists with legal training can make an effective input. While I agree that some legal training and a thorough understanding of the legal environment are useful, I am not willing to dismiss the notion that well-trained policy analysts can make an important contribution without such a background. There are enough problems to keep agricultural economists productively occupied on food protection issues for years.

Food Protection Issues Not New

The tendency, of course, is to claim that research in this general area is new. The fact is, however, that public debates about food protection issues predate most of the major public actions dealing with farm commodity price and income support.

Federal inspection of meat began as early as 1890—as a mechanism necessary to ensure the safety of meat for exportation. Then, following publication of Upton Sinclair's *The Jungle* in 1906, meat for interstate commerce also became subject to federal inspection. The Federal Meat Inspection Act remained as the major piece of legislation regulating meat inspection until passage of the Poultry Products Inspection Act in 1957.

Those acts were designed to protect the public from unwholesome, unadulterated, or misbranded meat and poultry products. They

required mandatory, *ante-mortem, post-mortem* and processing inspection of all meat, poultry, and derivative products prepared for commerce. Today, federal inspection is also required in states which do not maintain inspection systems at least equal to the federal law.

Coincident with passage of the Meat Inspection Act was the Federal Food and Drug Act—the first federal effort in the area of food processing inspection. The Act was administered by the Bureau of Chemistry in the U.S. Department of Agriculture. In 1938, new legislation, the Federal Food, Drug and Cosmetic Act (FFDCA) was passed in order to protect the public from dangerous and unwholesome products. In 1940, administration of the FFDCA was moved to the Federal Security Agency, a predecessor to the Department of Health, Education and Welfare.

The original statute included prohibitions against poisonous or deleterious substances in food which might make it harmful to health, but did not include provisions for premarket testing of substances such as food additives, new animal drugs and/or color additives. Subsequent amendments, including the "Delaney Clause" (21 U.S.C. 348(c) (3)(A)), have been enacted to prohibit the addition to food of additives that have not been shown to be safe by appropriate tests.

In addition to these so-called food safety laws, a number of rules govern the labeling of food products. In total, these rules are designed to protect consumers from economic adulteration—fraudulent sale for the purpose of economic gain—and to facilitate trade by grouping (through labeling) relatively homogeneous product gradations.

Important in this area are the food product grades and standards programs administered by USDA. These programs are voluntary and supported by payments from the industry. Those two features, of course, distinguish the grades and standards programs from the mandatory programs of federal inspection. Additionally, most such programs were instituted to facilitate trade between producers and processors. They were not designed to communicate meaningful messages to food consumers.

Increasingly, however, there are questions regarding the appropriate role for government in this area. What discretion should be allowed if, in fact, the grades applied are used in consumer trade? Economists, it would seem, have a role to play.

The Research Agenda

The final part of this paper deals with research needs identified by the policy setting and the legal environment just described. There seem to be three identifiable areas where economic research and policy analysis can contribute significantly to the solution of problems in food protection.

The areas include the economics of information, research on the concept of relative risk and finally, policy studies to help define the consequences of proposed regulatory actions and evaluate present institutional frameworks.

Economics of Information

Most problems in the food safety and quality area relate to the delivery and interpretation of product information. In some cases, it is simply decided (by society) that the potential social costs flowing from misunderstood product information are greater than the private benefits to be derived from consumption. In those cases, product sales are prohibited.

There is also the question of "fair trade." Products are labeled to facilitate trade. If the market is to be used as a resource allocator, consumers must know what they are buying so that value messages can be relayed to producers.

Producers, too, must be protected from sales which occur in an information void. And producers of various grades of the same product do have an economic interest in labels which differentiate their products from those of other producers.

Examples in the food system are numerous. The present debates regarding "appropriate" labeling for mechanically deboned meat products, turkey ham, and imitation food products are all examples. The appropriate labeling of product weight (wet or dry tare) is another.

These are not trivial issues. They all relate importantly to the type of information needed by producers and consumers to facilitate trade. And economists have a stake in the way these issues are resolved.

Even beyond the question of "appropriate" product labeling there is the question of how consumers actually use the information provided. Presumably, the Surgeon General's warning on cigarettes was designed to dissuade product purchases. But has it? If not,

why not? Is it because consumers do not comprehend the information provided or is it because they personally are willing to accept the consequences of their purchase decision? If it is the latter, can one argue that the information has served its purpose? If it is the former, it seems to raise a research question regarding the form in which information is provided.

Surely, economists have worked on information problems in the past. But too little emphasis is being put on those problems now faced in the food sector. Since food products are purchased frequently and at relatively low per-unit costs, exploring the information trade-off between experience (using little information) and search (requiring a great deal of information) would appear relevant. Also, since food products are potentially dangerous to health, it can be anticipated that more information will lead to intensified pressures to ban products from sale. Applying economic concepts to these problems would also seem beneficial.

Concept of Relative Risk

A great deal of the present frustration with food safety and quality regulations stems from lack of an application of the concept of relative risk. As technology is developed, it becomes easier to identify small quantities of harmful compounds. Making the situation even more difficult is the fact that human beings cannot be used in scientific experiments to verify the extent of potential harm.

To date, therefore, the legal and political environment has relied almost exclusively on a concept of zero tolerance. Any evidence of harm, particularly of carcinogens, is sufficient to ban the use (and/or sale) of the product. There has been little deviation allowing for a formal incorporation of the concept of relative risk in the rule-making process.

But the political system so far has not acted. There is uncertainty about how a rule allowing incorporation of relative risk might be enforced. When does the potential social and economic harm resulting from prohibition exceed the potential harm from continued use? When are the potential health benefits worth the economic and social adjustments flowing from a regulatory action?

Economic research should be able to help answer these questions. But research on both benefits and costs is needed. Helping society clarify the concept of relative risk will require more than a set of studies that focus attention on identifiable (and measurable) costs.

Then, too, research assessing the overall consequences of additive actions is needed. Any particular action, taken by itself, may generate little measureable benefit or cost. But, when taken in total, a set of actions may well produce a significant social impact. Significant research progress will require that we learn how to deal with such additivity.

Policy Studies

In many cases, the policy debate related to food safety and quality issues could be improved significantly by a clear, concise discussion of the specific problem. While the entire scientific community has a role to play in this area, economists who understand both the political and the legal system have a potentially significant role. (Often the available options are constrained by statute—regardless of how "unreasonable" they appear. In other instances, the political setting is such that only incremental changes are possible, even if a total reform would appear to be the best option.)

One area that has received attention in recent years relates to proposals for effecting compliance with the animal drug and food additive provisions of the FFDCA. The research typically involves an assessment of the economic effects of a specific proposal to alter regulatory procedures. Studies assessing the impacts of restricting the use of animal growth hormones, antibiotics and food additives are examples.

The continued subtherapeutic use of some chemicals is being questioned because of scientific evidence linking resistant strains of certain organisms to the chronic intake of antibiotics. The development of such resistance is of concern because it makes the drugs potentially less effective in dealing with human health problems. Other drugs are being proposed for use restrictions because they have been found to produce tumors in laboratory animals.

While all producer advocacy groups have strongly opposed such regulatory changes, the available research indicates that the proposals would likely have little noticeable effect on resource use in the aggregate. Indeed, since the demand for most agricultural products is inelastic, the short-run effect of a unit-cost

increasing action is to increase industry revenue.

An immediate ban on the use of nitrite to cure bacon, for example, would create the need for some adjustments. Hog prices would fall—about $2-3 per hundred weight—reflecting the fact that large quantities of pork bellies would have to be rendered into lard. Food prices, though, could be expected to increase, in the longer run, because of the higher pork processing costs and the increased demand for substitute meat products. While the adjustment cannot be termed as disastrous, there is a possibility, at least initially, that some hog producers would go out of business.

But cattlemen would probably benefit from such a ban. Because of the increased demand for beef products, cattle producers' receipts could be expected to increase. If there were a total ban on the use of nitrite in the curing process, cattlemen potentially would stand to gain even more since only about 10% of all beef is now cured with the chemical—over 55% of all pork is now nitrite cured.

The interesting story that unfolds from most of these studies is that it is consumers rather than farmers who end up shouldering the impact. Food prices tend to rise, but aggregate farm income either increases or remains about unchanged.

Do consumers really end up worse off? If these actions do have the effect of improving the nation's health, then perhaps it means higher food costs, but lower costs for medical care.

Policy research in this area must initiate as well as respond. Over the years, agricultural economic research has played an important role in shaping policy. Parity price support programs, land diversion schemes, and food distribution programs were all influenced in important ways by researchers who had a vision of the need for alternatives and then did something about it. Future research programs in the area of food safety and quality should build on that tradition.

Efficiency of Present Systems

Apart from the questions related to specific policy issues and program options is the need for evaluation of present systems. The broad social objectives in an area tend to be specified in the statutes. In almost every case, responsibility for the administration of programs designed to achieve those objectives is lodged with the federal bureaucracy. Once in place, there is an important continuing need to assess the relative performance of the system.

There are essentially two questions that need to be addressed by the research.

(*a*) Is the present (or proposed alternative) system effective? (i.e., does it work?), and

(*b*) Is it efficient? (Are the programs being administered in a cost-effective way?).

The effectiveness question is difficult to research. We almost never have a benchmark. Most will agree that the food supply should be safe—that the public should be protected from the deliberate or even unintentional sale of foods that will cause death or disease. But putting this protection into operation is a program question. And alternative programs produce different results at different costs.

Quite often there is little or no opportunity for controlled experimentation. But that does not negate the importance of or the need for research in this area. Decisions will be made and economists would seem to have a responsibility to provide information about the likely resource use impacts associated with alternative program options.

Program efficiency studies are probably easier to do but are no less important. Efficiency, of course, is measured by the degree to which present organizational structures achieve a given level of service. Questions about administrative costs relative to the task being performed, and appropriate sampling for a given level of accuracy are both important aspects of the research needs in this area.

The obvious difference in inspection philosophy between USDA and the Food and Drug Administration (FDA) is an excellent example. The FDA approach is less labor intensive and is based more on sampling. "High risk" operations are visited most often but, even then, there is no inspection of each food item. USDA's procedures now require the actual physical inspection of each carcass. The system is labor intensive. What would alternative systems cost? What would be the probability of reductions in the safety of the food system? How might the present system be changed to improve the delivery of services and perhaps reduce costs? In an age when inflation pressures are foremost in the minds of policy makers and most citizens, it would seem that economic research addressing the simple question of how efficiently government ser-

vices are being performed could have high payoff.

Concluding Thoughts

This paper has been developed to spark discussion. The research agenda is not project-specific but rather covers the broad areas of needed research.

Agricultural economists have done such research in the past. Some are working in these areas at the present time. But more and better research is now needed. Decisions in the area of food protection policy are being made. Whether we contribute as a profession is our choice.

If we decide to do more in this area, we too will be faced with a resource allocation problem. Some resources will undoubtedly have to be allocated to longer-term work on the conceptual issues like information and relative risk. Such work is needed. But the shorter-term policy studies will continue to be needed as well. The historical cooperative working arrangement between ESCS and universities provides the institutional setting for getting both jobs done. Hopefully, the work will proceed at a relatively rapid rate.

Price and Income Policy Issues

Preston E. Laferney and J. B. Penn

In this paper, we develop the concept of price and income policy as a sub-set of the larger set of regulation policies. It follows, therefore, that price and income policy research is an integral part of regulation research as discussed at this conference.

The Scope of Regulation Research

Regulation can be viewed narrowly, as agricultural economists have tended to do—one specific issue at a time. Setting quality standards for one product—wheat or beef—and operating an enforcement system is an example of a specific, narrow issue. Or, regulation can be viewed in a much broader sense. The broad view encompasses all government interference or involvement inside or outside the market system, regardless of the specific objective. Objectives vary widely from income redistribution (a primary goal of price and income policies) to specific social goals arising from market failure (such as maintenance of environmental quality) to those essentially not market oriented at all (tax policies, for example).

The semantic arguments we get into over what constitutes regulation research as distinct from other research (policy and other kinds) are in the main unnecessary—they are probably counterproductive unless the varying views which give rise to the arguments are hindering the identification of important issues and the scope of our total research efforts. We feel that the real need is to air the issues in fora such as this conference, not just tc "define" regulation research, but to move us toward a closer integration of all regulation (policy) research.

Agricultural Price and Income Policies

Price and income policy in agriculture is concerned, among other things, with the redistribution of incomes to achieve specific social goals. The goals arise not so much from a market failure as from society's unwillingness to accept the adverse adjustment effects that would be accomplished through the operation of a free market. With society unwilling to leave the market free to make the adjustments in agriculture, the objective has been to achieve an income redistribution through government intervention while minimizing the resulting economic inefficiency.

Price and income policy formulation involves trade-offs. As we examine these trade-offs, we begin to see the interrelation between price and income policy and other kinds of regulation. Some of these trade-offs are:

(*a*) Between large, medium, and small farmers. These units are all within the agriculture sector, but nonagricultural regulations, such as tax policy affect income distribution among them.

(*b*) Between grain and livestock producers. Again, both groups are within agriculture, but other regulations, such as control of point source pollution, affect their relative income positions.

(*c*) Between the freedom of individual decision makers and the extent of government involvement in production and marketing decisions. This trade-off, by definition, is true of all regulations.

(*d*) Between producers and consumers. Here, one begins to see the interdependence of farm and nonfarm sectors. For example, a ban on nitrites in bacon would affect the two groups differently.

(*e*) Between segments of the food system—producers and processors, for example. In crop set-aside decisions, decreased volume of production is detrimental to processors and beneficial to producers.

(*f*) Between taxpayers and producers. The concern with Treasury outlay effects of price and income policies for agriculture is a prime example.

(*g*) Between domestic policy and foreign

Preston E. Laferney is Acting Chief, Crops Branch, and J. B. Penn is Deputy Administrator for Economics, Economics, Statistics and Cooperatives Service, U.S. Department of Agriculture.

policy objectives. Higher domestic support prices tend to reduce the volume of our foreign trade.

(*h*) Between sectoral or microeconomic objectives and macroeconomic objectives. Examples are higher commodity prices for farmers versus inflation, and Treasury outlays to help farmers versus the budget deficit.

What is the point of discussing a traditional area like price and income policy at a regulation research conference? This is a research-oriented conference—its purpose is to stimulate interest in regulation research, to identify issues of high priority for future research and to identify information needs that can be met by research for public policy discussion and formulation.

Our primary point of emphasis is to argue for a more comprehensive perspective in research planning—to suggest that price and income policy research and analysis cannot be done well in isolation from other regulation research and vice versa. In food and agriculture, whether the broad view of regulation (policy) research is accepted or whether a more narrow view is preferred, the interdependence of governmental actions—both inside and outside the marketplace—must be treated simultaneously. They must be analyzed in the real world context as they operate in conjunction with one another. We submit that informed public policy debate and its formulation requires this—that fragmentation and partial analyses may provide misleading results and prove to be a disservice to our immediate clients and to the public interest.

Conditions Requiring a Comprehensive Perspective

Price and income policies—in fact most all regulatory policies—are formulated to meet relatively narrow objectives. The attendant programs focus on the means of achieving the stated objectives. For price and income policy, this was not grossly inappropriate for many years—the farm sector was *not* closely interrelated with the domestic economy.

This is no longer true. Agriculture, by virtue of increased instability, which arises to a great extent from the increased dependence on foreign markets, now transmits that instability to the entire domestic economy. And, the changed structure of the food system means the performance of the domestic economy now has much more influence on the food and agriculture system. This is evidenced by the following characteristics:

(*a*) Farmers are still price takers. The farm sector is sandwiched between the input-supplying and food processing and distribution sectors, both highly concentrated and able to influence prices—to pass through cost increases. Thus, developments in these sectors, whether changing wage rates in the labor market or government regulations, eventually have an impact on the farm sector. This is not new.

(*b*) But, other things are changing: There is a growing industrialization of the farm sector—it is now big business; there is an increased reliance by agriculture on inputs purchased from the nonfarm economy—something like 70% of the total at present; there is a growing capital intensity within the agricultural sector; there is an increased use of nontraditional exchange arrangements—integration and coordination; there is a shifting within the cost structure toward more fixed relative to variable costs; and there is the ever-present phenomenon of increasing land prices.

(*c*) Also, the increasingly greater proportion of the food dollar accounted for by nonfarm inputs represents a significant change. Something like 60% of the total expenditures for domestically produced food is for inputs and services other than the raw material (commodities) provided from the farm.

Increasingly, regulatory actions in the food system and in other sectors of the economy significantly affect the farm sector. These regulatory actions, even individually, and certainly in concert, often have effects that offset or enhance those of the more narrowly formulated price and income policies.

Price and income policies, as well as other regulatory policies, may have unintended and undesirable indirect consequences, or even direct consequences, when all policies operate at the same time. As an example, consider the escalation of target prices based on cost of production estimates. Environmental Protection Agency, Occupational Safety and Health Administration, and Federal Grain Inspection Service regulatory actions directly or indirectly affect the cost structure of farms. They either increase costs, causing target prices to subsequently increase and programs to become more expensive, or they affect one type or size of farm relatively more than another,

giving a competitive advantage to certain types and sizes of farms relative to others.

Today, there are other regulatory policies that may be having an equal or greater impact on the structure of agriculture than are the price and income policies, even though these effects usually are much less direct and less obvious to most observers. For example:

(*a*) Transportation policy: trucking industry deregulation, Interstate Commerce Commission rate structures and rules, waterway user charges, rural area rail line abandonment, and others.

(*b*) Tax policy: rate structures, accounting rules (cash versus accrual), capital gains treatment, inheritance tax provisions, use value taxation, property taxes, and others.

(*c*) Energy policy: natural gas deregulation, deregulation generally, priority fuel allocations, and others. These bear a close relation to cost of production, thus to price and income policy.

(*d*) Macroeconomic monetary and fiscal policies: the growth policy, anti-inflation program, changes in the money supply (interest rates), the balanced budget goal, and others.

(*f*) Alien investment—generally and in agricultural land specifically.

(*g*) International commodity policy.

(*h*) International trade policy.

A Structure Policy for Agriculture

The structure of the farm sector is an issue now being widely discussed. There is a growing, if not general, consensus that the price and income policies and specific commodity programs, over time, have produced unintended and unwanted consequences. Even though the preamble to every farm bill enacted since the 1930s has contained the explicit objective of helping the family farm, these policies, in fact, may have served to hasten its demise. What segments of agriculture benefit most from agricultural policies? What are the structural effects of these policies over time? What kinds of policies can be designed to assure a viable agricultural sector in some proper balance with other sectors over time?

The discussion above serves to point out that should an explicit structure policy be pursued, price and income policy will be but one component among many, and perhaps a relatively minor component. All the areas noted above, plus several others, will be integral parts. Each has a significant bearing on the structure of agriculture and on the well-being of those who farm.

The import of this for us, and the message of this discussion, is that our research on policy alternatives must be more all-encompassing in the future. To be adequately researched, all regulatory (policy) alternatives must be considered as they operate in conjunction with one another.

Economic policy issues are seldom simple. They are complex now and will become more so as the arguments above indicate.

The Secretary of Agriculture has placed the formulation of a new structure policy on his—and our—high priority list. To meet the need he perceives will require that we think about much more than just traditional price and income policies. Regulation research in its broader sense, as discussed in this conference, must be integrated with traditional price and income policy research.

Product Market Regulation: Implications for Research

John W. Helmuth

The purpose of this conference—to serve as a catalyst for further research on regulatory issues in the U.S. food system—requires going beyond safe, familiar ideas. It gives us an opportunity to broaden our perspectives. If an idea is of significance, people who hear of it will reflect on it, take it apart and accept it or reject it. My objective is to put forth some ideas which will create that kind of response.

I will begin by summarizing possible methodological approaches to economic evaluation of regulation; then I will highlight the existing areas of product market regulation; mention some of the current areas of controversy; and conclude with some recommendations for research.

Economic Evaluation of Regulation

I define "product market" regulation as federal involvement in any or all aspects of the marketing of food or fiber commodities in the chain from producers to final consumers.[1] Evaluating the economic effectiveness and/or impact of regulation immediately brings benefit-cost ratios to mind along with all the attendant measurement problems. Direct costs of federal regulation are the easiest variable to measure—they, of course, are the federal costs of administering a particular regulatory program. Other indirect and/or social costs are much more difficult to quantify as are the direct and indirect social benefits.

Possible approaches to estimating benefits and costs include market structure, conduct, and performance comparisons before and after regulation or between similar marketing channels with and without regulation. Unfortunately, such approaches are plagued with the difficulty of realistically applying the *ceteris paribus* assumption.

On the less quantitative side, it is interesting to consider more subjective measures which might be termed content/discontent ratios or possibly a compliment/complaint ratio. Such measures certainly give a feel for how a particular industry or group views the effectiveness of the regulatory process, but must be used cautiously. Different industry segments—producers, middlemen, consumers—generally will have different perspectives which usually lead to different compliment/complaint ratios. Such ratios take on more meaning as experience with a given body of regulation develops over the years and are less useful during the uncertain period when a new area of regulation is being considered.

Existing Product Market Regulation

Federal product market regulation relating to food and fiber can be grouped under the following headings: safety and quality assurance; protection against misrepresentation of products or unfair business practices; and industry self-help programs.

Safety and quality assurance regulations generally fall under the Food Safety and Quality Service of the U.S. Department of Agriculture (USDA) as well as the Food and Drug Administration (FDA) of the Department of Health, Education and Welfare (HEW).

Regulations dealing with protection against product misrepresentation or unfair business practices fall under the Agricultural Marketing Service (AMS) of USDA, the FDA and the Federal Trade Commission. In addition, independent regulatory bodies such as the Commodity Futures Trading Commission administer laws dealing with transaction integrity.

Each of these regulatory areas could provide the basis for a detailed analysis of the economics of regulation. However, in order to

John W. Helmuth is an economist with the Committee on Small Business, U.S. House of Representatives, Washington, D.C. The views expressed are solely those of the author.

[1] The author excludes state regulations to limit the scope of the discussion.

limit the scope of this paper, I will concentrate on the last area of regulation—industry self-help programs.

In this category I group the commodity research and promotion programs (check-off programs) and the marketing order programs of AMS. The common characteristic of these programs and the reason for the term "self-help" is that, under enabling legislation, such programs only come into existence if the affected industry voluntarily chooses to have them in referendum.

The research and promotion programs might be termed quasi-regulatory since the only federal involvement other than administrative oversight is to enforce collection of fees to be used for research and promotion efforts. Interesting questions can be raised regarding the benefits and costs of the generic advertising aspects of these programs, particularly with respect to food commodities and in light of the fixed size of the "American stomach." What is gained, from society's point of view, in having orange juice compete through advertising with tomato juice for a place on the breakfast table? One has to wonder if the advertising agencies might not be the only ones realizing long-run net gains.

Approximately $140 million was spent by all programs combined on research and promotion in 1972 (Parlett and Henderson). The majority of such expenditure goes for advertising. The significance of this issue takes on a new dimension when one considers that the beef research and promotion program currently under consideration would generate an estimated $60 million in revenues. Microeconomic studies have been done on the impact of advertising for particular commodities (Thompson), but what is sorely needed is a careful analysis of both the short- and long-run costs and benefits for all commodities viewed as a group. Only then can meaningful social decisions be made regarding the worth of existing and future promotion programs.

Marketing Orders: Successful or Inflationary?

As a self-help program, marketing orders are legal instruments authorized by Congress in the Agricultural Marketing Agreement Act of 1937. They serve as a means through which farmers can organize to market their product, increase their bargaining strength in the competitive-oligopsonistic markets in which they sell and generally work together to solve marketing problems they cannot solve individually.

Marketing orders are currently prominent in the fruit, vegetable and dairy industries. Their broad objective is to achieve "orderly marketing" by regulating in some way the flow of raw commodities into the marketing system. Specifically, this currently is achieved by using the following methods: (*a*) smoothing the flow of commodities to avoid gluts and shortages; (*b*) specifying minimum quality standards; (*c*) standardizing quality, size or packing requirements; and (*d*) in the case of milk, establishing minimum prices handlers must pay producers according to the use made of the milk, pooling proceeds on a market-wide basis, auditing of receipts and utilization, verifying weights and tests and providing market information to all parties (USDA, p. 1).

The marketing order decision-making process reflects the views of producers, handlers and consumers with final authority resting with the Secretary of Agriculture (USDA, p. 1).

In the current budget-cutting, inflation-fighting economic climate marketing orders have come under renewed attack as potential contributors to inflation. The budding controversy surrounding orders is addressed in the next section.

Controversy over Marketing Orders

The health of the American economy is significantly dependent upon a sound, healthy agricultural sector. Maintaining a healthy agricultural sector can be achieved only if we set an equitable rate of return to agricultural production as a primary social goal. Given the unavoidable uncertainties of such production and assuming as a goal the maintenance of the family farm, an equitable rate of return can be achieved in two primary ways: (*a*) by government use of tax revenues for income programs employing various methods to restrict production and establish price floors; or (*b*) by recognizing the inherent competitive-oligopsonistic nature of agricultural markets and the need to provide farmers with self-help tools to countervail the economic power over price held by buyers of raw agricultural products. In other words, the government can attempt to ensure farmers an equitable rate of return and/or the government can create a climate in which

farmers can do it themselves. By allowing farmers to organize for marketing and bargaining purposes, some movement toward countervailing economic power can be achieved and the concept of the family farm is maintained.

If one accepts this line of reasoning then one is placed in apparent conflict with consumer interests, recognizing that consumer interests are characterized as desiring a high quality, wholesome, reliable supply of food and fiber products on a year-round basis at the lowest possible price.

Current attacks on marketing orders are coming from two directions with two levels of intensity. At the lower level of intensity the National Commission for the Review of Antitrust Laws and Procedures recently recommended that the Secretary of Agriculture be required to take competitive factors into account and to choose the least anticompetitive alternative consistent with statutory goals when marketing order decisions are made. The Commission's recommendation suggested that there is an explicit antitrust exemption for marketing orders in the Agricultural Marketing Agreement Act. However, the Act itself is an exception to antitrust laws and it should be clearly understood that any review of the antitrust status of marketing orders is really a review of whether the Agricultural Marketing Agreement Act should be retained in any form.

With respect to the specific recommendation concerning marketing orders, the Department of Agriculture's current rule-making procedures provide a framework for the consideration of competitive factors based on evidence presented at formal hearings. The hearings help to ensure the selection of the least anticompetitive alternative consistent with the record of evidence and the statutory goals of the Agricultural Marketing Agreement Act.

Even though the statutory goals of market orders recognize that it is socially desirable to restrain destructive price competition, the Commission's recommended requirement could place the Department of Agriculture in the position of proving this over and over in the day-to-day exercise of its responsibilities in administering marketing orders.

Carrying out the intent of this recommendation could cause much misunderstanding and controversy because of the apparent conflict with the statutory goals of marketing orders. Market orders were designed to put agricultural producers on a more equal footing with large buyers and thus achieve a greater degree of price competition between buyer and seller. This was done through provisions which restrain destructive price competition between individual farmers.

A more intense attack on marketing orders is coming from the President's Council on Wage and Price Stability. As part of their laudable effort to control inflation, the Council is seriously questioning the need for marketing orders. The Council's approach is based on short-run consumer interest. It implicitly assumes that short-run commodity price increases are inflationary regardless of longer-run trends and does not properly consider the long-run implications of doing away with marketing orders. The Council's approach has been to bring the marketing order decision-making process under review via Executive Order 12044 which calls for economic impact analysis of Executive Branch decisions.

Even though Executive Order 12044 exempts marketing order decisions made under the formal rule-making procedures of the Administrative Procedures Act, the Department of Agriculture, under the Secretary's Memorandum Number 1955 has included these decisions in the requirement for impact analysis. Through this mechanism the Council has been strongly questioning any decision which has any price-enhancing aspects. One must ask whether such an approach is consistent with the statutory goals of the Agricultural Marketing Agreement Act.

Are marketing orders inflationary? Evidence to date on fruit and vegetable orders indicates that most orders regulating grade and size of fruits and vegetables have no significant price-enhancing results. In addition, while quantity control programs have inherent price enhancement capabilities, they have increased price stability and have thus stimulated production of the affected commodities beyond levels which could be expected without such orders (USDA). Evidence for milk orders indicates: (*a*) Since milk orders have no provision for control of supply, any efforts to maintain prices at levels higher than warranted by supply-demand conditions tend to be self-defeating; (*b*) While the federal milk order program establishes minimum prices, the system plays essentially a passive role in price change; (*c*) Milk order prices fluctuate in a fixed relationship to competitive prices in the manufacturing milk market; (*d*) These man-

ufacturing prices, in turn, are influenced by supply-demand conditions in the dairy industry and by government dairy price support policy; (*e*) the dairy price support program is the primary factor influencing federal milk order prices at the present time—if current prices are too high, the appropriate vehicle for reducing them is the price support program, not the marketing order program.

Are minimum prices set under milk marketing orders inflationary? Consumer prices for fluid milk have risen substantially less in the last ten years than the index of prices paid for all foods or the aggregate of the consumer price index. This longer-run trend may indicate that pricing under milk orders has not contributed substantially to inflation in food prices. Also, milk orders have helped maintain adequate supplies of high quality milk for consumers. This has served to keep prices down.

Higher farm product prices may appear superficially to be inflationary. But when the higher price is associated with a higher quality product, or a more stable, year-round supply the consumer is getting a better buy.

Why not abolish marketing orders? Because orders generally are not inflationary, and do help solve marketing problems. They contribute to market stability and efficiency. This is beneficial to the public, both to producers and consumers. Orders promote long-run stability in supplies for the consumer and in income for the farmer, both of which are obviously more desirable than the boom-bust cycle that might otherwise prevail.

If marketing orders were abolished, what would be the consequences? In the absence of marketing orders, some or all of the following consequences might be expected: wider price swings; more bankruptcies; more variability in quantity and quality supplied; higher government spending on commodity support programs; a greater reliance on commodity imports; farmer cooperatives strongly motivated to attempt to control the amount produced; and an accelerated trend toward corporate agriculture.

The long-run dangers of taking a short-run view of marketing orders and striving to stop any price-enhancing aspects of orders can be illustrated with reference to a recent study by Hammond, Buxton and Thraen. They indicate that, by changing the current milk marketing orders to allow for the pricing of reconstitutable milk at less than Class I prices, which would make inter-order shipment of reconstitutable milk economically feasible, retail milk prices could be expected to advance approximately 1¢ per gallon in the Lake states, and 2¢ per gallon in the Southwest while declining 2¢ per gallon in the Northwest and 14¢ per gallon in the Southeast. A slight increase in the price of manufactured dairy products also is predicted. Superficially, this might appear to represent, from the consumer viewpoint, a socially desirable change in the orders.

But what of the long-run consequences? One may observe the waste involved in shipping heavy, high volume grain all over the country on an outdated, crumbling rail system to supply feed to dairy farms and consider action to concentrate dairy production near input supplies. However, this would imply some severe production shifts. What would be the social cost of displacing thousands of farm families? Would viable alternative employment be available to them?

What are the indirect social benefits of prosperous dairy farms in Connecticut or Florida? Of what social value is the family farm a hundred miles from New York City? What are the total costs of shipping feed grains from the Corn Belt to the Eastern Seaboard? How do these compare to retail prices a few cents per gallon lower? What does 5¢ per gallon mean as a percentage of consumers' disposable income?

The Potential for New Orders

The current attack on orders may be the best available indication of the success of the marketing order program. To the extent that orders have been successful in accomplishing their purpose of coordinating agricultural marketing activities at the producer-first handler level and achieving an orderly marketing system; to the extent that they have stabilized the flow of product and avoided gluts and shortages; to the extent that they have helped maintain product quality and promoted standardization within marketing channels; and to the extent that they have helped stabilize product prices and producer income, they can be considered one of the most successful agricultural regulatory programs. If this is true one must wonder about the potential for marketing orders in commodities other than fruits, vegetables and milk.

What is the potential for orders in grains and livestock? Critics of such an idea immediately point to the diversity of cost structures, geographically dispersed production areas and sharply differing producer viewpoints in these commodities. They point out that much of the success of orders is dependent upon the relatively confined nature of fruit and vegetable production where producers are strongly bound by common interests. In response, I would point to the nationwide system of milk orders which share many common characteristics but yet remain flexible enough to deal with the unique problems of a given geographic area. Has the time come for this concept to unite grain and/or livestock producers?

Farm groups are calling for "a bushel of wheat for a barrel of oil" in response to increasing crude oil prices. Grain exports have become a significant positive element in our balance of trade. Those who advocate using our grain exports for leverage against high crude oil import prices are suggesting a government grain export board to withhold exports until higher prices are achieved. Not withstanding the moral question of using food as a international bargaining chip, the merit of such an idea hinges on the extent of the inelasticity of demand for U.S. grain exports.

A grain marketing order should be seriously considered in lieu of a government grain export board. Such a marketing order would leave the decision power in the hands of the producers; it could possibly provide countervailing power for producers against the multinational grain companies; and it might reduce the USDA budget for support payments and remove the government from a direct decision role regarding the production and marketing of grains.

Research Implications

I see a need for research in several areas. I previously mentioned the need for a macroeconomic benefit-cost look at the research and promotion programs.

In addition, the entire fruit, vegetable and dairy marketing order complex needs careful evaluation to measure, where possible, the short- and long-run benefits and costs. Some of the work being done is a start in the right direction. But if new substantive evidence weighing on the current inflation question is to be obtained, a much larger, coordinated research effort is needed.

In my opinion, the time has come to carefully study the feasibility of marketing orders in grains. The information imbalance in international grain trading resulting from U.S. producers voluntarily providing estimates of U.S. supplies while multinational grain companies keep export demand information secret sets the stage for significant redistribution of returns to increased producer market power. Estimates of the redistribution effects along with estimates of the costs of an order program compared to present government support program and other USDA costs are needed to form the basis of benefit-cost analysis of the marketing order alternative.

A marketing order for grains might be viewed as acquiescing to oligopsonistic market power by establishing some degree of monopoly power on the part of the farmer. But what is the likelihood of significantly reducing the oligopsonistic power of the multinational grain firms through government action? For instance, is it possible to provide accurate, timely and complete export demand information to farmers so that their selling decisions can be made with as much knowledge of demand as their buyers have regarding supply?

A significant research opportunity exists to study the present grain trading system from a pricing efficiency and resource allocation point of view and to compare it to the potential which might be achieved by obtaining accurate, timely and complete information on U.S. export sales. How much does it cost U.S. producers to sell into a market where supply information is public knowledge and export demand information is secret? Given the resultant price uncertainties from such a market, what are the total costs of incorrect resource allocation decisions? If complete export sales information were mandated how would this impact on U.S. export sales? If export sales declined as a result of requirements for increased demand information, would the aggregate export revenues lost be less or greater than the aggregate revenue gains to producers from improved marketing decisions plus the gains resultant from improved resource allocation? Who would gain or lose from a change toward the perfectly competitive model via improved market information?

A marketing order for grains probably would not generate more information regarding demand and might result in less supply

information if farmers viewed such a move as beneficial to their position under an order. How then would an order compare to the present system or to an environment of mandated, comprehensive export sales reporting?

Panel Discussion[2]

Robert W. March. The milk order program is one in which agricultural economists have played an important role since its inception. Many of the changes in orders have been based on their recommendations. I know of no other government agricultural program where agricultural economists have participated in the program development process to the extent they have in the milk order program, or where economic analysis has been used so extensively. The milk order program has attempted to utilize the tools of agricultural economics to bring order and stability to milk marketing. The program has numerous elements that have stimulated the interest of economists—price discrimination, pricing formulas, location differentials, pooling, and other unique aspects to tempt the imaginative researcher. There are forty-seven orders spread throughout the nation. Orders provide detailed information by markets regarding sources of milk, sales, intermarket shipments, plant locations, and prices, which greatly facilitates research.

Charles R. Brader. Dr. Helmuth's vision of the social role of marketing orders certainly runs counter to the general comments lately being directed towards these programs. I do not envision expansion of these programs as a panacea for the supply-demand problems which U.S. farmers have been confronting for many decades.

The forty-seven federal marketing orders for milk have a common means of advancing their orderly market objectives. Many perceive fruit and vegetable marketing orders to be similarly uniform. However, this is not the case. There are currently forty-seven marketing agreement and order programs in effect for commodities other than milk, covering more than thirty commodities. Many of these programs use quality control provisions to effect orderly marketing. In fact, this is the most common type of fruit and vegetable program. However, various forms of quantity control such as flow-to-market regulation, market allocation, and producer allotment provisions, are also used. Provisions for container requirements, production research, marketing research, and promotion are common.

Better understanding of these programs would eliminate most misconceptions. For example, many people perceive a strong interdependence between fruit and vegetable marketing orders and cooperatives. However, a little study would reveal this to be an erroneous generalization. It would be helpful if university agricultural economists would develop marketing order expertise in the fruit and vegetable sector.

Regarding Dr. Helmuth's comments on the research and promotion programs and the "fixed-stomach-size" theory, the fundamental idea cannot be refuted. But I believe it is an overly simplified argument. We in agriculture would not advocate the advertising of orange juice to replace tomato juice on the breakfast table, as in Dr. Helmuth's example. But we could quickly find social value in substituting orange juice for soda pop or other highly sweetened, flavored drinks. Likewise, we can find social benefit when grapes and raisins are advertised as snack foods in lieu of sweets.

I agree that a careful analysis of both short- and long-run costs of such programs is in order. There is no argument that social costs may be considerable. I merely wish to point out that there may be social benefits as well.

Edward V. Jesse. Helmuth's remarks provide the basis for numerous comments. I will limit my remarks to three areas.

In the past I have proposed that generic advertising programs prompt countervailing promotion activities on the part of competing commodity producers. This results in only transitory demand increases and a higher cost structure in the long-run. In addition, free rider problems are inevitable.

Proponents argue that these are consumer education programs. The benefits of these programs may be substantially less clear than suggested by Helmuth. Consumer education and information programs may be highly beneficial to society and producers, without cutting back consumption of competing agricul-

[2] Ed. Note: Helmuth's presentation included a formal panel discussion. Discussants were: Robert W. March, Dairy Division, Agricultural Marketing Service (AMS), U.S. Department of Agriculture (USDA); Charles R. Brader, Fruits and Vegetables Division, AMS, USDA; Edward V. Jesse, National Economics Division, Economics, Statistics and Cooperatives Service, USDA; and Ted Moriak, Office of Budget, Planning and Evaluation, USDA.

tural products. There may be a high payoff to studies of individual programs. We know too little about generic advertising in general to properly study the gross impacts of all programs as a group. But few agricultural economists seem willing to conduct the studies necessary to appraise the potential success of specific generic programs.

Glaringly absent from Helmuth's short list of possible ways to achieve an "equitable" rate of return to agricultural production is more stringent enforcement of antitrust laws. If agricultural markets are inherently competitive-oligopsonistic in nature, actions to remove competitive barriers on the buyer side of the market would (at least superficially) appear to be more efficient than actions designed to make the seller side of the market less competitive.

Helmuth outlines directional changes in measures of market performance consistent with the abolishment of marketing orders. Few would argue about these changes. But their magnitude is of substantially more critical concern. Specifically, would aggregate negative impacts from abolishing orders exceed the benefits of removing constraints to competitive resource allocation? I have much more faith in the "free" market system than implied by Helmuth's discussion.

On the other hand, I fully concur with Helmuth's observation that the social impacts of orders and other regulatory programs are of very high concern. Unfortunately, these are typically ignored in analyses of marketing orders and other regulatory programs. The effects of marketing orders on the structure of the production sector is especially important. A fundamental farm policy question concerns the kind of farming structure desired by society. If such a desirable structure can be identified, research on marketing orders and other types of regulatory programs must focus on how these contribute to or detract from this desirable structure.

Ted Moriak. The Secretary's Memorandum No. 1955 expressed a belief that the Department should minimize unnecessary burdens on the public while achieving maximum effectiveness from all decisions including regulations, agency directives, legislative proposals and reports, and other program actions. Consequently, the USDA decision system is more comprehensive than the President's Executive Order 12044 for improving government regulations, and provides authority for policy analysis of price impacts as envisioned by an Interagency Task Force several years earlier.

The analysis regards meaningful alternative actions as selected by policy officials. Impacts are estimated on employment, prices, competition, terms of trade, production and utilization, input markets, energy use, resources, technology and productivity, investment, credit supplies and taxpayer costs for USDA and other Federal agencies. Social impacts on health, safety, nutrition, civil rights, institutions, and invasion of privacy should be estimated. The geographic concentration of the impacts, the distribution through time, and the effect on income classes or size of business operation within each of the impacted groups need consideration. Although benefit cost ratios and internal rates of return may be included, the decision need not rest solely on their ranking.

The timing for conducting policy analysis under the formal rule-making procedures used in market order decisions is critical. *Ex parte* communications are in effect from the time of the notice of hearing through the final decision. The final decision must be based entirely upon evidence presented at the hearing. Frequently, studies exist, but the material may be outdated or the witnesses do not fully understand its importance. Thus, such work is ignored in decision making.

The department is developing a procedure for pre-hearing investigations. It will describe the issues, the alternative actions and list the range of estimates on the important consequences which have appeared in various professional studies, prior to the notice of hearing. If an important analysis is not included in the prehearing investigation, then the researcher should come to the hearing and explain the analysis in order that it be considered in the decision.

Environmental Regulation: A Framework for Determining Research Needs

Wesley D. Seitz

I assert that there is now and will continue to be regulation of the food system directed toward the attainment of environmental objectives. While some may make a persuasive case for reduced regulation, I submit that the number of people favoring elimination of all environmental regulations affecting agriculture is a very small minority indeed. And we, as economists, using concepts such as market failure, externalities, and public goods (or bads), can explain why quite easily. We can demonstrate that society is better off if government constrains the private sector than if it does not.

Of course, it is impossible for agricultural economists or others to determine a perfect level of intervention because we do not have a social welfare function. But my purpose is not to provide a lesson in welfare economics; it is to give the audience a means of identifying important research areas relating to environmental problems. I am not going to share the list of specific research problems which strike me as interesting, rather I am going to lay out a framework for your use in determining where important research problems are likely to be found. But first I am going to outline the nature of the beast we confront and the implications of working in this area on the client relationship between the agricultural research community and the private sector.

The Environmental Problem

From an economic perspective the environmental problem is one of market failure or externalities. The classical case occurs when a pollutant is generated in the process of producing a normal economic good. The pollutant is discharged into the environment where it reduces the profit or satisfaction of others. It has been demonstrated that in the simple two-person case a mutually beneficial resolution can be achieved through a bargaining process. However, these simple cases are rare exceptions. In the common case, many farms, firms, and individuals generate varying mixtures of pollutants which impact receiving farms, firms, and individuals with varying consequences. Most of the consequences are negative, but there are cases where some benefit from the pollutants.

Two additional factors complicate the problem. First, in many cases the adverse impacts occur in the future, often beyond the time horizon suggested by a social, and certainly the current market, discount rate. These impacts can be considered externalities between generations. Reservoir siltation, the accumulation of pesticide residues, the development of pest resistance, the delayed development of cancers, and the loss of productivity due to erosion are examples of delayed impacts. A second complication results from the fact that the economic value of each pollutant is often small relative to the value of the normal good with which the pollutant is associated. In addition, each contributor to the pollution problem often adds but a small portion of the total and each receiver incurs a minor share of the damage. It is through processes of aggregation and accumulation that a problem becomes large enough to warrant attention and sufficiently complex to make private sector bargaining solutions unrealistic. Because the aggregated effects are external to the individual or firm, environmental regulation appears unwarranted to individual agents.

Due to these characteristics of pollutants, little data exists on the quantities produced, the locations of production, the movement of the pollutants, and the extent of damages done. This lack of data requires that the economist work closely with physical and biological scientists to generate estimates of the quantities involved, their sources, and their impacts. From such estimates economists can

---

Wesley D. Seitz is a professor of agricultural economics and associate director, Institute for Environmental Studies, University of Illinois, Champaign-Urbana, Illinois.

attempt to estimate values that will be useful in making policy recommendations. Of course, these values are needed because prices are not available from markets.

The Research Client

The clientele of publicly supported research is society. In much of agricultural research, and other research areas, society is benefited by developing and encouraging the adoption of techniques or institutional arrangements which will increase the short-run profitability of the private operators. In the long run, society benefits as the gains pass through the market system. To the extent that the agricultural research sector is able to operate in this mode, it is most effective if it views private operators in the food system as its clientele and vice versa. Generally, this client relationship has existed in the agriculture.

Research on environmental regulation of the agricultural sector puts this client relationship in jeopardy. Rather than aiding the agricultural sector to serve society by producing more food more economically, the researcher is considering constraints on the sector aimed at improving the quality of the environment by reducing pollutants generated. At least in the short run, the operator perceives this as a reduction in flexibility or profitability. This role will often involve the researcher in conflicts between the agricultural sector and those who are adversely affected by pollutants generated. Depending upon the research results, the researcher may be appreciated by either of the groups but seldom by both. Thus the traditional client relationship is not likely to exist for the agricultural researcher working on agriculture's environmental problems. It also follows that in many cases the most productive research areas will be those where the sharpest conflicts exist.

Perhaps because of the acceptance of the existing client relationship, perhaps because the environmental thrust was generated outside agriculture and to a degree forced upon it, many in the research establishment do not seem to share the belief that the relationship between the agriculture research establishment and industry needs to be changed. Some, perhaps in an attempt to maintain the existing client relationship, would have the agricultural research enterprise attempt to thwart environmental policy initiatives. At the extreme, this perspective leads to a search for the negative aspects of environmental policy, rather than an evaluation of the total impact on society, both positive and negative. The question, "What are the costs of an environmental constraint?" is asked instead of, "Are the benefits greater than the costs?" A less dramatic reaction which will maintain the traditional client relationship is to determine the least-cost means industry can follow to comply with the environmental requirements. This is a viable and valuable role for the research establishment, but it leaves it outside the policy formulation process where a major contribution may be made. The more negative approach will involve the agricultural research establishment in the policy-making process but as a lobbyist. The more objective involvement suggested in the next section should be more productive.

Environmental Policy Research

It follows then that there are significant research needs in the policy-making process. In this discussion, I characterize policy making as a continuing process of assessment of conditions, identification of policy alternatives and analysis of their impacts, policy change, and a re-assessment of conditions. Research can play an important role in each phase. Since the policy-making process will make several iterations and may cycle continuously, the need for research is ongoing, which should provide some measure of comfort for researchers. At this point, I will attempt to indicate several of the research activities which may be pursued in relation to this process.

Analyzing Current Performance

Analyzing the performance of the economic-environmental system is one of the research roles in which agricultural economists may be involved. The initial identification of a possible or potential problem may be a research product, or the problems may be brought to the attention of the researcher as the result of a conflict between an agricultural group and a group affected by an agricultural pollutant. There are also, of course, cases in which the agricultural sector is adversely influenced by a pollutant from the urban or industrial sector. In any case, when a problem area has been identified, it is necessary to determine whether the performance of the system is acceptable or if it could be improved by intervention of the

public sector. The paucity of data and the newness of the phenomenon make some of these efforts quite challenging. Often it will be appropriate for the economist to team with individuals from other disciplines in order to deal adequately with the research problems faced. I will return to the topic of interdisciplinary research, but will observe here that attempting to piece together results from numerous separate single-discipline-oriented studies is not likely to be a satisfactory alternative. For example, the physical scientists may produce results at the extremes of a production function and not in the relevant range. Finally, this performance analysis research task may become a continuing monitoring and assessment process regardless of whether policy is enacted. If the policy has been enacted, it becomes a policy assessment activity.

Identifying Policy Alternatives

If, or when, the level of performance of the environment-economic system is not satisfactory, the policy formulation or reformulation process becomes a viable activity for the research community. This identification of policy alternatives is the second major research activity. The basic policy approaches to be used in the development of alternatives are education or persuasion, economic incentives (taxes or subsidies), regulations, and direct investments. Given the thrust of this conference, it is worth noting that all of these alternatives involve some form of regulation in a broader context. Even the education policy will establish a requirement that the individuals conducting the program perform in a certain manner. It is also worth noting here that the participation or compliance rate will not necessarily be higher with a mandatory rather than a voluntary policy. Anyone who has studied the policies developed in the environmental area will realize that they are often complex combinations of several or even all of these four basic approaches. Further, within each of these approaches there are numerous alternatives which will have greatly different impacts on the economic system and on the success of the policy in meeting the environmental goals. As an aside, a simple recommendation by an economist such as that a tax approach is preferable to regulation may not be considered fully because details on how it could be implemented are not provided. In some cases, the development of a policy approach not previously considered in the public arena may be an extremely valuable contribution to the development of efficient, effective policy.

Potential Performance of Alternatives

Given that alternative policies have been developed and specified in some detail, the research community can make its major contribution in the third area: comprehensive analysis of the potential performance of these alternatives. The research community can be expected to bring together the analytical tools and the, at least relatively, unbiased perspective necessary to assess accurately and credibly the impacts of the various policies. As economists we will automatically begin by assessing the relative costs and benefits of each alternative. Making this assessment is often complicated by the difference in data availability. Often it will be possible to develop rather detailed estimates with a reasonable degree of confidence on the costs of some of the policies. This is especially true when the cost impacts occur in the production and food processing sector. Estimating the benefits of reducing damages is much more difficult due to the lack of physical and market data on damages. Some progress, of course, has been made in this area by both economists and physical scientists but additional work is needed. Because of the difficulty of the research task, this area will remain important for some time.

Researching Various Policy Combinations

In order to conduct an adequate analysis of costs and benefits it usually will be necessary to consider the impacts of the several policy alternatives at various levels of aggregation. In addition to considering the local, state, national, and perhaps international dimensions of the problem, it often will be appropriate to consider the impact on regions that are not defined by political boundaries. An obvious example is a watershed.

The need for analyses at several levels of aggregation can be appreciated by considering several examples. In an analysis of the local impacts of an environmentally-oriented restriction the researcher will be able to include considerable detail on farm characteristics and production technique responses. However, it

will not be possible to estimate aggregate price or production impacts. In a national model the opposite will be the case, and both are necessary to understand the full impacts of each policy alternative adequately. It is not possible to determine the price impacts from a local model or the detailed production responses from a national model. Recognizing these limitations will help avoid drawing unwarranted conclusions from either model. The pervasive nature of most environmental problems means that the policy response is likely to be at the national level. This, of course, makes a nationally-oriented analysis of the several policy alternatives a high priority research activity. However, it does not eliminate the value of an analysis of the local impacts. A policy that has positive impacts at the national level but imposes severe burdens on individuals in certain areas will generate strong opposition from individuals in the affected areas. The political process would opt for an alternative that generated somewhat lower national benefits but avoided the severe local burdens, if the alternative existed.

In some cases, the regional analysis of policy alternatives will need to be supplemented by an analysis of the impacts on appropriate producing or receiving groups. When positive or negative impacts are concentrated on a small number of economic groups, these groups can reasonably expect that an analysis of policy alternatives will include special reference to their situation. Further, such groups can be expected to ensure such consideration by politicians, if not researchers, through lobbying efforts.

Long-Run Impacts

In the analysis of the impacts of the policy alternatives, the long-run impacts will need to be addressed. This becomes a special topic of concern here because many environmentalists do not discount the future. They imply a zero discount rate and may reject both the market and the lower social discount rates. Any analysis should reflect the fact that private firms will discount at the market rate of interest, and it is appropriate to include analyses of the social impacts at a range of discount rates. Conducting such analyses will allow the researcher to recognize the importance placed on the future by those who do not feel it is appropriate to discount the future and will provide a means of assessing the cost of policy options selected under such value systems. As an aside, it is my belief that economists need to continue to spend considerable effort attempting to define the appropriate discount rate(s) for use in the formulation of public policy. Relying solely on the inflated market rate is not acceptable to me. Possibly we should develop a range of discount rates for use in various classes of policy decisions. The time dimension of policy analysis is, of course, most important in those cases where the problem may become cumulatively more severe over time.

Equitability of Policy Alternatives

The final area of impact research that I feel needs significantly more attention is the equitability of the several policy alternatives. Often consideration of the equity aspects is omitted from or is a minor part of the overall analysis of the expected performance of alternative policies. This may explain some of the instances where the economist's input is not seriously regarded in the political arena. When several policy alternatives have roughly similar efficiency consequences, the equity aspects are likely to weigh heavily in the choice among them.

An equity analysis must include an assessment of the impact of the several policies on income and wealth distribution of those affected by the policy. However, the analysis of equity need not, and in my opinion, should not be limited to an equality-based equity criterion. Other criteria also are used in policy evaluation. If we could develop a systematic means of dealing with these criteria, the economist's contribution to the evaluation of policy would be enhanced. I am attempting to develop such an approach. One of the additional equity criteria I am considering reflects a commonly held belief that all in society should share in the cost of achieving social objectives. Farmers certainly believe that the cost of soil erosion control for the purpose of achieving water quality goals should be shared by all. The apparent general belief that all should participate in any energy conservation policy is another example. I am also working with a criterion which reflects the attitude that individuals should be rewarded, either positively or negatively, according to their contributions. The principle that the polluter should pay exemplifies this criteria. The at-

titude of many concerning the appropriate levels of environmental protection for future generations can also be viewed as an equity criterion. To the extent that such equity criteria are viewed as legitimate in the policy-making process, an equity analysis must address these criteria if the analysis is to be useful to the policy maker.

Given that the researcher or research team has conducted an analysis of the impacts of the several policy alternatives, he or she is, of course, in a position to make recommendations on the relative desirability of the several policy alternatives. Whether such recommendations are made will depend on the researcher's perception of the appropriateness of this activity. Clearly, debate on whether the researcher should enter the policy arena will continue and just as clearly, some will make detailed policy recommendations, and do so in a very visible manner, while others will carefully refrain from making any recommendation.

With or without the recommendation of the researcher, and almost always before a full analysis is accomplished, the political process will result in a policy change. The adoption of a new policy opens another research area. The research community can concentrate effort on the policy that has been adopted and conduct much more detailed analysis than was reasonable when the several alternatives were being considered. In addition to providing additional details on impacts, research can be conducted on the appropriate responses to the new policy. Determining how industry can comply effectively and efficiently with the new policy would lend itself extremely well to the agricultural research enterprise. It is analogous to analyzing industry response to any other technical or institutional change. This may include the analysis of alternative technologies and the managerial actions necessary to implement such technologies. While this type of research is, as indicated above, inadequate as a total response to the problem area, it may be a very important research area.

Analyzing Institutions

A somewhat similar avenue of research, but one in which we have much less experience, involves the development of institutional arrangements for efficient implementation of the policy which has been adopted. Ideally much of this detail would have been included in the initial specification of policy alternatives. It is my impression that the development of institutional arrangements under which policies are adopted may be a very important factor in determining the economic impact of that policy. Often it is in this phase of the development of an overall policy that the choice between performance and technique standards is made.

If economists believe that technique-based standards can stifle innovation, they need to conduct research and make input on this choice in order to counter the general preference of lawyers and "bureaucrats" for more easily enforceable technique standards. Often the guidelines are developed by state or federal bureaucracies through an iterative procedure that includes seeking expert advice and public comment on several drafts of guidelines for policy implementation. Since industry input tends to be discounted as biased, the research community may be able to make a significant impact on the guidelines adopted. However, because of the short time periods available, it is difficult to secure resources to support an analysis or even to formulate a comprehensive set of recommendations. When these problems are considered in combination with the often mundane nature of the task, it seems likely that we will continue to do less in this area than might be warranted. While building recognition of this activity into the reward structure may help, I doubt that it will bring forth adequate effort.

Assessing Policy Performance

The final major area of research—policy performance assessment—may begin as experience accumulates under the new policy. Research conducted will be of the same nature as the assessment prior to policy adoption. Clearly, policies should include provisions for accumulating data on performance although they often do not. The cumulative nature of the pollution problem requires research on the cumulative impacts of policies for environmental objectives, just as we need analyses of the cumulative costs of regulation.

It is my expectation that, while there occasionally will be rather drastic changes in public policy, more commonly rather minor adjustments will be made on an incremental basis. Thus, the assessment of policy performance, the development of policy alternatives, the assessment of their impacts, the development of

efficient means of implementing policy, and the renewed assessment of policy performance will be a continuing process. In part, this is a continuing process because neither the research enterprise nor the policy-making process operate with sufficient precision to specify an optimal policy. In addition, because there are constant changes in the economic and the natural systems, the policy-making process is aimed at a moving target.

Other Research Needs

In any research area there is a continuing opportunity to improve the quality of the research through the development of improved research techniques. For example, we probably will find increased use of systems analysis techniques as they are adapted to the problems we face. As noted above, the need for improved techniques in the measurement of the benefits associated with the reduction in pollutant levels is an area that has begun to receive some needed attention.

My experience indicates that attempting to develop the cost of institutional arrangements necessary to implement policies is a nearly uncharted area. If the public sector is to continue to be active in the environmental area, the challenge of developing efficient institutions to implement these policies will continue to be important. As in several other areas, an interdisciplinary team of researchers is probably needed to deal effectively with this problem.

A somewhat analogous need is to make the research enterprise more efficient. Conducting a comprehensive analysis of a significant question is preferable to aggregating the results of several less ambitious research efforts. However, because the research task is extremely large and complex, it is often necessary to utilize the aggregation approach. Thus we need to know how to do it, and the resources needed must be allocated to get the job done. We also need to consider the nature of the research enterprise itself, the allocation of resources and rewards, to determine whether it is possible to generate a system better able to deal with the large and complex problems found in the environmental area. Here again the team approach may be a part of the answer.

On several occasions I have referred to, or implied, that there is a need to work with individuals from other disciplines. It is apparent that environmental policies are not formulated on the basis of the recommendations of economists alone. Further, not all of the expertise needed is likely to reside in the agricultural establishment. Severe problems can be expected if we attempt to conduct research in areas outside our training. If the research on alternative policies is conducted in an interdisciplinary mode, we force the integration of information from the several disciplines. If operating an interdisciplinary team is to be more than time-consuming and frustrating, this team will need to develop a research plan. Simply dividing a large grant among several researchers who conduct independent subprojects and then attempt to integrate their findings will very seldom produce the real integration needed. But it may be better than no integration at all. Under the alternative of separate analyses by disciplinary specialists, the politician must select from among the analyses conducted by the economist, political scientist, sociologist, engineer, ecologist, lawyer, and other in order to determine the desired policy alternative.

Summary

Environmental regulation is here to stay. Because the physical and economic phenomena involved are complex and not adequately understood, a research response is needed. Because there is an area of conflict between people in the agriculture community and some of those advocating environmental regulation, our involvement will require a new client relationship which likely will be somewhat uncomfortable to some. Our major research tasks can be best seen in relation to the policy formulation process. We need to consider involvement in the identification and measurement of problems, the development of alternative policies, the analysis of these alternatives, the development of efficient responses to policy initiatives, and the assessment of policy performance.

In addition, we need to seek improved research techniques and attempt to improve the operation of the research enterprise. One of the major changes needed may be the utilization of interdisciplinary research teams rather than relying on the aggregation of results from separate, smaller research activities.

Agricultural Workplace Safety: A Perspective on Research Needs

Stan G. Daberkow and Conrad F. Fritsch

"Safety is a scarce resource. To allocate this resource optimally, two basic questions must be answered. What level of safety shoud we be seeking? (How safe should we be?) What is the least costly way of achieving this level? (In what ways can we buy safety most cheaply?)" (Lave 1968, p. 512).

These two questions are simple and direct, but, unfortunately, answers to them have proven elusive. Response to the first is contingent on understanding the costs and benefits associated with each attainable level of workplace safety. Answers to the second are obtained by evaluating alternative technologies and public policy options.

In recent years, safety standards have been the most frequently advocated method for reducing the level of workplace injuries, illnesses and deaths. Billions of dollars have been expended and thousands of new regulations have been written. In the agricultural sector alone, estimates prepared prior to promulgation of the roll-over protection standards for tractors and the farm machinery guarding standards suggested that first year costs of these combined standards equaled about 20% of the total annual agricultural wage bill (U.S. Department of Labor 1974).

The regulatory approach, as embodied in the Occupational Safety and Health Act of 1970 is but one of five possible approaches to address the goals of workplace accident reduction. The others include: (*a*) the competitive market approach (i.e. setting wage differentials to compensate workers for higher levels of risk); (*b*) resorting to the judicial process for assignment of fault and awarding of compensatory judgments; (*c*) allocating the risk and compensatory payments through the insurance industry; and (*d*) the use of educational and informational institutions to distribute results of safety research efforts to workers, employers and self-employed entrepreneurs.

It is the opinion of the authors that an optimal solution to the two questions posed at the beginning of this paper will come about only as a result of an integration of these five approaches. To foster discussion of this desired goal the present paper is designed to: (*a*) provide a cursory examination of workplace accident causal factors; (*b*) define the nature of each policy alternative which impacts on the level of workplace safety; (*c*) describe the application of each policy to the agricultural sector; and (*d*) identify the research required to move in the direction of providing policy responses to the twin questions of "how much" and "at what cost?"

Accident Causal Factors

Accident causation typically is discussed in terms of two factors: improper employee behavior, including a negligent fellow worker, and a hazardous work environment. Under this view, workplace accident and disease are jointly produced by the work environment and worker behavior (on and off the job). For example, a National Safety Council study (quoted by Keefer) showed that 18% of all accidents were caused by environmental factors; 19% were due wholly to behavioral factors; and 63% were a combination of these factors.

A review of accident data by industry exposes several empirical regularities over time. While industrial injury rates have varied among industries with some rising (e.g. meat packing) and some declining (e.g. logging, highway construction) the ranking of industries, by injury rate, has shown remarkable stability over time. An industry with a relatively high injury rate in 1940 will tend to have a high rate in 1970. An obvious variation in injury rate exists across industries (e.g. refuse

---

Stan G. Daberkow is an agricultural economist, Economics, Statistics and Cooperatives Service, U.S. Department of Agriculture and Conrad F. Fritsch is senior economist, Minimum Wage Study Commission, Washington, D.C. The views expressed in this paper are solely those of the authors.

The authors wish to express appreciation to R. Adams, D. Fisher, W. Glasier, E. Jesse, and R. Phister for comments on earlier drafts.

collection has an injury rate of 63.9/million man-hours while banking incurs 2.4 injuries/ million man-hours). Table 1 gives the most recent injury rates by highly aggregated industry classes.

Another empirical regularity found in industrial injury statistics relates to firm size. Table 1 indicates this association for several selected industries. The majority of industries tend to follow an inverted u-shaped curve when injury rate is plotted against firm size. Possible reasons for lower injury rates among the very large and small firms may be related to labor market factors. Large establishments have lower labor turnover rates, hire fewer young workers, have a small proportion of workers which are production rather than office or clerical oriented, or employ more safety personnel or resources. On the other hand, smaller firms supposedly enjoy closer employee-employer relationships, making safety a personal factor.

The incidence rate for agriculture does not follow the trend of other industries. Agriculture's incidence rate increases as size increases. In the one to nineteen employee category, agricultural firms have only the fourth highest incidence rate, while firms in the 1,000 to 2,499 employee class have the highest incidence rate for all industries listed.

Using the standard errors published by the Bureau of Labor Statistics (BLS) one can detect statistically significant differences between industries. At the 95% confidence level (assuming a normal distribution and that all the variation arises from sampling error) contract construction, manufacturing and mining have significantly higher incidence rates than agriculture while wholesale and retail trade, and transportation and public utilities are not significantly different from agriculture.

The accident rate (on and off job premises) is also associated with the age and sex of workers. The age group 20–24 has twice the injury rate of all other workers. However, the total injury rate masks another phenomenon. Younger male workers are more likely to be injured but less likely to be killed. Conversely, males over 50 are less likely to have accidents but when they do, they are more likely to die. Furthermore, males are three times more likely to be injured than females. Oi (1974) suggests that sex/age differentials in work injury rates may be proxy variables for other causal factors such as innate accident liability (accident proneness), perceived costs of work injuries, attitudes toward risk bearing, occupational and industrial affiliation, and job experience.

Labor turnover and job experience have also exhibited a strong association with injury rates. Preliminary evidence indicates that injury rates for less than one month on the job are two-and-one-half times higher than after six months on the job. Obviously, lack of familiarity with one's tasks could account for this relation. Age and experience are highly correlated, providing an explanation of lower injury rates of older workers by their cumulative work experience. Seasonal workers are an obvious example of workers with a high turnover and little job experience. Agricultural workers certainly fit in this category as do those in the logging and food processing industries.

Alternative Approaches to Workplace Safety

Market Approach to Workplace Safety

Use of a competitive labor market model to illustrate the economics of safety dates back to Adam Smith, who was the first to assert that individuals could be induced to take risky jobs only by offering a risk premium. More recent analysis can be found in the formal models of Oi (1973, 1974), Smith (1973, 1974, 1976), Gregory and Gisser, and Russell.[1]

Workers employed in higher risk occupations or industries supposedly *ceteris paribus*, receive higher wages (a risk premium) over their fellow workers engaged in less hazardous tasks.[2] The relevancy of this risk premium

[1] Most of these models are neo-classical firm optimization models where profits are maximized or costs minimized subject to the appropriate constraints. Oi (1973), however, views injuries as inherent in the production process and treats this topic in a joint product framework where injuries are a by-product with no market. As such, injuries are viewed as externalities and treated in the same manner as environmental problems. The similarity of standards setting in this discussion with those in the environmental field can be ascertained in Baumol and Oates (1975, p. 140–144). A distinction between workplace and environmental side-effects of externalities can be made conveniently on the basis of the participating parties. Workplace side-effects are confined to the parties making the transaction whereas environmental side-effects impose costs (or benefits) on a large number of people who were not parties to the transaction.

[2] Smith (1974) did conclude that employers in the manufacturing sector have responded to incentives to provide workplace safety. He found that in manufacturing industries where the yearly death rate is 16/100,000 workers, employees receive approximately 1.5% higher wages per year on the average than do employees with comparable skills in manufacturing industries which have an average rate of 8 deaths per 100,000 workers. However, many hazardous jobs do not pay well and they are often held by nonunion, unskilled, minority groups with limited options. Obviously factors other than "risk" influence wage levels.

Table 1. Occupational Injury Incidence Rates, Private Sector, by Employment Size and Industry Division, United States, 1974 and 1975

Number of Employees	Private Sector 1974	Private Sector 1975	Agriculture, Forestry and Fisheries 1974	Agriculture, Forestry and Fisheries 1975	Mining 1974	Mining 1975	Contact Construction 1974	Contact Construction 1975	Manufacturing 1974	Manufacturing 1975	Transportation and Public Utilities 1974	Transportation and Public Utilities 1975	Wholesale and Retail Trade 1974	Wholesale and Retail Trade 1975	Finance Insurance Real Estate 1974	Finance Insurance Real Estate 1975	Service 1974	Service 1975
	Incidence Rates per 100 Full-Time Workers[a]

Notes: Dashes indicate no data reported. Data refer to Wage and Salary workers only.
[a] The incidence rated represent the number of injuries per 100 full-time workers, and were calculated as: (N/EH) × 200,000, where N—number of injuries
EH—total hours worked by all employees during the calendar year
200,000—base for 100 full-time workers (working 40 hours per week, 50 weeks per year).

market model is linked to four key assumptions: (*a*) available information and employee understanding of risks associated with each job opportunity; (*b*) mobility of workers; (*c*) employer's perception that benefits are received from supplying job safety and health; and (*d*) the existence of risk premiums.[3] The optimal level of safety may not be attained when one or more of these assumptions are violated. If workers are ignorant of risks associated with their job they may incorrectly assess the value of their risk premium. Thus, employees' underestimating the risk (or correctly estimating the risk, but having no alternative employment) will allow employers to pay a lower wage which will not adequately compensate an employee for the risk. Employers are assumed to recognize the profitability of making safety investments.

The assumptions regarding full understanding by workers of workplace hazards, risk premiums, and free mobility of workers between occupations and industries are rarely realistic in practice. Indeed, many current labor market institutions including unionization, minimum wage guarantees, internal firm wage bargaining procedures, passage of Worker's Compensation laws, and the improvement of voluntary workplace health and safety programs suggest that, as a society, we have opted to provide workers with basic guarantees against the vagaries of free market labor allocation processes.

Judicial System

Tort law (i.e. a wrongful act, injury or damage for which civil action can be brought) is one mechanism whereby an injured employee can recover costs incurred by him due to the employer's negligence. For agriculture, tort law is one method of encouraging farm safety on the part of both the farm employer and farm worker especially in states where agricultural workers are exempt from coverage under Worker's Compensation laws.

The tort law approach to setting the level of safety relies on the court's ability to identify the negligent party *ex post*. However, the judicial system can still encourage optimal behavior from both the employee and employer viewpoint (Kasper). Theoretically, the court system can allocate the accident costs in such a way that the sum of accident costs and accident prevention costs would be minimized. To accomplish this goal, fault would be assigned to the party which could have avoided the accident at least cost.

The legal system has not fulfilled the ideal successfully. For example, in the case of workplace safety, an employer may invoke three common-law defenses: "(1) contributory negligence on the part of the employee himself; (2) contributory negligence on the part of another employee (fellow servant rule) and (3) assumption by the employee of the risk that led to the injury in question when he took the job" (Fisher, p. 12). Furthermore, the causal link between the work environment and an employee's health status can be very tenuous, resulting in inappropriate incentives for the provision of safety. In light of the difficulties associated with identifying chemical-related maladies it is understandable that cases of machine failure are more likely to bring compensation for injury than is the misuse of a chemical. The expense in time and money of operating the legal system can be extensive. One does not receive compensation for time spent in litigation; no interest accrues to the awards for the time delay between the accident and the liability judgment; and court costs and legal representation can consume a major part of the compensation even before the case is tried. An employer (or his insurer) is often in a position to negotiate liability suits more effectively than is the employee. The uncertainty of outcome plus the large variation in settlements and awards for similar incidents also limit the incentives for the provision of optimal safety levels (Cornell, Noll and Weingast). The cumulative effect of these factors is that employers do not have reliable information on which to allocate safety resources.

Another aspect of tort law, which is more applicable in the case of the self-employed farmer, is product liability. The general area of product liability is currently in a legal turmoil. A study by the Department of Commerce Interagency Task Force on Product Liability has found that some industries are experiencing an increase in litigation because of liability imposed on them for injuries caused by their

[3] This model minimizes the sum of accident costs and accident prevention costs. Minimizing one or the other leads to a misallocation of resources as Lave points out (1971, p. 101). For instance, since over half of all accidental farm fatalities occur to persons over 45 years of age, society could cut farm deaths in half by requiring all farmers to be less than 45 years of age. This step surely would reduce deaths, but it is not consistent with maximum societal welfare. When the cost of preventing an accident or illness is greater than the accident costs, welfare is maximized when the prevention costs are not incurred and the accident is allowed to occur.

products. In the case of defective farm equipment, which has caused an injury to either the farmer or his employee, the injured party has recourse through the judicial system. This assumes of course that the injured party meets certain due care standards (Diamond).

Traditionally, farmers as a group, have not articulated a strong desire to improve the safety features of farm equipment. However, representatives of the Farm Implement and Equipment Institute have indicated to the authors that the increased likelihood of product liability suits arising from injuries and deaths associated with the operation of farm machinery has become a major concern of farm equipment manufacturers in recent years. In spite of that, no systematic data are available on the number of liability suits filed by producers against input suppliers on the basis of injury or disease.

Insurance System

Insurance is another mechanism to encourage the optimal level of safety for both the employee and employer. Assuming both have insurance against damages (protection from liability damages in the case of the employer and health costs, rehabilitation costs and loss of income in the case of the employee) their premiums are theoretically based on the probability of an adverse event.[4] Therefore, employees and employers have direct pecuniary incentives to keep expected losses as low as possible.

Nevertheless, insurance has its drawbacks. Accurate estimation of the probability of loss is necessary to establish premiums, which in turn inspire insurance owners to behave so as to minimize their insurance costs. In current practice, premiums are not set on an individual or firm basis, but on a group basis, thereby blunting the incentive mechanism. (However, firms known to be poor risks can be placed in an assigned risk pool.) This problem is really a manifestation of the insurance carrier's inability to estimate the probability of an event occurring to any one individual.

A special case of insurance which was partly designed to influence workplace safety is the system of Federal/State Worker's Compensation law (Rosenblum). This program, administered by individual states, basically provides for compulsory no-fault insurance. In a number of states, an employer is required to buy liability insurance (or to self-insure under certain conditions). In the remaining states, the employer can voluntarily subscribe to Worker's Compensation insurance. These laws obligate the insurer to compensate the employee for lost income, and medical and rehabilitation costs deriving from a job-related injury regardless of who was at fault. In return for fixed schedules of benefit payments for a job-related injury, the employee's recourse to further legal action is limited.

Several arguments were proffered for the establishment of Worker's Compensation, most of which attack the assumption of the market model presented earlier. Perfect perception of workplace hazards and perfectly competitive labor market operations were assumptions thought to be unrealistic in practice. It was argued that workers would "prefer current consumption over protection and will demand the risk premium in cash" (Rosenblum, p. 230). Furthermore, by linking premium costs to the firm's accident experience, Worker's Compensation was designed to provide employers with incentives to prevent accidents.

Although assigning premiums to employers in an inverse relationship to accident occurrences is theoretically enticing, actual rate setting procedures are complex, vary by state, and may have little impact on the workplace environment. Under current procedures each state (or private carrier) anticipates the total loss (i.e. benefits to employees injured on the job) resulting from industrial or occupational accidents (Fisher). Losses are calculated as a function of the frequency and severity (dollar amount) of claims. In turn, the number and severity of claims is a function of the inherent hazards in the industry as well as the interpretation of the statutes and the level of the awards allowed by the state institutions involved. The rate calculation procedure is then subject to an additional adjustment called experience rating, which takes into account the individual employer's recent accident record as measured by benefits paid out to employees. In most states, firms having premiums in excess of $750 per year (generally firms with four or more workers) are experience rated. It is estimated that only about 30% of all employers meet this criterion.

[4] If the worker is uninsured, in regard to on-the-job health, rehabilitation, and/or loss of income insurance, he may shift these costs onto the taxpayer via welfare payments. Social Security supplements are also available to families whose breadwinner is permanently, partially, or fully disabled because of on-(or off-) job accidents.

Since Worker's Compensation premiums should have an inverse relationship with the number of workplace accidents, it can be expected that states with high benefit levels should have lower injury rates than low benefit states. Chelius (1974) did not find this relationship to hold. Russell and Smith (1976) also pointed out that the premium-setting mechanism for Workman's Compensation does not encourage optimal safety levels.[5]

Legislatively Mandated Workplace Standards

If the market model produces less safety than consumers or workers are willing to pay for (in either higher product prices or lower wages, respectively), and the litigation and insurance options are deemed inefficient or ineffective approaches, then at least one rationale (i.e. market failure) for government intervention exists. The assumption underlying regulatory action is that those standards promulgated and enforced by the agency have a "significant" effect on reducing workplace injuries and disease (Oi, 1973). However, two practical issues about these government regulations immediately arise: (*a*) costs and returns of safety standards will vary by firm since rules which are the same for each firm are unlikely to be optimal for each firm and (*b*) it will be unlikely that a government employee enforcing these standards will be aware of the least-cost technology available to each firm (Chelius, 1973).

The Occupational Safety and Health Act of 1970 created the most comprehensive workplace standard setting institution at the federal level. The key provisions of the Act are as follows:

1) General Duty Clause (sec. 5(a)(1)): Each employer shall furnish to each of his employees, employment and a place of employment which are free from recognized hazards that are causing or likely to cause death or serious physical harm to his employees.
2) General and Specific Standards (sec. 5(a)(2)): Each employer shall comply with occupational safety and health standards promulgated (by the Secretary of Labor) under this chapter.
3) Employee's Duties (sec. 5(b)): Each employee shall comply with occupational safety and health standards and all rules, regulations, and orders issued pursuant to this chapter which are applicable to his own actions and conduct (Miller, p. 615).

The first two provisions apply to the employer and, if he is found in violation of either, the Act provides for fines and penalties or even plant closure if there is imminent danger of death or serious physical harm. The third provision applies to employees but the Act contains no penalty for violation of this provision.

There seems to be some consensus, at least among economists, that economic efficiency was not part of the Occupational Safety and Health Administration's (OSHA) initial criteria in evaluating standards. The approach taken by OSHA administrators at the time the agency was formed, a legitimate one in view of the congressional mandate, is that absolute protection or zero-risk was to be attained in the workplace (Oi, 1975 and Smith, 1976). The attainment of these goals (as interpreted by various court rulings) could be constrained only by the reduction of risks to the technologically feasible minimum or "that protection which can only be achieved by ceasing production" (Oi, 1975, p. 2).

The current approach to workplace standards setting at OSHA has the following hierarchy: (*a*) engineering design; (*b*) administrative procedures (i.e. forbidding certain employee work practices or behavior); and (*c*) personal protective gear. Generally, reducing accidents through the engineering design is much more capital intensive and costly whereas personal protective gear, while less costly, may impair worker productivity or increase worker discomfort. From an efficiency or cost-effective point of view, a sumultaneous rather than hierarchial analysis of the three options is necessary.

Economic considerations have taken on greater significance in recent years. Under executive orders in effect since 1975, inflationary impact statements or regulatory analyses must be prepared to estimate the costs of implementing any proposed federal regulation. Regulations expected to cost more than $100 million in one year are subject to a more comprehensive inflationary impact analysis. Although this method provides a crude measure

---

[5] Workman's Compensation premiums can also be viewed in the broader context of a percentage of the total payroll. This percentage varies over time, industries and states. Between 1940 and 1970, this percentage for all industries and states has varied between 0.89 and 1.19 (Rosenbloom, p. 179). In manufacturing, in 1969, the average percentage was 1–2%; nonmanufacturing was 0.5% with a range of 0.1% for insurance companies to 1.8% for primary metals. State variations in 1971 were from .67% in Utah to 3.12% in Arizona. Although, the total dollar amount of premiums is significant, (almost $5 billion in 1970) the incentive for an individual firm to change its safety behavior is marginal since Worker's Compensation premiums are only a very small and relatively constant level of total payroll.

of economic costs, no attempt is made to estimate the value of benefits received.

In addition to regulations which are ineffective (rules with no impact on injury rate) and cost inefficient (hazards which can be eliminated with techniques less costly than those required by law) several other difficulties beset regulatory agencies. Extremely complex or stringent rules are likely to lead to noncompliance by firms, as are rules which lack enforcement by inspectors. Detailed standards for each occupation within each industry are impossible. However, standards applicable at the industry level lack specificity. Controversial standards (i.e. those eliciting strong pressures from opposing interest groups) become difficult to change or adopt. Constant changes in technology and materials create constant need for new or different standards.

Safety in Agriculture

Agricultural production firms are noted for their diversity including variations by region, farm type, production processes, and size of farm (acres, sales, or number of employees). However, some unique characteristics of farm firms and their implications for safety can be identified. Most farm operators and employees perform a wide variety of tasks (i.e. heavy equipment operator, construction work, chemical applicator, mechanic). Very little farm work is of the assembly line type nor is it of a repetitive nature. Length and intensity of farm work days also exhibit high variation. The number of hours per day devoted to planting, harvest, certain livestock operations and various other activities are often dictated by weather conditions. In addition, many agricultural activities require transitory work sites as opposed to permanent surroundings. Nonadjoining fields require mobile farm equipment which may traverse variable types of terrain. An increase in part-time farmers leads to added unfamiliarity with job tasks as well as fatigue from a second job.

The 2.7 million persons aged 14 and over who did some hired farm work in 1977 had several interesting characteristics: (*a*) 55% of hired farm workers were under 25 years of age; 28% were 14–17 years old; (*b*) 77% were male; (*c*) 50% were not in the labor force most of the year (the majority of these were students); (*d*) 39% worked on farms less than 24 days (casual workers) and 36% worked between 25 and 149 days (seasonal labor); (*e*) 41% had non-farm jobs at some time during the year (Rowe).[6]

As noted earlier, empirical consistencies exist between worker characteristics and injury rates. Age, sex, and work experience were among the significant variables related to differing probabilities of accident occurrence. The relatively young age of the hired farm workers plus the preponderance of males would lead one to conclude, *ceteris paribus*, that farm workers would have a relatively high injury rate. Combined with the fact that many farm workers are part-time, one would suspect that labor turnover is high and work experience low. In fact, of the 700,000 farms hiring workers in 1974, about two-thirds hired workers for fewer than 150 days per year (U.S. Department of Commerce, 1974).

These factors, the farm workplace environment and the hired work force provide a general explanation for the relatively high workplace injury rates recorded for the agricultural sector. Of course, variation by farm type, region, etc. modifies these generalities.

The Judicial System

"Farmers sentiment about the need for safer machinery has never been intense, and the generally conservative farm community has failed to produce even the vocal minority characteristic of users of other products" (Kurdle, 1975, p. 69).

The above quotation may explain the nonlitigious nature of farm operators and farm workers. From a farm-operator perspective, the court system might provide a mechanism to increase workplace safety via product liability related to farm equipment.[7] From an employees' view, the tort system is often the only recourse in the case of the employer's workplace negligence, unless the worker is covered under Worker's Compensation laws. In reality, not everyone has equal access to legal mechanisms. Farm workers would not appear to have the resources to claim access, at least not in relation to the employer or farm operator. This is especially true in view of the

---

[6] The farm worker survey is restricted to farm workers who are residents in the United States during the December survey week.

[7] 'Since farmers are in the business of "manufacturing" food, are they liable for damages caused by "dangerous" food products consumed by the public? Chemical residues (i.e. stilbestral, herbicides, pesticides, nitrates) would appear to be the biggest problem. Could farmers force this liability back to chemical manufactures? Does inspection of agricultural products by a government agency relieve farmers of product liability?

employer's three common law defenses noted earlier.

The Insurance System

A large number of farm operators and most farm employees apparently employ a combined strategy of self-insurance, market insurance and self-protection when dealing with workplace hazards (Ehrlich and Becker). Obviously, the more time or money spent on self-protection (i.e. workplace behavior) the less will be spent on market and self-insurance. This strategy is complementary to coverage under the Social Security system, which provides for benefits payments in case of permanent partial or full disability, regardless of whether the injury was occupation related or not.

Some states require farm employers to purchase insurance coverage under Worker's Compensation laws while other states allow elective coverage by farmers (Schramm). In these states a farmer who qualifies for coverage and choses not to come into the Worker's Compensation system, loses his three common law defenses should he be sued for negligence. Thirteen states currently make no distinction between agricultural employees and other types of industrial employment and, except for New Jersey, these states have compulsory coverage laws (Daberkow and Fritsch). Another seven states cover farm workers except under some relatively minor circumstances. Four other states require coverage after a substantial payroll threshold ($15,000–$25,000) is reached. The remaining states exempt agricultural employees specifically or exempt a large number by allowing employers of three or fewer workers to come voluntarily under the Worker's Compensation insurance system. Therefore, an exact account of the number of farm workers actually covered by Worker's compensation is unknown, but the aggregate number of farm workers in the above 24 states accounts for over 55% of the total (U.S. Department of Agriculture, 1977).

The impact of experience rating on the safety record of farm employers who are required to purchase Worker's Compensation insurance is not available from secondary data sources. Experience rating of very small firms causes actuarial principles to be compromised. Insurance firms serving farms or other relatively small employers have little data (or incentive) to experience rate these firms (Lewis). However, firms with extremely poor safety records can be placed in assigned risk pools with premiums substantially above ordinary rates.

Even though over 50% of the U.S. hired work force is estimated to be covered by Worker's Compensation laws, one study indicates a lack of awareness by employees of available benefits. Howitt and Moore, using a primary survey of farm workers in California, found that nearly 70% of the farm workers sampled were unaware of Worker's Compensation laws. In addition, they found that premiums for farm firms did not change by claim history. Obviously, the incentives for cost internalization by the firm, through this institution, are rather weak.

Agricultural Workplace Safety Standards

Although various states may have additional workplace regulations or standards affecting farm workplace safety, the Occupational Safety and Health Administration currently enforces five specific regulations affecting agriculture. Agricultural production firms covered under these federal regulations are exempt if they do not hire more than ten employees. Present regulations in agriculture cover the following: (*a*) storage and handling of anhydrous ammonia; (*b*) temporary labor camps; (*c*) tractor roll over protection equipment (ROPS); (*d*) machine guarding; and (*e*) slow-moving vehicles. Re-entry standards for organophosphate pesticides have been recently rescinded and placed under the jurisdiction of the Environmental Protection Agency.

A brief look at OSHA's agricultural enforcement program will emphasize the limitations of this approach to reducing workplace accidents. In formal terms, the incentive for employers to comply with OSHA standards is a function of the probability of being inspected, the probability of an inspector detecting a violation, and the amount of the penalty imposed. OSHA reports inspection activity by industrial category and, therefore, agricultural statistics include firms in forestry and fisheries. The most current data (from 1974) indicates that there are fewer than 120,000 farms which hire ten or more employees during any part of the year (U.S. Department of Commerce, Bureau of the Census, 1977, Table 15, Part IV).

Table 2 isolates the three variables noted

Table 2. Selected OSHA Inspection Data for Agriculture, 1975 and 1976

Item	1975	1976
Total inspections	1,116	2,317
First time inspections	892	1,697
Citations	720	1,373
Total violations	3,282	6,325
Serious violations	31	45
Total penalty ($)	27,840	44,870
Total employees covered[a]	46,925	90,801
Share of firms inspected first time (%)	0.7	1.4
Number of citations per first-time inspection	0.81	0.81
Number of violations per citation	5.56	4.61
Share of serious violations (%)	0.9	0.7
Penalty per citation ($)[b]	38.70	32.68
Penalty per violation ($)	8.49	7.09
Penalty per employee ($)[c]	0.59	0.49

Source: OSHA Inspection Activity Data, 1975 and 1976 unpublished, Occupational Safety and Health Administration.
[a] Employees covered is somewhat misleading since follow-up and repeat inspections count the same employees a second time.
[b] Penalty paid per serious violation is not available.
[c] Based on the estimated number of farms with ten or more employees.

above. The probability of being inspected in 1975 and 1976 was 0.007 and 0.014 respectively.[8] Once the inspector had arrived, the probability of receiving a citation was 0.81 in 1975 and in 1976. Each inspected firm violated an average of four to six standards in either year, while the number of serious violations (life-threatening) was less than 1% of total violations. The average penalty per citation was $38.70 and $32.68 in 1975 and 1976, respectively, while the average penalty per violation was $8.49 and $7.09. The average penalty per employee was even more miniscule—$0.59 and $0.49 per employee in 1975 and 1976 respectively.

The above exercise suggests that even though the probability of receiving a citation once an inspector arrives is high, the probability of arrival and the average penalty levied is quite low. This translates into a very small *ex ante* incentive for the employer to comply with OSHA standards.

[8] This is an admittedly back-of-the-envelope estimate, since inspections are not entirely random. Accidents or employee complaints can trigger an Occupational Safety and Health Administration (OSHA) inspection. Furthermore this analysis does not include the probability of a state inspection in those states which have their own inspection system.

Safety Education Institutions

Several organizations ostensibly have improved the level of farm safety via their safety education programs. Such programs rely on voluntary compliance with suggested safety practices. Repeated warnings and educational safety notes are designed to keep farm operators constantly aware of farmstead hazards, thus lowering the risk of injury. The federal government's role in agricultural safety education has been primarily through the U.S. Department of Agriculture via the Extension Service. The Land-Grant University System has also contributed to this education effort. One notable nongovernment nonprofit agency associated with farm safety and safety in general is the National Safety Council (NSC). This group develops educational information and presents seminars for safety specialists employed with private industry and state Extension Services.

One can view the educational safety expenditures of the federal and state agencies as a safety information accumulation, synthesis, and distribution system. In this context, the agricultural industry's ability to secure safety information subsidized by the public sector seems somewhat unique. A number of economists have suggested that the "proper" role of government in the area of workplace safety should be restricted to safety research (analysis of risks) and information dispersal (Goldberg). Workers, employers and self-employed farmers thus are able to use the available information to determine their optimum level of safety consumption. Workers might respond by demanding risk premiums in their wages, seeking other employment, opting for greater self-protection through diligent work behavior or a combination of both. Employers and self-employed farmers are likewise induced to change their workplace environment or change their work habits.

Agricultural Safety Data

No discussion of safety is complete without a discussion of data problems. The 1970 Occupation Health and Safety Act included a provision to secure data on workplace injuries. The system was designed to ascertain accident causal factors as well as to determine accident injury rates across all industries over time and in a consistent manner. Published statistics include the number of workplace accidents,

injuries, illnesses and fatalities by two and three digit Standard Industrialization Code groups. Agricultural coverage is limited to workers employed on farms hiring ten or more workers.

The NSC annually releases data that purports to measure levels and rates of farm and farm work injuries and fatalities. These estimates are not developed using scientific sampling procedures and, hence, the reliability of the estimates is not known. In some cases, estimates appear to vary considerably from those developed by the Bureau of Labor Statistics (BLS), but population differences preclude direct comparison with BLS statistics.

The NSC, in cooperation with the state Extension Services, also collects comprehensive state accident data on a recurring basis. States are requested to participate at five year intervals. The purpose of the surveys is to identify the type of accident and its severity, determine the characteristics of the victim and describe the factors associated with the occurrence. These surveys provide a large mass of data but weak sampling designs limit their usefulness. The absence of consistent measures of the population at risk further hampers their usefulness for the purpose of monitoring trends or for studying factors associated with accidents.

State Workers Compensation systems are a third source of accident statistics. They reflect only persons covered under the respective state compensation system. Data included and the classifications by which data are presented vary from state to state, further reducing the comparability of results.

A fourth data source is the National Center for Health Statistics compilation of accidental fatalities from Coroners First Reports. Providing simply a count of fatalities, by age, state and major contributing causal factors, the data are classified to include all fatalities occurring on farms. Direct distinctions between work and nonwork fatalities are not possible but Fritsch and Zimmer have developed a methodology to provide such estimates.

The above sources use differing definitions of population at risk, and, furthermore, the criteria used to identify a recordable accident also differ. The National Safety Council defines accidents as injuries or illnesses requiring professional medical care or loss of one-half or more days from usual activities. State Worker's Compensation systems use other definitions. The Bureau of Labor Statistics, which collects data for OSHA, does not require that an injury or illness victim lose any work days or be attended by medical personnel. Obviously, OSHA records a large number of minor injuries, but they also record the number of work days lost.

The population-at-risk or an exposure time measure is probably even more difficult to ascertain than a count of injuries or illnesses suffered. In agriculture, risk exposure times by activity are not readily available. It is plausible to hypothesize that accidents per farm worker vary by activity or production process. An enlightening statistic would be accidents/activity-hour. This ratio emphasizes the fact that many employers, particularly farm workers, perform a number of different tasks throughout the year, all with varying levels of risk. Using this criterion Doss and Phister have identified farm grain and hay elevators as being associated with the highest number of injuries per activity-hour.

Summary and Research Recommendations

"As a means of adjudicating matters of personal and property rights, the adversary process has major advantages. But it is a poor replacement for making highly complex economic policy. We should compare an imperfect market with an imperfect regulatory scheme, not with some ideal and omniscient abstraction" (Schultz, p. 61).

In all models (market, judicial, insurance and regulatory) the final result is supposedly that those who demand goods and services from industries in which employment is risky must pay for the costs of employee injuries and diseases which are by-products of the production process. Obviously, coal miners, policemen, farmers and firemen will continue to be demanded despite the higher than average risks of injury and disease. The crucial question becomes whether the public policy programs of Worker's Compensation, and OSHA and, to some extent the judicial system, can allocate safety resources so as to move us closer to the socially optimal level of workplace safety.

Recommendation 1

A comprehensive review of available agricultural workplace safety statistics should be un-

dertaken. This review should include an assessment of availability of data suitable for determining causal factors contributing to accident occurrences and make recommendations for a unified data base. The focus should be limited to work-related accidents. Factors affecting the identification of work accidents, such as the dual environment of farms as places of work and places of recreation, require specific identification.

Recommendation 2

Continue to evaluate the effectiveness of the public provision of workplace safety information. Agriculture is unique in that the public sector financially supports a number of activities designed to enlighten farm workers and farmers about farm safety. The market model suggests that the well-informed worker will use knowledge of job risks to assess the attractiveness of his potential work environment and to encourage work behavior that would lower the probability of job-related accidents or diseases. Questions to which this research is directed include: Can the delivery of safety services in agriculture be improved? Does the provision of public safety information by the Extension Service provide the most cost-effective method of reducing farm accidents? How important and cost-effective is information from private sector sources such as insurance companies or the NSC?

Recommendation 3

A comprehensive evaluation of the cost and effectiveness of the current piecemeal approach to agricultural workplace safety is a prerequisite for forming a basis for developing a more integrative system of safety institutions. The current safety system has evolved somewhat haphazardly over time. Data on use of the judicial system by farm workers or employers is limited, and therefore its role as a deterrent to workplace accidents or diseases is unknown. Coverage of the agricultural sector under Worker's Compensation is still not complete in certain states. Furthermore, the relationship between experience rating of agricultural employers and farm injury rates appears weak. Product liability may have been a factor in improving the safety design of farm equipment but the relationship between the two is nebulous. OSHA standards in agriculture do not cover self-employed farm operators and currently exempt employers with fewer than ten workers. Thus the standards approach to workplace safety may have little impact on the agricultural injury rate. The question becomes, to what extent do each of these institutions impact on the level of agricultural safety at acceptable social costs.

Economic Research Conference on U.S. Food System Regulation

Richard A. King

This conference grew out of concerns that food system regulation is not a well-defined research area, that economic regulation is a much more inclusive subject than is commonly recognized, and that regulation is likely to be a major policy issue in the years ahead. Cosponsorship by the Economics, Statistics and Cooperatives Service (ESCS), the Food System Research Group (NC-117), the Farm Foundation and the American Agricultural Economics Association (AAEA) provided a broad base for planning the agenda and for assuring representation of a wide variety of interests. This conference and the conference proceedings will contribute to raising the consciousness of the profession regarding the importance of this area of investigation and will bring new insights concerning the dimensions and complexity of the field of economic regulation.

The potential scope of economic regulation research suggested by the conference speakers is broad. Useful economic research can be done at all four stages of the development of a regulation: law making, rule making, implementation/enforcement, and litigation. Much attention has been given to the law-making aspect of regulation while the roles of rule making, implementation and litigation often have been ignored. Conference papers were selected to bring into focus these other dimensions. The decision makers (Congress, department, agency, court) differ at each stage of the process. The contrast between direct regulation of performance and indirect or market structure actions was brought out in the forum led by Fritz Mueller.

It became clear as the conference went forward that few research workers are in a position to deal effectively with every aspect of regulation. Economic researchers are located in government agencies, universities, public interest groups, corporations and trade associations. The professional setting in which one works will influence the type of research that he or she can best accomplish. Several distinct types of research—pre-legislation, post-legislation, research on agency operations and research on cumulative effects—were discussed in some detail by Dale Dahl.

Richard A. King is M. G. Mann Professor in the Department of Economics and Business, North Carolina State University–Raleigh.

The Economics of Regulation

In the opening paper, Jim Shaffer identified the key issue as: "What has to be taken into account?" Simplified models often are inappropriate representations of the regulatory process in the real world. The relevant choice is not between regulation and no regulation, but rather how the inherited regulatory system is to be modified. It is not logical to assume institutions and the distribution of wealth and power to be given, and then to use that model to conclude that a particular rule reduces total welfare. Citizen preferences are articulated both through the market and through the political process. Neither is of a higher order than the other. Both must be considered in examining the supply and demand for government regulation of economic behavior.

Bruce Gardner put supply and demand for regulation in the context of marginal social costs and marginal social benefits. He emphasized the importance of considering the distribution of costs and benefits among participant groups. In making such calculations it becomes clear that elasticities do not provide sufficient evidence; shifts in the relevant functions often are equally important. This was demonstrated in the evaluation of alternative milk pricing procedures.

Jane Campana called attention to the different perspective of lawyers and economists toward regulation—lawyers viewing regulation as the product of political processes and economists as decisions having economic impact. In her view, economic considerations will be-

come more important over time. Procedures to be followed in economic impact analysis are often specified by congressional action. To be effective, economic analysis must be translated into language that is comprehensible to lay persons. Timeliness in providing economic evidence in the rule-making process is especially critical.

Politics and Regulation

Politics and regulation provided the focus for the second series of papers. Jim Hildreth contrasted the "old" regulatory environment, in which the industry being regulated often played a dominant role, with the "new" regulatory environment in which lengthy and specific legislation often spells out procedures in great detail and provides for a functional rather than an industry orientation. Much of what passes for deregulation is the phasing out of the "old" regulatory process. Identification of the optimum amount of regulation may be difficult, but the traditional agricultural policy approach of issue identification, consideration of alternatives and specification of consequences of each is a promising place to begin.

Nina Cornell suggested that politics be viewed as a series of decisions, of communicating, having influence and winning. Informal rule making through notice and comment procedures is where the action is today. It is important to avoid economic jargon. Be brief and be relevant. Working for a decision maker often has more impact than having the role of co-equal. The record is all-important since decisions must be based only upon the evidence found there. A focus on future benefits and future costs will be more effective than historical documentation.

Tim Hammonds commented on the research needs of the regulated firm. He suggested an active posture toward evidence offered in public hearings as part of the record-building process.

Regulation Research Methods

Session three focused on regulation research methods. Dale Dahl provided an operationally useful paper, outlining in some detail four classes of regulation economics research issues. He pointed to the limited understanding of the law on the part of economists as a potential handicap in providing relevant research results. The need for more comprehensive pre-legislation research was emphasized by Tom Grumbly. He commented that intuitive processes must substitute for analysis in the absence of research. Post-legislation research on milk price policy was outlined by Boyd Buxton. His conclusion was that we are hard pressed to predict the behavior of the real world in the absence of regulation. The essence of regulation research is the comparison of outcomes expected under alternative regulatory environments.

Gary Seevers summarized the development of the Commodity Futures Trading Commission over the last four years as a new independent regulatory agency getting off the ground. He cited serious obstacles to increasing the role of economic analysis in regulatory agency operation.

Barry Bosworth detailed the sources of inflation and the prospects for containment through alternative government initiatives. He expressed concern for the decline in productivity growth and for the effect of shocks like farm price and energy price inflation on the stability of the economy. He described the new emphasis in the federal budget process on trade-offs, pointing out that many actions now lie outside the budget process. While many individual programs have small impact, the aggregate effect is important.

Regulation Research Issues

The fourth session forums provided an opportunity for small group consideration of regulation research issues by the conference participants. It was noted that familiar analytical tools may require more careful treatment when addressing regulation issues. For example, few economics texts teach students to draw marginal revenue curves so that the full range of quantities displayed on the demand curve is represented on the marginal revenue curve. Since marginal revenue is negative when price elasticity of market demand is less than one, and since the market demand for many products such as food and gasoline is inelastic, it follows in such cases that only the portion of the marginal revenue curve lying below the quantity axis is relevant for policy analysis. Graphic demonstrations found in the literature implicitly assume that demand is elastic, a convention that facilitates equating marginal cost and marginal revenue but may be inconsistent with empirical evidence.

Summary

To sum up briefly, more information about the structural and behavioral characteristics of markets is needed in order to evaluate the effects of regulatory changes in agricultural industries. New variables must be considered and better measurement tools will be required. For many purposes, identification of relevant variables and rough measures of impacts on participant groups will have a high payoff. Economists can increase their effectiveness in injecting economic findings into regulatory decision processes if they are familiar with decision-making procedures and recognize the importance of rule-making calendars.

This conference represents a way-station toward more effective regulatory analysis. Much remains to be done in providing better economic intelligence through improved methods and models. Perhaps that should be the focus of the next conference.

American Journal of Agricultural Economics

Volume 61 Number 5
December 1979 Proceedings Issue

In this issue: Proceedings from the annual meeting of the American Agricultural Economics Association held 29 July—1 August 1979 in Pullman, Washington

Editorial Council

Staff for volumes 60–62

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri Columbia, MO 65211

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

Varden Fuller

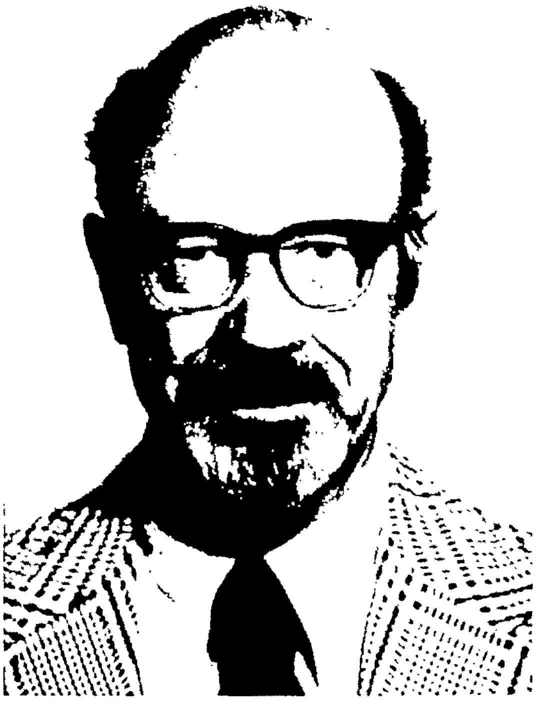
1979 Fellow

Professor Emeritus, University of California, Davis, 1975–present; professor, Department of Agricultural Economics, 1970–75.
Professor, Department of Agricultural and Resource Economics, University of California-Berkeley, 1948–70.
Editor, *American Journal of Agricultural Economics,* 1968–71.
Member, National Manpower Advisory Committee, 1967, 1963–65.
Social Science Research Council Fellowship, 1961–62.
Executive Secretary, President's Commission on Migratory Labor, 1950–51.



Varden Fuller has achieved national recognition as an authority on agricultural labor and for his contributions in agricultural policy and rural development. His work has been distinguished by its scholarly content, its objectivity, its high degree of perception with respect to emerging socioeconomic developments, and a vigorous and persistent concern for social change.

Born in Utah, Fuller received his A.B. degree in economics in 1934 and a Ph.D. degree in agricultural economics in 1939, both from the University of California, Berkeley.

Fuller's doctoral dissertation, "The Supply of Labor as a Factor in the Evolution of Farm Organization in California," attracted nationwide attention as one of the first objective analyses of agricultural labor supply. The dissertation refuted the long held belief that the growth of large-scale farming in California was due mainly to favorable soil and climatic conditions. Fuller's analysis revealed that continuing decades of historical episodes, with causes external to agricultural development, provided an abundant supply of low-opportunity laborers who could be obtained to do seasonal and casual farm tasks, and without overhead cost or significant recruitment effort. Thereby, impassively, appeared a profitable impetus to the large scale, labor-intensive farming system that subsequently was to become a source of strife and embattlement in rural California.

His subsequent work with the U.S. Department of Agriculture's Bureau of Agricultural Economics, while stationed in California, was concerned with displaced migrants from the Southern Great Plains and their assimilation in the Western States. His continued work in farm labor and rural development has pro-

duced a flow of highly regarded research writings and service to many national and regional bodies. This has included service as Executive Secretary to the President's Commission on Migratory Labor in 1950–51, membership on the National and the Western States Manpower Advisory Committees, and consultive advice to the U.S. Departments of Labor, Agriculture, and Interior. His writings and consultation contributed significantly to the final enactment of the California Agricultural Labor Act, the first of its kind in the nation. Many of Fuller's early proposals for improved management-labor relations and for worker fringe benefits and rights, which were originally received with some hostility by agricultural employers, are now regarded as efficient and effective personnel policies by leaders in California agriculture.

At the University of California, Dr. Fuller has had a distinguished career on two campuses. At Berkeley from 1948 to 1970, his courses in agricultural policy were noted for emphasis on political issues in agriculture. He was active in University affairs, serving on the Graduate Council as an associate in the Institute of Industrial Relations and on a wide variety of academic senate and administrative committees. In 1970 he transferred to Davis where he continued to teach agricultural policy and farm labor and expanded his early interest in rural community development.

He was editor of the *American Journal of Agricultural Economics*, 1968–71, and was for many years on the editorial board for *Industrial Relations*. To summarize, Dr. Fuller has enjoyed a long and productive career in the fields of agricultural labor, policy, and rural development.

Ruy Miller Paiva

1979 Fellow

Advisor and consultant to governments of Sao Paulo and Brazil on state and federal agricultural policy.
Published *Agriculture in Economic Development: Its Limitations as a Dynamic Factor*, 1979.
Long-time collaborator with the late William Nicholls in studies of Brazilian agriculture.
Federico Menezes Veiga award by EMBRAPA, the national agricultural research service of Brazil, 1977.
Awarded special honor by Brazilian Society of Agricultural Economists, 1970.
Cotton breeding researcher at Agronomic Institute, Campinas; chief of a rural economics subdivision, Agronomic Institute.

Ruy Miller Paiva is the father of modern agricultural economics in Brazil. More than any other individual he implanted this ''alien'' profession in his native land and nurtured it to fruition. He was an institution-builder before the importance of that concept was recognized. He contributed to agricultural policy analysis in his country when the policy-making process was dominated by the general economists. His original contributions to the literature in economic development are well known both at home and abroad.

Ruy Paiva was born in the state of Sao Paulo of American stock that had moved to Brazil from the American South after the Civil War. He was trained as an engineer-agronomo at the prestigious ''Luíz de Queroz'' College of Agriculture in Sao Paulo. His first employment was in the equally prestigious Agronomic Institute in Campinas, where he spent several years in cotton breeding research. The Institute sent him to Texas A&M to study plant science, but Ruy discovered and then shifted to the field of agricultural economics, and eventually earned the degree of Master of Science.

During the early 1940s, Ruy became chief of a small subdivision of rural economics in the Agronomic Institute. At that time there was no discipline of agricultural economics in Brazil, and general economics was dominated by the French school of distribution economics. Ruy developed a staff by taking engineer agronomos and giving them a self-help, in-service training program. They taught each other by working through texts, discussing journal articles and other sources, and working on practical problems.

Paiva himself became an important advisor on agricultural matters to the state government of Sao Paulo. As he gained recognition in government circles, so did his group of agricultural economists. Eventually transformed into one of the three Divisions of the State Secretariat of Agriculture, responsible for the policy research for the state government, this group became one of the strongest institutions of agricultural economic research in Latin America.

Ruy Paiva eventually gained national recognition, and represented Brazil in numerous international conferences. He helped develop the first national income accounts for Brazilian agriculture and became an advisor to the federal government on agricultural policy.

Paiva was a long-time collaborator of the late William Nicholls in a study of Brazilian agriculture. Scholars will be in debt to Paiva and Nicholls for many years to come for their careful measures of productivity, their penetrating insights, and the historical perspective in which they put their data. Dr. Paiva's own contribution to our understanding of technological dualism and his model of the "Auto-Control of Technological Change" has generated a lively and sustained debate in the Brazilian literature.

Paiva has been honored by his compatriots. In 1970, he was given a special honor by the Brazilian Society of Agricultural Economists in recognition of his pioneering contributions to agricultural economics in Brazil. In 1977, he was honored with the Frederico Menezes Veiga award by EMBRAPA, the national agricultural research service in Brazil. This award corresponds to the Browning Award in the United States, and is in recognition of a lifetime contribution to Brazilian agriculture.

Paiva has not rested on his laurels. He continues to play an active role in policy analysis in the Ministry of Planning, while remaining intellectually vigorous as well. His most recent book was published earlier this year. Titled *Agriculture in Economic Development: Its Limitations as a Dynamic Factor,* this monograph takes a comprehensive look at the factors which limit the expansion of agricultural output and which therefore limit the contributions which agriculture can make to the development of the general economy. As with much of his earlier work, the contribution of this monograph will most likely be in the provocative questions he asks. But provocative questions are the feedstock of continued intellectual endeavor.

Kenneth L. Robinson

1979 Fellow

Liberty Hyde Bailey Professor of Agricultural Economics, Cornell University.
Visiting professor or economist at University of California at Berkeley, University of Sydney, University of Hokkaido, and the International Institute of Tropical Agriculture.
Graduate Faculty Representative, Agricultural Economics, Cornell, 1968–70 and 1976–79.
Vice-President, American Agricultural Economics Association, 1966–67 and Editorial Council, *American Journal of Agricultural Economics,* 1965–67.
Elected the Professor of Merit by the senior class, College of Agriculture, Cornell, 1959.

Kenneth L. Robinson has been an important contributor to agricultural economics in the fields of agricultural policy and prices. He is unique in his ability to do high quality work and provide leadership in all functional areas: teaching, extension, and research. His work symbolizes the combination of academic excellence and breadth that most of us seek, but few attain. His intellect, humility, integrity, and a strong sense of public service combine to make him an outstanding individual and agricultural economist.

Raised on a fruit farm in the State of Washington, Robinson earned a bachelor's degree from Oregon State College (now University) and a master's degree from Cornell University. He was the first holder of the Elmhirst Fellowship for graduate study in agricultural economics at Oxford University, England, and completed a Ph.D. in economics at Harvard. He joined the faculty of the Department of Agricultural Economics at Cornell in 1951 and was elected the Liberty Hyde Bailey Professor of Agricultural Economics by the Board of Trustees of Cornell in 1977.

Professor Robinson is a superb teacher. He has taught one or two courses in every semester since becoming a Cornell faculty member, except when on sabbatic leave. He coauthored (with W. G. Tomek) the popular text, *Agricultural Product Prices,* and he has prepared a comprehensive set of readings for his undergraduate policy course. In recognition of his excellence as a teacher, Robinson was elected the Professor of Merit by the seniors of the College of Agriculture and Life Sciences in 1959.

Robinson also has given high priority to the education of farm and rural people. He has been a willing participant in countless exten-

sion meetings, and he has prepared a wide variety of extension materials on farm and food policy and economic outlook, including a contribution to the award-winning series, *Your Food*. He is widely respected both in New York state and nationally for his capacity to analyze and to present policy alternatives and their consequences. He is an especially effective public speaker who has contributed significantly to the economic comprehension of his audiences.

In addition to a distinguished career as a teacher and extension economist, Robinson has found time to direct the thesis research of dozens of graduate students and to do personal research and writing. Three of his students have received AAEA thesis awards. He is a careful analyst and writer and his own most demanding critic. These attributes are reflected in such frequently cited articles as "The Impact of Government Price and Income Programs on Income Distribution in Agriculture" and "Unstable Farm Prices: Economic Consequences and Policy Options."

He has contributed to the American Agricultural Economics Association as a vice-president and as a member of the editorial council. Robinson has been a visiting lecturer or professor at the University of California, Berkeley, the University of Sydney, Australia, and the University of Hokkaido, Japan, and he also was a visiting economist with the International Institute of Tropical Agriculture in Ibadan, Nigeria. He has served in numerous advisory capacities, including consulting with the Ford Foundation on its role in supporting research on domestic food and agricultural policy.

Robinson has made lasting contributions to the analysis of domestic and international policy issues through his teaching, research, and public service. Few in our profession can match the scope and depth of his accomplishments.

Richard A. King

1979–80 President

Fellow, American Agricultural Economics Association, 1978.
M. G. Mann Professor of Economics and Business, North Carolina State University.
Former president, Southern Agricultural Economics Association.
Visiting professor: University of Virginia, Universidad Agraria (Lima, Peru), University of California-Berkeley, North Carolina Agricultural and Technical State University, and the USDA.
Elected to Academy of Outstanding Teachers in 1967, Certificate of Merit, NCSU Chapter of Gamma Sigma Delta in 1975.
Consultant to the Research Triangle Institute, the Ford Foundation, USAID, and the Council on Wage and Price Stability.
Editorial Council, *American Journal of Agricultural Economics,* 1955–57.
Chairman: Employment Committee, 1958–61; M.S. Thesis Awards Committee, 1961–63; International Activities Committee, 1967–70, American Agricultural Economics Association.

Richard A. King holds the M. G. Mann Professorship in the Department of Economics and Business at North Carolina State University. He was born in Massachusetts and grew up in Connecticut, where he and his brother, Gordon, were active in 4-H affairs. He attended the University of Connecticut, receiving the BS degree in agricultural economics in 1946. He earned the MS degree in agricultural economics at the University of California-Berkeley in 1947. He received a Littauer Fellowship at Harvard University, completing the Master of Public Administration degree in 1948 and the Ph.D. degree in economics in 1951. He was appointed a postdoctoral fellow in political economy at the University of Chicago in 1955–56.

During the period 1944–46, King was field assistant in farm management in the Department of Agricultural Economics and Farm Management at the University of Connecticut. He served as assistant professor in that department from 1948 to 1950. In 1951, King joined the faculty at North Carolina State University as associate professor of agricultural economics engaged in teaching and research.

King was a member of the North Carolina Agricultural Mission to Peru in 1964–65 and a visiting professor in the Faculty of Social Sciences, Universidad Nacional Agraria, near Lima. He was a visiting professor in the Department of Agricultural Economics at the University of California-Berkeley in the spring

of 1969 and a member of the Food Economics Group, NEAD ESCS, U.S. Department of Agriculture in 1978. He has been a visiting lecturer at North Carolina A&T State University, at the Graduate School of Business Administration, University of Virginia, and was appointed external examiner in agricultural economics at the University of Malaya 1973–77.

Interest in the application of location theory to a variety of production, marketing, and rural community problems is reflected in King's writings. These have included a book on markets and trade with R. G. Bressler, a book on the economics of agricultural development in Peru with A. J. Coutu, and an edited collection of papers on interregional competition. He served as president of the Southern Agricultural Economics Association in 1976, and was elected a Fellow of the American Agricultural Economics Association in 1978.

He is married to the former Alfreda Smedberg from Southington, Connecticut. They have four children and live in Raleigh, North Carolina.

Choices and Consequences

Richard A. King

Choice making is at the heart of all of economics. Agricultural economists in particular—whether as classroom teachers, researchers, policy makers, or extension persons—have a long tradition emphasizing choices and consequences. However, there is always room for improvement. The annual meeting of this Association provides an opportunity to take stock, to look ahead a bit, and to find a new sense of purpose for what we do.

Economics is often defined as the study of the allocation of scarce resources among competing ends. The difficulty with this definition is that it does not focus on who is making the choices and what these choices are. We need to deal explicitly with who bears the consequences and what these consequences are. Only in a Robinson Crusoe economy do all consequences bear solely on the decision maker.

Economic theory can be an aid to choice making, but it is not an end in itself. As Hicks once said, "The place of economic theory is to be servant to applied economics." Many interesting problems cannot be attacked with an economic model that snaps from equilibrium to equilibrium as quickly as the rubber band you remove from the morning paper. The process of adjustment is at least as important as the ultimate equilibrium position, probably more important because equilibrium is never achieved. We often encounter considerable difficulty in dealing with single-valued objective functions. Public policies, however, are made in a multiple-objective setting in which equity and security considerations cannot be ignored. Attempts to draw policy recommendations directly from static, single-objective functions likely will lead to disappointment.

Economists often have a unique contribution to make in evaluating consequences. Few other specialties pay as much attention to foregone opportunities, a key element in the measurement of consequences. To say that there are externalities may be just another way of saying that our model is incomplete or that we have paid more attention to some participant groups than to others, or to some relationships than others. For these reasons it is important to identify our clientele and to understand where they come from. It is unlikely that they wish to have someone make their decisions for them but rather provide insights into the consequences to be expected from the several choices under consideration.

The remarks that follow center on some choices that are open to economists in the selection of analytical models and on the relationship between these choices and the consequences to be evaluated for individual or public clients. The topics reflect current interests of mine rather than a representative sample of pressing issues facing the profession.

This paper will deal with what I regard as serious limitations of linear expenditure models that dominate current demand literature. Applications include estimation of income elasticities, changes in elasticities over time, the relative size of income and price elasticities, and the importance of proper documentation of research results. We open with some comments on hypothesis formulation and testing.

Hypothesis Formulation and Testing

Modern computers and detailed systems models make it feasible to analyze larger sets of choices than ever before. However, such models have an insatiable appetite for input data. Time and money seldom permit estimation of all the needed underlying relationships. Earlier research that has been carefully documented can be very useful to today's model builders.

Some years ago Brandow urged agricultural economists to build their economic findings into a coherent framework. He likened the process to the trimming of a Christmas tree. My search for the exact quotation lasted well

---

President's address.

Richard A. King is M. G. Mann Professor of Economics and Business at North Carolina State University.

over a year. It finally turned up a month ago in the proceedings of a seminar held in Lincoln, Nebraska, in 1968, on the topic "Better Economic Research on the U.S. Food and Fiber Industry." Here it is:

> A lot of short-term research is just putting together something we already know to provide some meaningful answers. We need a framework within which to organize our research results. That is, we need a "Christmas tree" on which to hang the results of individual research. (1969, p. 14)

As Brandow suggested, the results of previous research ought to be carefully arranged. New work may lead to the fashioning of replacements for damaged ornaments or placing of new ornaments on parts of the tree where before there were none. Manchester urged that we take care to select a living tree to decorate, given the rapid pace of change around us.

The point to be emphasized is the need for a stock of relationships that constitute a coherent whole rather than individual ornaments to be admired. Explicit hypothesis formulation and testing is a useful device for generating these relationships. In our *Journal* last year hypotheses were explicitly stated in only five of twenty articles reporting empirical results. Popper has argued cogently that the only way for science to progress is through the formulation of refutable hypotheses (see Magee). We can never prove a hypothesis to be true, only that it can be regarded as false with a certain level of confidence.

Establishing explicit, refutable hypotheses is not sufficient. It is also important to have relevant hypotheses. Economists place undue reliance on nought for the null hypothesis. Whether this is because of the frequent use of nought in statistics courses and computer printouts or simple carelessness is open to question. In order to stir up interest in this issue, I refer to the use of nought as the null hypothesis as the "Village Idiot" hypothesis. In any case, last year in the *Journal* eighteen out of twenty studies used nought for the null hypothesis. The same was true in twenty-five of twenty-nine *American Economic Review* (*AER*) articles reviewed.

The price elasticity of demand for food will serve as an illustration. In a recent Canadian study, price elasticities for all but eight of ninety-seven food items were different from zero (Hassan and Johnson). MacGregor suggested that we test .5, 1.0, and 1.5 as alternatives to nought, providing a means for grouping foods in terms of responsiveness to price change. This is clearly a step in the right direction. More sensitive yet is the use of the elasticity estimates found in previous studies.

Immediately following Brandow's Christmas tree quotation is the following remark. "We often have not gotten significant results because we have not been explicitly framing and testing meaningful hypotheses. For example, in demand analysis we test E significantly different from zero when we should be testing E significantly different from one." It was a surprise to note that the comment was attributed to me. More than a decade later I am still selling the same old line. The argument should be more persuasive today.

What are the implications of all this? First of all, it is important that we select explicit hypotheses that have interesting implications. Second, it is seldom the case that tests of the "Village Idiot" hypothesis are particularly informative. It is not necessary to start at ground zero every time a new set of hypotheses is formulated. Third, failure to establish relevant hypotheses inhibits the growth of economic understanding.

The Question of Model Design

We are reminded by Johnston that model construction takes place at three levels: the economic model, the mathematical model, and the statistical model. Each of these three model components must be given proper weight. Selection of an appropriate economic model obviously depends on the hypotheses to be tested. Emphasis on technique—to mathematical and statistical innovation—may lead to insufficient attention being given to economic content.[1]

It may be of interest to develop an example of economic content ignored. In figure 1 we find a linear demand function $P = 10 - 2Q$ extending from the vertical price axis to the horizontal quantity axis and the corresponding marginal revenue function. Some authors draw a straight line starting at the price intercept and stopping at the quantity axis at a point one-half the distance between the origin and the quantity intercept. Question: Does

[1] In this connection, it is interesting to reread the method-methodology debates that took place at our annual meeting in 1963 and at the American Economic Association meeting the previous December.

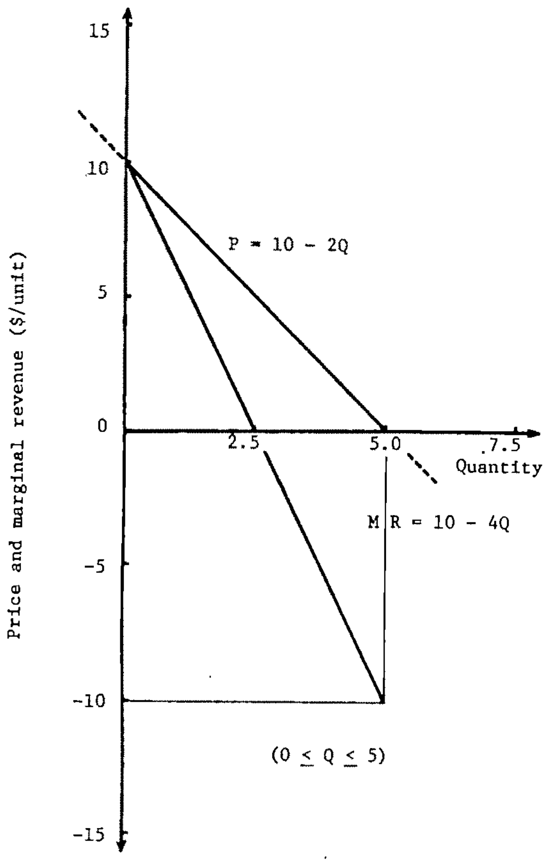

Figure 1. Marginal revenue function corresponding to linear demand function

this provide a value of marginal revenue for each Q represented on the demand function? Answer: No. Second question: Is the elasticity of demand for food larger than or smaller than 1.0? (George and King say it is $-.24$.) Where is price elasticity of demand smaller than 1? Answer: to the right of the midpoint. It follows that the food supply function intersects the food demand function three-fourths of the way down from the price intercept. If so, only the negative portion of the marginal revenue function is relevant for food policy analysis. In fact, the marginal revenue function must extend as far to the right on the quantity axis as does the demand curve.

How many of the textbooks on your shelf picture marginal revenue functions correctly? How many use negative marginal revenues when discussing choices such as livestock policy options or the effects of gasoline output changes on price and revenue? Do your students learn how to draw marginal revenue functions that include values for all relevant quantity observations? Why not find out when you meet your next class.

Let me emphasize that this is not simply a matter of accurate draftsmanship. It goes to the heart of the proper interpretation of price elasticities which for many products lie in the inelastic range. Proper specification of graphic models can be a first step to sound analysis of economic consequences.

Linear Demand Systems

Choices and consequences flowing from alternative mathematical models can best be discussed in terms of specific hypotheses. We turn first to the estimation of income elasticities from linear expenditure models. The literature on linear demand systems is very extensive but much of it is difficult to follow. The Rotterdam model, for example, is the subject of a two-volume work by Theil (1975) who has relied heavily on this model for economic forecasting. Phlips offers a very readable explanation of linear demand systems, interspersed with mathematical proofs that are heavy going for my generation of agricultural economists. Applications to food demand are reviewed by Prato and by Tomek and Robinson.

In a linear expenditure world, income elasticity can be calculated directly from marginal budget share (the slope of the expenditure function) and budget weight (expenditure divided by income), being ratio of the first to the second. With any linear expenditure function, elasticity approaches one as income increases. In the case of an expenditure function with a positive a value, elasticity approaches one from below, that is to say, it rises as income increases. For expenditure functions with a negative a value, income elasticity falls as income rises.

The relationship between expenditure functions, budget weights, and elasticities for a static two-group linear expenditure system is illustrated in figure 2. The notation follows that used by Green, Hassan, and Johnson in a very readable article in the February 1978 *Journal*. Expenditures on food and nonfood sum to total expenditure. At income levels below two nonfood expenditure is negative, offset by food expenditures that exceed total expenditure. This identifies the break between subsistence income and supernumerary income. When supernumerary income is zero,

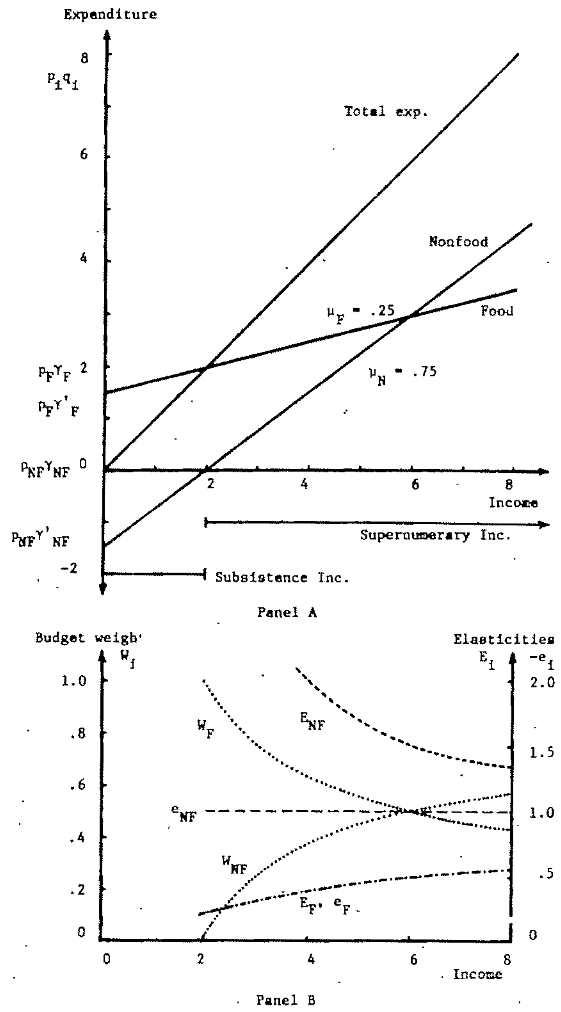

Figure 2. Expenditure functions, budget weights, and elasticities, 2-group linear expenditure system

expenditures are identified as $p_F\gamma_F$ and $p_{NF}\gamma_{NF}$. When extended back to the expenditure axis, the intercepts are $p_F\gamma'_F$ and $p_{NF}\gamma'_{NF}$.

Expenditures larger than two are allocated in fixed proportions, μ_F and μ_{NF}, of supernumerary income. The budget weight for food decreases from 1.0 while that for nonfood increases from zero as income rises from the level 2.0. Since the marginal budget shares are fixed, the income elasticity for food rises toward 1.0 and that for nonfood decreases from very large values toward 1.0 as shown in panel B of figure 2. In this simple example price elasticity for food is equal to income elasticity, but of opposite sign, while price elasticity for nonfood is constant at -1.0.

Hypotheses Concerning Income Elasticities

The article by Green, Hassan, and Johnson documents an application of linear demand systems that is useful for illustrating choices concerning hypothesis formulation. The data set comes from Canada covering the years 1947–72. Annual household expenditures were aggregated into four groups: services, nondurables, semidurables, and durables. The budget share allocated to each at average income for the period was 37¢, 34¢, 14¢, and 14¢, respectively. The marginal budget share was estimated for each group using three static linear demand systems—the Rotterdam model, the linear expenditure system (LES) and the indirect addilog system (table 1).

The question is: What is the appropriate hypothesis to test? The first possibility is that each marginal budget share is equal to zero. This hypothesis implies that the expenditure function is horizontal. Since these three mathematical models are designed so that the sum of the marginal budget shares shall equal 1, this is not a particularly informative option. A second possible hypothesis is that marginal budget share for each of the four expenditure groups is equal. That is to say, 25¢ of every additional dollar will be spent on each. A third possibility is to test, for each group, whether the marginal budget share is different from the budget share at mean income. This is a test of whether a given expenditure function passes through the origin. This third hypothesis is the appropriate test of Engel's laws concerning changes in expenditure shares.

The first hypothesis was selected, testing whether or not the marginal budget shares were different from nought. The authors concluded that this hypothesis can be rejected in every case for each of three systems. Testing the second hypothesis, that the marginal budget share for each of the four groups is equal to .25, we find that this can be rejected for two groups: services (larger than .25) and semidurables (smaller than .25). The marginal budget share for a third group, durables, is also found to be smaller than .25 as estimated by the linear expenditure system but not by the Rotterdam model.

We compare marginal budget share with budget share at mean income to test our third hypothesis. If the marginal budget share is found to be smaller than budget share at mean income, this implies that income elasticity is smaller than one and rising with income. If

Table 1. Estimated Marginal Budget Shares, Canada, 1947–72

Commodity Group	Budget Share at Mean Income	Marginal Budget Share[a] *ROT*	*LES*	*IAS*	Income Elasticity (*LES*)
Services	.374	.418*	.495*l	.469	1.32
Nondurables	.345	.229s	.237s	.252	.68
Semidurables	.143	.121*	.084*s	.085	.58
Durables	.138	.233l	.184*l	.193	1.34
	1.000	1.000	1.000	1.000	

Source: Green, Hassan, Johnson (tables 2 and 3, pp. 99 and 100).

[a] Static demand systems: Rotterdam Model (*ROT*), Linear Expenditure System (*LES*), and Indirect Addilog System (*IAS*).

Marginal Budget Share Hypotheses:

$MBS_i = 0$;
models require $\Sigma\, MBS_i = 1.00$. Rejected for all 12 coefficients.

$MBS_i = .25$;
equal response across groups. Rejection indicated by (*).

$MBS_{ij} = MBS_{ik}$;
subscripts j, k identify estimating method.

Rotterdam higher for semidurables and durables.
vs. *LES*: lower for services (*LES* = *IAS*).

Income Elasticity Hypotheses:

$E_i = 0$;
models require $\Sigma ABS_i\, E_i = 1.0$.

$MBS_{ij} = MBS_{ik}$;
implies $E_i = 1.0$; rejection of linear homogeneous expenditure function indicated by l (larger) or s (smaller).

marginal budget share is found to be larger than budget share at mean income, we know that income elasticity is larger than one and falling with income.

In the Canadian example, the LES estimates show that services and durables have marginal budget shares that are larger than budget shares at mean income. Therefore, income elasticities for services and durables are larger than one and falling with income. On the other hand, nondurables and semidurables have income elasticities that are smaller than one and rising with income. These conclusions are more relevant for evaluating choices and consequences than are tests of the hypothesis that marginal budget shares are equal to zero.

Changing Elasticities over Time

A second issue is whether price and income elasticities for food in the United States have increased or decreased over time. Several respected authors, including Breimyer, Burk, Doll, and Waugh, have argued that these elasticities have decreased over time. In a recent *Canadian Journal of Agricultural Economics* note, Hassan, Johnson, and Finley (1975) reexamined the proposition that the demand for farm products in the United States is becoming more inelastic. They suggest that this proposition has been advanced based on limited empirical evidence. Using U.S. Department of Commerce data for the period 1929–69, they find that price and income elasticities of demand for food increased over the data period. These authors used a static demand model proposed by Barten and Theil (1967) to estimate a system of equations for nine commodity groups, one of which was food.

> We find price and income elasticities less than one, as expected, but increasing over time. This result, although attributable to the fact that constant coefficients in the Theil-Barten model are being applied at increasing expenditure levels, is interesting in the sense that it suggests that this generally accepted estimation method, if applied to sample data covering a sufficiently long time period, produces results which run counter to the current thinking. (pp. 50, 52)

At least one reader was unconvinced by the evidence provided. In a comment on the Hassan-Johnson-Finley paper, deJanvry argued

> This paper is an extraordinary demonstration of the possibilities of using sophisticated mathematical economics for the purpose of public mystification. The reasoning followed is completely tautological; the models chosen imply that the stated hypothesis cannot be rejected. Yet, the mathematical complexity of the models used and their only partial explication in the article prohibit most readers from uncovering the tautology. (p. 55)

This may whet your interest in reading the remainder of the exchange for yourself. In

their reply, the authors comment that "ou paper is advanced as a basis for stimulating discussion on the question it raised" (p. 105). It does, indeed, raise questions about the relation between linear expenditure models adopted by many leading economists and consequences for policy evaluation.

Given a linear expenditure function, the relation between income, budget share, and expenditure elasticity is a mathematical identity. As we noted above, whether elasticities rise or fall as income increases is a consequence only of the intercept of the function and are readily graphed over all values of income, given the estimated expenditure function.

If an expenditure function itself rises over time, the budget share is larger and the expenditure elasticity is smaller at every level of income. The empirical problem, then, is to measure the upward shift in the function relative to the increase in income over time. Only if this upward shift is sufficiently rapid would it be possible for expenditure elasticity to fall, given that income has risen over time.

A static linear demand system has the attractive feature that the sum of expenditures on all groups equals total expenditure at every level of income. It has the unfortunate limitation that each function in the system is assumed to be unchanging over time. For this reason, the static linear demand system of Barten, Theil, and others is inappropriate for testing a hypothesis such as that considered here.

The Relation between Price and Income Elasticities

Estimates of U.S. income elasticity of demand for food reported by Hassan, Johnson, and Finley fall in the range of 0.6 to 0.8 in their two-commodity model and 0.5 to 0.8 in their nine-commodity models, well above a number of competing income elasticity estimates. That leads us to a third linear demand systems issue.

It is useful to relate income and price elasticities to one another as shown in figure 3. Income elasticity is plotted on the vertical axis and price elasticity on the horizontal axis. In quadrant II we find positive income elasticities and negative price elasticities. The 45-degree line drawn through the origin represents equal absolute values for the two.

Income elasticity for necessities is defined

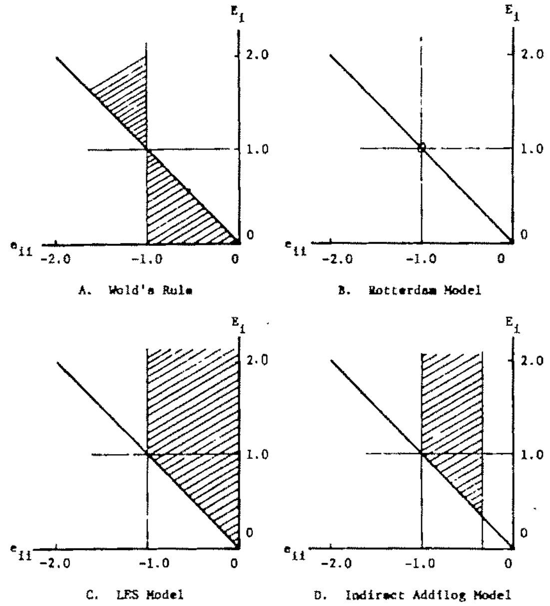

Figure 3. Income and price elasticities for selected linear expenditure models

to be smaller than 1.0 and for luxuries as larger than 1.0. The horizontal line through $E = 1.0$ shows this division. Following Tornqvist (Wold and Jureen, p. 115) we agree that price elasticity for necessities is smaller than 1.0 and luxuries is larger than 1.0. The vertical line where $e_{ii} = 1.0$ shows this division. We now have two squares in quadrant II, one for necessities and one for luxuries, and the 45-degree line dividing each in half. We are now ready to get down to business.

As a matter of fact, we are halfway through our business at this point. Formulating hypotheses that each elasticity taken individually is equal to nought leaves a lot to be desired, as Wold and Jureen demonstrated some years ago (pp. 230–4). In what follows the implications for model selection will become clearer, I trust.

Question: What is the relationship between price and income elasticities? Wold and Jureen say that "As a rule, income elasticites of necessities are smaller than their price elasticities, whereas income elasticities of luxuries are greater than their price elasticities" (p. 115). In terms of our diagram, this means that we should expect to find elasticities of necessities below the diagonal line in the square nearest the origin and to find elasticities of luxuries above the diagonal line in the upper left square (fig. 3, panel A).

Do we have empirical evidence on the rela-

tionship between price and income elasticities? Returning to the four Canadian commodity groups studied by Green, Hassan, and Johnson, we find elasticities that uniformly lie above the diagonal line (p. 100). The same is true for their nine-commodity estimates of Canadian food elasticities, whether using the Rotterdam, linear expenditure, or double-log models (p. 104). Is there something unusual about Canadian consumers in this finding that the income elasticity of food is larger than price elasticity, thereby violating Wold and Jureen's rule for necessities? Is this finding a peculiarity of the mathematical model selected?

In support of their results, Green, Hassan, and Johnson cite three other Canadian studies and three studies of U.S. food consumption, all of which report similar findings that income elasticities are larger than price elasticities (table 2). These seven sets of food demand estimates stand in direct opposition to earlier work of Brandow (1961), Waugh, and George and King who found that income elasticities were smaller than price elasticities, as expected under Wold and Jureen's rule. The implications for food policy analysis could be quite substantial if the earlier work were shown to be in error.

Can the divergence in findings be explained? Phlips (pp. 108–9) demonstrates that the Rotterdam model—in which utility is directly additive, marginal budget shares constant and income flexibility constant—requires income elasticities to be 1.0 and price elasticities −1.0 (fig. 3, panel B). According to Phlips, the reason that empirical estimates vary from these values is to be found in the finite approximation method used in the Rotterdam model estimation process. A brief explanation of why unitary income elasticities characteristic of the infinitesimal model are not obtained from the linear approximation (finite change) Rotterdam model is offered by Theil (1975, p. 105). He notes that income elasticities obtained from the Rotterdam model are not all equal to 1. However, the empirical estimates he reports are all larger than corresponding direct price elasticities.

This is not the time for detailed mathematical proofs. The general idea is quite straightforward, however. Form the ratio of income elasticity to direct price elasticity. Then investigate what is known about permissible values of that elasticity ratio, given the underlying assumptions of alternative model specifications. The formulas assembled by Green, Hassan, and Johnson are very handy for this purpose.

For values of income elasticity greater than 1.0, it is easy to show the Rotterdam model produces income elasticities that are larger than price elasticities. The elasticity ratio for income elasticities smaller than 1.0 is not as clear cut. The empirical estimates reported in the literature are found to be larger than 1.0 as well.

It can be demonstrated that the linear expenditure system (LES) requires income elasticities to be larger than price elasticities and

the latter must lie between 0 and -1.0 (fig. 3, panel C). This region is located between the area defined by Wold's Rule and the vertical axis. The indirect addilog system is more restrictive than LES, requiring that price elasticities lie between the negative of budget weight, $-w_i$, and -1.0 (fig. 3, panel D). (Note that both systems require marginal revenue to be negative for all commodities!)

The suggestion that the elasticities reported by Brandow (1961), Waugh, or George and King be selected as hypotheses to be rejected loses its appeal when one realizes that linear expenditure systems cannot possibly produce elasticity estimates comparable to the earlier values since these lie in the elasticity space defined by Wold's Rule, a region that is unattainable using linear expenditure models.

The consequences that follow when researchers choose among alternative mathematical models must be considered in terms of theoretical properties and uses to be made of the findings. Given my views concerning the reasonable sign for cross-price elasticities between food and other budget items, the damage caused by the requirement that income elasticities be larger than price elasticities is sufficiently great to make static linear demand systems completely unusable for food policy evaluation purposes.

After listening to these arguments against the use of linear expenditure systems, a colleague brought to my attention a line from a book by Röpke. "Only too often does mathematical economics resemble the children's game of hiding Easter eggs, great jubilation breaking out when the eggs are found precisely where they were hidden" (p. 249).

Documentation

Proper documentation of the data base can lead to wider acceptance of results and greater user confidence. It is my view that inadequate summary statistics such as means, ranges, and measures of variability are being provided in current economic literature. A review of quantitative findings reported in 1,052 pages of the 1978 *Journal* and 994 pages of *AER* in the same year confirmed my suspicions. In the *Journal* only four of nineteen articles provided mean values. In the *AER* only five of twenty-nine authors provided this information. In none of the nineteen *Journal* articles was the range of each variable provided and none provided information on variability. (A note by Smith and Snyder provided both means and ranges.) In the *AER*, two of twenty-nine articles provided ranges for a single variable while two provided standard deviations.

Last fall I was interested in providing my students with real world examples with which to practice plotting demand curves and calculating marginal revenue functions. Not a single usable function is to be found in the two journal volumes mentioned above. In a study summarizing demand relationships for California tree fruits, grapes, and nuts some 176 demand relationships are provided (Nuckton). However, I found that students would be unable to plot any of the 176 equations unless I made some assumptions as to appropriate values for each of the independent variables. Correspondence with the author indicated that mean values also went unreported in nearly all the studies that were reviewed. It may be too costly to use space in a *Journal* article to reproduce a data set. Information on means, ranges, and variability, however, would occupy very little space and in many cases could be included with the definition of variables that is customarily provided.

Reproducing a data set is not without its dangers. Some years ago we published a study of the demand for green peppers in which the data set appeared in an appendix. This data set provided one of Hildreth's graduate students an opportunity to demonstrate the folly of assembling the model as we had done. In a note of apology warning me of the forthcoming study, Hildreth commented that ours was the only published data set that could be found which was suitable for demonstrating their methodological innovation! In spite of such dangers it would be of great use in relating choices to consequences to have a complete data set provided whenever that is feasible, or comprehensive summary statistics reported when it is not.

A second set of data issues relates to accuracy, precision, and relevance. Three types of misplaced precision are to be avoided. The first is unwarranted precision. This occurs when the number of reported digits is greater than the accuracy of the data base. Numerous examples might be cited where the mean of a series or the a-value in a regression equation is reported with a larger number of digits than are to be found in the original data set.

The second type of misplaced precision is irrelevance. Irrelevant precision is typified by

t-ratios which are reported with four decimal places.

Finally, we come to unusable precision, typified by variation in the number of significant digits among the coefficients reported in a regression equation. Unusable precision was found in 90% of the articles reporting quantitative findings in the *Journal* and *AER* last year. In the *Journal* only one article reported the same number of significant digits for each coefficient (that was a study by Rausser and Stonehouse in which they used scientific notation). Articles in which the smallest number of significant digits was one reported three, four, and five significant digits for other coefficients. In articles where the smallest number of significant digits was two, the largest number ranged from four to seven. In the *AER* the results were similar. In only three of the twenty-nine *AER* articles examined were the significant digits uniform across coefficients. In fact, in two articles no significant digits were provided for at least one coefficient.

These findings I interpret as confusion between holding the number of decimal places constant and providing a uniform level of precision for all coefficients. In an attempt to provide neat summary tables we have opted for lining up decimal places rather than providing equal precision. Clearly the option taken by Rausser and Stonehouse should be used more widely. Scientific notation avoids the publication of long strings of irrelevant zeros and unusable digits.

To summarize this point, incomplete and inappropriate documentation limits the usefulness of findings for those who are interested in making choices based on quantitative estimates. For classroom teachers it is clearly time to go back to the basics, providing greater emphasis on summary statistics and their accuracy, precision, and relevance.

Change Brings New Choices

Agricultural economists are particularly open to change. Change can be seen all around us. The opening of the Erie Canal brought dramatic change to the hill farmers of New England whose homesites are now marked only by old cellar holes and ancient lilacs. The irrigated fields of the Central Valley of California once produced hides and tallow for Eastern markets while the meat was left behind to rot for lack of refrigerated transport. Interstate highways through the Appalachian mountain range have brought new market links between the Midwest and Southeast and opened new opportunities for many isolated communities.

Change brings new choices with new consequences to be weighed. But, to borrow Solow's illustration, there is always the danger that we may devote our efforts to rearranging the deck chairs on the Titantic. What do agricultural economists do best? Where does our comparative advantage lie?

Leontief had some observations on this question that bear listening to again.

> An exceptional example of a healthy balance between theoretical and empirical analysis and of the readiness of professional economists to cooperate with experts in the neighboring disciplines is offered by Agricultural Economics as it developed in this country over the last fifty years. . . . Close collaboration with agronomists provides agricultural economists with direct access to information of a technological kind. . . . Preoccupation with the standard of living of the rural population has led agricultural economists into collaboration with home economists and sociologists, that is, with social scientists of the "softer" kind. While centering their interest on only one part of the economic system, agricultural economists demonstrated the effectiveness of a systematic combination of theoretical approach with detailed factual analysis. (p. 5)

Can we maintain that "healthy balance" between theoretical and the empirical, reflect a "readiness to cooperate" with neighboring disciplines, and continue our "preoccupation with the standard of living of the rural population"? Surely we can.

Many of the choices in the 1980s will be those of the 1970s, perhaps with a new sense of urgency. What is the appropriate mix of private and public goods? How can a balance be found between goods and services for individuals and communities and those for military preparedness? What kind of an environment will we choose as measured by access to clean air, fresh water, open spaces, and sea coast? How much health shall be produced and how? How much economic security can we afford and for whom?

These questions emphasize trade-offs, trade-offs among region, socioeconomic class, time, and nation. Choices will be made through political processes and by firms and households in the light of whatever economic intelligence happens to be available. These days in Pullman offer an opportunity to gain new insights into choices and consequences

that are of particular interest to each of us and to our clientele. The potential benefits from new information flows, new models for evaluation and interpretation, and new communication methods between analyst and decision maker have never been greater.

Working with Other Disciplines

Earl R. Swanson

In this paper the term "discipline" simply refers to a specialized field of knowledge. Each discipline thus defined usually has a professional association and at least one journal. Equating a discipline to a profession is not completely satisfactory for all purposes, but it is consistent with common usage and convenient for the task at hand. Within a university context, a discipline corresponds approximately to an academic department, and disciplines develop when both faculty and administration come to recognize reasonably distinct areas of inquiry.

It is important to recognize that each discipline is usually composed of a set of narrower specializations and that the comprehensiveness of the discipline has at least three properties. First, there is a common conceptual model, shared to some extent by individual members of the discipline. Second, there is also a set of phenomena common to the various specializations within the discipline. Finally, it is a collection of individuals with varying specializations, and the breadth of the discipline is rarely embodied within any one scholar (Campbell, pp. 328–31). Cohesiveness of the discipline is achieved through the overlapping of the multiple narrow specialities which facilitates communication to a greater degree than is possible between disciplines.

Agricultural economists have a long tradition of relationships with other disciplines. These relationships have taken a variety of forms. For many of us, our undergraduate education included a substantial component of the natural sciences, together with an occasional sampling of the social sciences. In graduate study the contact with other disciplines frequently focuses on the so-called tools that can be used by the agricultural economist. These contacts are absorbed into our cluster of specialties and become a part of our collective professional competence. In our diverse professional activities we characteristically use data assembled by, and to some degree concepts borrowed from, other disciplines. But our profession also has a history of contributing to other disciplines as well as benefiting from them. Although it is not always apparent to our colleagues in other agricultural disciplines, our influence as an integrating discipline for the applied natural sciences in agriculture has been pervasive. The assessment of this potential by Black in 1925 was essentially accurate. Just after the passage of the Purnell Act, in a talk to the Association of Land Grant Colleges and State Universities, Black emphasized the relevance of production economics to experiment stations:

> If I had time to do it, I could show that most of the problems of an economic nature which confront our (experiment) stations, require a combination of economics and natural science analysis. All problems of the relation of input to output are of this nature, all fertilizer input studies, many feeding experiments, and cultivation experiments. (p. 662)

Our record of joint research with the natural sciences and with engineering is well documented in Association surveys of agricultural economics literature. For example, French has reviewed the marketing work that has been done with engineers and other specialists. Jensen and Woodworth have reviewed the parallel work of production economists with the biological scientists, in particular with those in agronomy and animal science. Johnson and Rausser have inventoried and evaluated simulation models, a number of which have dealt with data from natural science disciplines.

Relating of agricultural economics in a systematic way to the social sciences other than economics does not have a parallel record. For at least two decades, a recurring theme of presidential addresses, invited papers, and Fellow's lectures at our annual meetings has been the admonition to borrow from or work with other disciplines, usually other social sciences, in a problem-solving mode. These

Fellow's Address.

Earl R. Swanson is a professor of agricultural economics, University of Illinois.

The author is indebted to C. B. Baker, F. C. Fliegel, and R. J. Hildreth for comments on an early draft. Responsibility for the final version remains with the author.

speakers gave advice in different forms, but the general direction, if not the implications, of the messages is clear.

AAEA Presidents Express Need for Interdisciplinary Approach

Well over half of the presidential addresses in the last twenty years have at least mentioned the need to relate to other disciplines. Only a sample follows. Allin in 1961 told us that in order to keep farm economics relevant to its dominant purpose of improvement of the relative economic position of farm people, our intellectual interest must not be bound by blind devotion to any single social science discipline (p. 1018). In his 1967 presidential address, Bishop discussed the urbanization of rural America and noted, "While we must lean even more heavily upon economics as our parent discipline . . . , we must also become more knowledgeable about the tools of the sociologist and political scientist" (p. 1007). Breimyer also pointed out the need to borrow from sociology and political science to better understand the emerging economic structure (p. 1102).

After identifying research needs and problems, Hathaway in 1969 indicated that, "if the needed research is to be done well, most of it must be interdisciplinary, involving technical as well as economic relations and other social sciences" (p. 1021). In the 1971 invited lecture, Johnson developed in some detail the rationale for working with other disciplines. Among the incentives for such effort, he recommended that our association join other associations in sponsoring an annual award for "distinguished public administration of issue-oriented problem-solving research programs" (pp. 737–38). In his 1972 presidential address, "Economics and the Quality of Life," Castle commented that supporting multidisciplinary endeavors was popular, but that the best way to organize for such integration with simultaneous disciplinary penetration was unclear (p. 729). The need for contributions from other disciplines in rural development was pointed out by Tefertiller in 1973 (p.771), and Nielson, reflecting his experience as an experiment station director, advised in 1974: "We ought to do more to serve other disciplines and more work on disciplinary teams . . . . Frequently the biggest contribution of our profession has been to help synthesize results from other disciplines" (p. 870). Bonnen's 1975 presidential address considered needed improvements in the design of agricultural information systems. He noted that if such a system is to solve problems, it will inevitably combine and use different fields of knowledge (p. 760). As an incentive for working with other disciplines in the public policy area, Farrell suggested in his 1976 presidential address that an Association award be given for outstanding contributions within the profession to the advancement of public understanding of major policy issues, with preference to contributions that are multiunit or multidisciplinary (p. 792).

Let us conclude this sample of advice on relating to other disciplines with Bottum's counsel given in an agricultural metaphor. In his Fellow's address in 1975, "Policy Formation and the Economist," he indicated in a summary statement that we should ". . . split some new rails and spend a little less time sandpapering the old and we will have a bigger pasture. And, let's put in a gate so some of the other pertinent disciplines can join us in this enlarged pasture" (pp. 764–65).

At this point we conjecture that these numerous prescriptions reflect not only the increasing complexity of problems addressed by agricultural economists but also the trend, accentuated in the post-World War II period, toward recognizing economics as the parent discipline of agricultural economics. As Boulding noted in 1950, the success of what was then called the Ames School in agricultural economics was attributed to the discovery that there was no such subject as agricultural economics—that there was only economics applied to agriculture (p. vii). This distinction implies that we do not have our own cluster of specialties but that we are a part of another cluster—economics. In commenting on this trend, last year Paarlberg observed: "The change in our discipline has been difficult for the traditionalists . . . some of our painfully acquired skills become obsolete. But, all members of the agricultural establishment have, to a degree, in their actions if not in their words, accommodated themselves to the change" (p. 774).

Some evidence that agricultural economics has retained its distinction from economics may be found in the 1978 presidential address of Koopmans before the American Economic Association. He pointed out the need for economists to work with other disciplines in

collaborative efforts but, noted that, "to economists (collaboration) is a new challenge and a new frontier" (p. 12). For agricultural economists, and to some extent for specialists in labor economics, finance, business administration, and other areas related to economics, it is an old frontier, but nevertheless one that needs our most careful attention.

A fundamental question has been raised: Who should integrate the results of research in the separate disciplines? Should it be the specialists working together in the research process, should it be the decision maker, or someone in between? Clearly, this question cannot be answered in the abstract, but the weight of professional advice has been to shift emphasis to additional integration in the research process itself.

Although difficult to document, there has been some response to the call for interdisciplinary research articulated by Association speakers. The fact that reports from cooperative studies with other disciplines do not often appear in the *American Journal of Agricultural Economics* indicates in part that the research output from such projects does not lend itself easily to journal reporting, but also that such studies are not perceived to be in the mainstream of our profession. An informal survey of the *Journal* over the last twenty years indicates that virtually the only kind of joint research reported is that with natural scientists within colleges of agriculture.

In the remainder of this paper the focus is on the process of research with other disciplines. An improved understanding of the process should assist us to allocate our research resources and, for that fraction devoted to working with other disciplines, to improve our effectiveness.

The Nature of Cross-Disciplinary Research

Before proceeding to analyze the nature of cross-disciplinary research, we distinguish the classes of research activity along a continuum. These classes range from unidisciplinary to multidisciplinary to interdisciplinary to transdisciplinary, depending on the degree of integration, a concept introduced by Rossini et al. Note that this classification refers to a particular research activity or project and not to other relationships among the disciplines. Castle (1970) has provided a more comprehensive analysis of cross-disciplinary relationships dealing with implications for university organization. Implicit in the concept of integration is an anticipated trade-off between comprehensiveness and depth of analysis. A narrow disciplinary mix may lead to analytical depth at the expense of comprehensiveness. This balance can only be judged with respect to the objective of the particular research effort. Research output in the form of a published report is the most easily available evidence for evaluating the degree of integration.

Editorial integration in research output is the lowest level of integration. It results in a report or a set of disciplinary reports on the same topic edited without accounting for differences in terminology and concepts among the disciplines. While the report or reports may share an introduction and a conclusion, these sections are not of an integrative nature and may simply describe the history of the research project. Improvement in editorial treatment may involve consistent use of terminology throughout the study and the avoidance of isolated vocabularies. The report(s) that result from editorial integration may be considered multidisciplinary, and in the nature of a patchwork quilt. On the other hand, interdisciplinary research ideally would yield a seamless garment.

Interdisciplinary research is characterized by systemic integration. This implies that there is a common view or representation which permeates and dominates the entire research effort. Such integration may be achieved by the use of a formal model, but this should not be viewed as a stringent requirement. However, evidence of strong integrative links among the various parts of the report is required.

Finally, the upper limit of our continuum, a theoretically complete integration, has been termed transdisciplinary (Rossini et al., p. 6). This classification implies that we transcend our individual skills and disciplines and that we work with other disciplines to create a new common cognitive map of the problem. This classification remains a theoretical ideal for any study of more than a very limited scope.

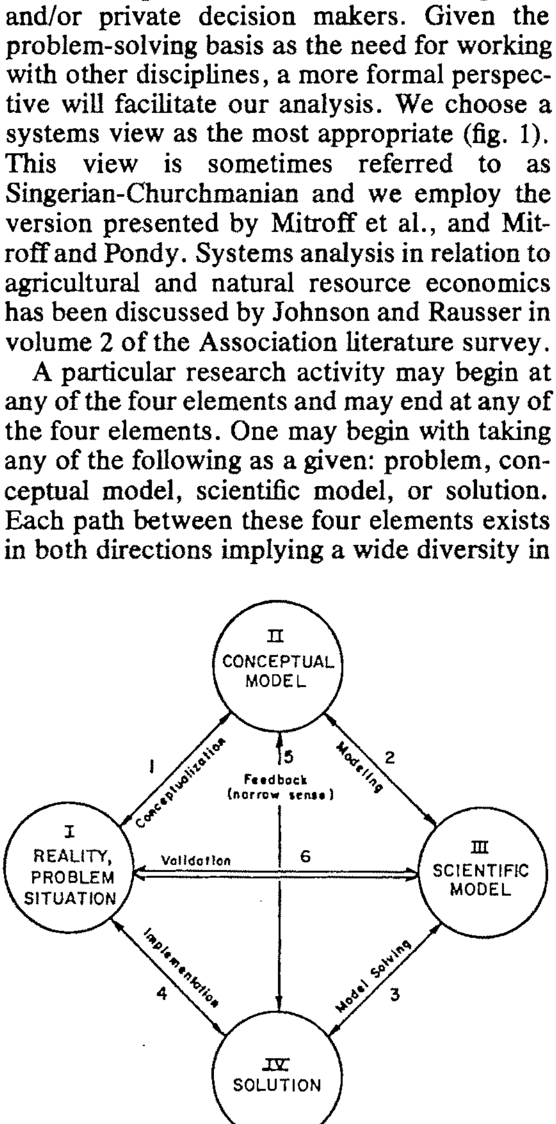
Obstacles to Cross-Disciplinary Research

If we wish to achieve the interdisciplinary or systemic level of integration in a research effort, what obstacles are to be overcome? Two related considerations are involved. The first

consists of the knowledge or epistemological problems and the second, of social elements (Petrie). The high level of interaction between these two elements implies that we find it difficult to separate them even for exposition. In this section we discuss the knowledge aspects of cross-disciplinary research.

The admonitions that we have received to work with other disciplines have been linked with problem solving, implying that the research output should be useful to public and/or private decision makers. Given the problem-solving basis as the need for working with other disciplines, a more formal perspective will facilitate our analysis. We choose a systems view as the most appropriate (fig. 1). This view is sometimes referred to as Singerian-Churchmanian and we employ the version presented by Mitroff et al., and Mitroff and Pondy. Systems analysis in relation to agricultural and natural resource economics has been discussed by Johnson and Rausser in volume 2 of the Association literature survey.

A particular research activity may begin at any of the four elements and may end at any of the four elements. One may begin with taking any of the following as a given: problem, conceptual model, scientific model, or solution. Each path between these four elements exists in both directions implying a wide diversity in



Source: Mitroff et al. p. 48.
Note: Figure 1 is reproduced with the kind permission of *INTERFACES*, published by the Institute of Management Sciences and the Operations Research Society of America.

Figure 1. A systems view of problem solving

the individual processes involved in problem solving. In fact, even the simple system of figure 1 has 3,555 total sub-systems that can be formed by considering all possible ways of combining two, three, and four elements. This number also includes the directionality of the connections between the four elements.

Although not every cross-disciplinary inquiry starts with element I, reality or the problem situation, it is appropriate for our discussion to start at that point. The first phase then requires formulation of the conceptual model. In some cases the conceptual model may be formal, a more likely occurrence in economics and the natural sciences than in the other social sciences. The conceptualization process defines and bounds the problem in broad terms, the variables that are to be considered, and the level of aggregation. Development of the scientific or formal model (III) is the next step. The modeling process includes the translation of the conceptual model into relationships which are then given greater empirical content. This is followed by the solution (IV) and, finally, implementation brings us back to an impact on the initial problem situation (I). For completeness, note that paths also exist for model validation, between I and III, and for feedback interactions between II and IV. Certainly, the ideal problem-solving loop I-II-III-IV-I is not often found in individual projects; more often a subset describes the activity.

It is tempting, and only somewhat diversionary, to classify the research efforts of agricultural economists operating in their single disciplinary mode through use of this diagram. The required skills vary among the elements and this variation represents another dimension of specialization among persons within our profession. Very few members of our profession have seriously worked in all four elements.

Among the many loops let us consider two illustrative ones, II-III-IV-II and I-II-IV-I. Those agricultural economists who follow loop II-III-IV-II are concerned primarily with the activities of modeling and model-solving. Improved solutions to more complex models with feedback in the narrow sense (fig. 1) and no immediate interest in implementation characterizes this loop. Many of our colleagues in the natural sciences operate with this loop and acknowledge this loop as the only valid form of scientific activity.

Another loop used in agricultural economics is I-II-IV-I. This loop omits element III (Scientific Model). There is confusion in this loop between conceptualization and modeling and an attempt to substitute a conceptual model for a scientific model. No matter how rich in detail the conceptual model might be, it does not, in my judgment, substitute for a validated scientific model. Omission of the scientific model implies the loss of the opportunity to develop the logical structure of the conceptual model in a systematic way and to perform the important validation process. Thus the approach implied by the I-II-IV-I loop weakens any potential implementation.

We now return to the knowledge aspects of cross-disciplinary research. In terms of our system view (fig. 1) it is necessary for participants to communicate with other, ideally, in each of the four elements—problem, conceptual model, scientific model, and solution. Perhaps the most important communication takes place with respect to the conceptual model. Each specialist can be expected to bring his own paradigm (Kuhn, Maruyama, and Johnson and Rausser) into play as he conceptualizes the problem. The degree to which core members of the research team share these paradigms is crucial in determining the level of integration in the final report.

As an example, let us consider three so-called pure paradigms (Maruyama): (*a*) unidirectional-causal paradigm, (*b*) random-process paradigm, and (*c*) mutual-causal paradigm.

There are, of course, mixtures and overlaps between and among these three paradigms as well as between these and many other paradigms. For example, the combination of *a* and *b* may describe the classical approach to production function analysis, with multiple regression forming a part of the scientific model. Suppose that an agricultural economist is using this *a-b* combination paradigm and that he is working with a biological scientist who subscribes to paradigm *c*, a mutual-causal paradigm, as a description of the system under study. Thus the biological research worker looks for feedback loops in the system and for self-cancellation or self-reinforcement based on concepts of homeostasis. Although the economist may be familiar with related concepts from general equilibrium theory, the concept of the production function from the static theory of the firm does not carry him very far toward achieving a common view with the biologist. Until they have at least moderate agreement on the paradigm, their prospects for successful interdisciplinary research are limited.

The concepts and terms from statistics may form a useful communication device. Discussion of the design of the experiment or the survey in the development of the scientific model will often lead to an improved understanding of the difference in paradigms originating in the disciplines of the participants.

Recent developments in the field of sociobiology have helped identification of certain concepts common to economics and biology (Ghiselin and Hirshleifer). Scarcity, competition, equilibrium, and specialization play similar roles in biological and economic systems. There are also certain terminological pairs—mutation/innovation, optimizing/adapting, and evolution/progress, which are common to the fields. In a sense, economics can be viewed as a subfield of sociobiology (Ghiselin). In the other direction, Becker has modified economic theory to provide an explanation for altruism among persons which parallels a biological explanation applicable to other species.

A few examples from the social sciences other than economics will indicate that there are also some common starting points for conceptualization of a given problem with these disciplines. The simple unidirection causal paradigm corresponds to a social organization that is hierarchical, while the mutual-causal paradigm implies a nonhierarchical social organization with considerable interaction among members. The equilibrium concept, a member of the mutual-causal paradigm, is also present in law (Timmons). The transaction is the unit of study in law, and the relative stability of the system's behavior is an area of inquiry. Although the more traditional political science concepts do not appear to be highly structured, they do appear to be contextual in the sense that they may utilize some variants of the mutual-causal paradigm with an embodied economics component (Nagel).

We should not underestimate the difficulty of achieving mutual understanding of paradigms between disciplines. Rossini et al. report that in a number of interdisciplinary studies, economics was the most difficult for participants from other disciplines to under-

stand. The jargon, methodological preoccupations, and world view frequently proved difficult for noneconomist research collaborators.

Without at least a minimum of the sharing of paradigms among the specialists involved in a joint research effort, the frustrations from communication are going to be very high. In particular, if the communicating parties are unaware that they are using different paradigms and are aware only of differences in vocabulary or language, each party will view the communication difficulty as resulting from the other specialist's lack of intelligence, deceptiveness, or insincerity. This leads us to the second aspect of research with other disciplines, the social process.

Organizational Alternatives

Before treating organizational alternatives for the research team itself, consideration should be given to the institutional setting (Petrie). If the research is to be both problem-solving and interdisciplinary, an academic institution is not likely to provide an ideal environment. The linking of research with graduate education leads to emphasis on loop II-III-IV-II in figure 1 which develops skills in conceptualization, modeling, and model solution, rather than the implementation phase associated with decisions made in the public and private sectors.

In order to encourage cooperative research among disciplines, a number of academic institutions have formed units outside the usual departmental pattern (Ellis, and Capener and Young). For example, special institutes have been established to study the energy problem, the environmental problem, and so forth. Less formal structures such as committees have also been employed, especially within agricultural experiment stations. The problems of a reward and incentive system that follows disciplinary lines and the attendant risks for younger staff members who participate in such interdisciplinary undertakings, have been spelled out elsewhere; in particular, in the papers by Johnson in 1971 and by Koopmans (p. 13). The most successful interdisciplinary research projects at academic institutions appear to be those that have been externally funded and that have a rather limited group, with no more than four or five disciplines represented. The institutional environment for the research team must be one that permits a substantial amount of start-up time and that has flexible hiring arrangements. It is important that institutions contemplating the support of interdisciplinary work understand its somewhat peculiar nature.

It is unlikely that a research team deliberately selects in advance the intellectual and social components that determine the organizational pattern. It is more likely that the organization evolves into a stable pattern by trial and error. Nevertheless, it is useful to identify four types of approaches to interdisciplinary research and briefly to discuss their strengths and weaknesses (Rossini et al.). These refer principally to teams containing from three to five core disciplines.

Common Group Learning

The research problem is defined and bounded by group decisions. Based on the interests and competencies of the team members, a division of effort is decided upon. Preliminary analyses are prepared and each member reads the analysis of every other member. After discussion, reports are rewritten by members who are not specialists in the area (fig. 2A). The final report is the common intellectual property of the group. This approach clearly limits the disciplinary penetration. In terms of our systems view (fig. 1), the interactions take place primarily between the problem (I) and the solution (IV).

Negotiation among Experts

The beginning of this approach is similar to common group learning, with assignments of parts to disciplinary specialists. Attempts are made to bring the full power of the appropriate discipline to bear on its assigned part, and integration takes place by negotiation (fig. 2B). Negotiation focuses only on the overlaps and linkages among the separate draft reports. The next iteration, done by the initial authors, takes into account the results of the negotiation. Nonexperts do not rewrite the separate sections of the final report. Many agricultural economists may be uncomfortable with this approach, especially when economics is competing with other disciplines as an integrator. Committees of the National Academy of Sciences and task forces of the Council for Agricultural Science and Technology often tend to follow this pattern in the preparation of assessment and state-of-the-art reports.

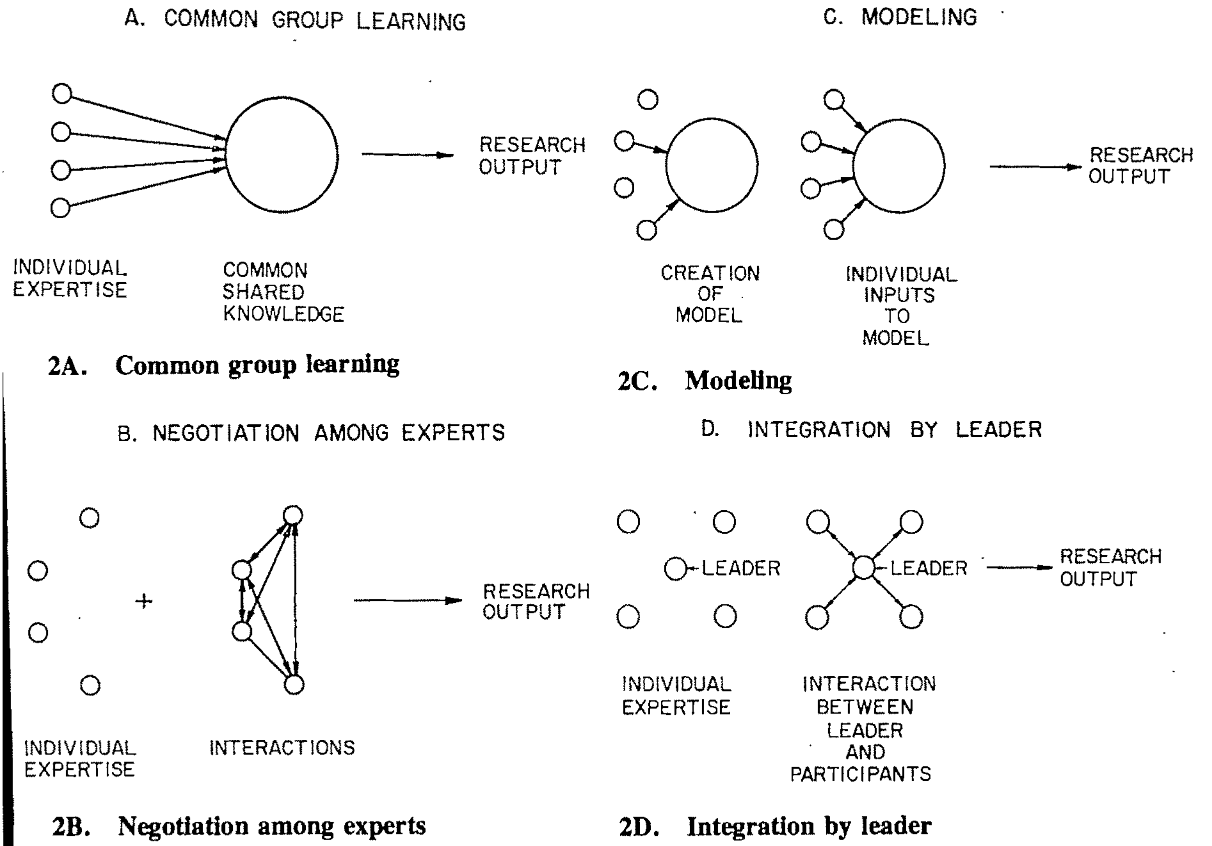


Figure 2. Organizational frameworks for cross-disciplinary research

Scientific Modeling

A formal model may serve a key integrative role. All members need not participate in model construction (fig. 2C), but ideally all should contribute data. Models often tend to narrow the research focus, but they also encourage systematic collection and analysis of data. This approach works best when closely related disciplines are involved in solving an easily defined problem. For public policy-related studies, implementation usually requires a framework broader than the model alone. Finally, the model may have the advantage of depersonalizing the process of getting input from each participant.

Integration by Leader

The problem is divided and allocated by the leader on the basis of expertise and interests of participants. The only interaction occurs between the leader and the individual team members (fig. 2D). The communication pattern is that of hub and spokes, an efficient one for communicating simple tasks in small groups (Bavelas, and Guetzow and Simon). In the other three approaches, common group learning, negotiation among experts, and modeling, the communication network needs to provide direct channels between most of the individual participants.

Each of these four ideal models implies a somewhat different kind of leadership style. Consider the following five leadership styles (Robinson and Clifford): (*a*) activator, (*b*) controller, (*c*) martyr, (*d*) cavalier, and (*e*) abdicator.

The activator uses a democratic-facilitating type of leadership in which the style is group-centered. He is active and flexible in structuring group behavior and recognizes that everyone in the group has some skill or knowledge which exceeds his own. The controller's pattern is described as autocratic or authoritarian with rigid behavior that strengthens his position in the group. The martyr is passive and hopes that the participants

will feel pity for him and perform their assigned tasks. The cavalier is permissive and, although he may entertain the participants, he cannot structure group behavior. The abdicator assumes little responsibility and behaves passively.

In the Rossini study, it was not surprising that the activator style of leadership appeared to be the most effective in terms of achieving integration in cross-disciplinary research. The second most effective was the autocratic or controller style, while the lowest level of integration was achieved with nondirective and permissive leadership styles (martyr, cavalier, and abdicator).

For the common group learning and negotiation among experts approaches, it is clear that the activator is likely to be most effective. The use of a scientific modeling approach should at least be initiated with activator leadership, but may require a shift to the controller pattern in the final stages.

The success of the integration-by-leader approach depends very much on the leader. The routine demands of administering the project may be such that, even in the unlikely event that the leader is an expert in all the separate disciplines involved, the integration will be weak and the research output multidisciplinary rather than interdisciplinary.

Four Examples

The type of research team organization that is used for a given project usually cannot be determined by reading the report of the results; participants in the research process are the only source of information. Consequently, in order to illustrate the use of the classifications and concepts presented, I now draw on some research efforts in which I have recently participated.

In the early 1970s, the college of agriculture at the University of Illinois received a grant of approximately $600,000 from the Rockefeller Foundation for the project, "Nitrogen as an Environmental Quality Factor." The funds were allocated largely on a departmental or disciplinary basis, with five major groups participating: rural sociologists, agricultural economists, agricultural engineers, agronomists, and veterinary scientists. The common theme of nitrogen and the environment was the connecting link in the five separate efforts (Deeb and Sloan, Dickey and Lembke, Swanson, Taylor, and van Blokland, van Es and Sofranko, and Welch). A book in preparation is being written by a single author. This study corresponds to our multidisciplinary category because the separate disciplines approached a common problem, and the integration was at the editorial level, not at the conceptual level. Thus, the grant provided additional funds for departments to do research on the topic but did not necessarily provide the ingredients to integrate the results. The members of the team met to discuss one another's progress only occasionally. Although useful and meaningful work came out of the project, it cannot qualify for the title "interdisciplinary."

A second project also had an environmental orientation. The project, "Soil Loss from Illinois Farms: Economic Analysis of Productivity Loss and Sediment Damage," was funded at a level of $122,000 by the Illinois Institute of Environmental Quality, a state organization. Six watersheds were studied (Guntermann, et al.). The organizational mode featured economics as the integrating discipline, and a formal model provided the scheme for integration. This organization is an example of the modeling approach discussed above. Contributing specialists included an agronomist, a hydrologist, an agricultural economist, and a finance analyst. All persons were hired to work in the department of agricultural economics, an arrangement that clarified administrative allegiance. Early establishment of a satisfactory economic model permitted the contributors to identify their own objectives and contribution to the project. The impact of the results on public policy can only be identified indirectly. A member of the Illinois Pollution Control Board mentioned that it would have been helpful if every important policy decision made by the board could have had a comparable base of information. The usefulness of the report was, in part, a result of the interdisciplinary character of the project, even though economics was the only social science discipline.

A third project, sponsored by National Science Foundation-Research Applied to National Needs, was an assessment of hail suppression technology (Changnon et al. and Farhar et al.). The eighteen-month project, carried out under a grant of $260,000, involved agricultural economists and other social scientists including sociologists, a political scientist, and a lawyer. Natural scientists included

those from atmospheric science, one of whom served as team leader, and an environmental scientist. The organizational approach was a combination of negotiation among experts and scientific modeling. Although the central economic analysis used the usual economic concepts implicit in a national spatial-equilibrium model and the theory of the firm at the individual farm level, these concepts were modified in the course of the project. The modifications represented important inputs from sociologists and the lawyer as well as others. In the preparation of the conclusions and policy recommendations, the political scientist and the lawyer had important contributions to make. Among other things, the study recommended that funds for research and development of hail suppression either be substantially increased or eliminated. As a result of the study, National Science Foundation has now discontinued the $5 million line in their budget for hail suppression research. In addition, many of the recommendations have found their way into statements of national policy (report to U.S. Secretary of Commerce from the Weather Modification Advisory Board 1978). The success in terms of policy impact was due, in a large measure, to the interdisciplinary nature of the study.

A final example is the National Defense University Long-Range Climate Project. This project proceeded in three phases. First, climatologists assessed global temperature and precipitation changes to the year 2000 for different major crop-producing areas of the world. Then, five climate scenarios were constructed. The second phase produced estimates of yield responses to weather variables made by agronomists. This permitted an assessment of the yield consequences of each climate scenario. The final phase was the input of this information into the U.S. Department of Agriculture's grain-oilseed-livestock (GOL) model to determine the impact of the five climate scenarios on location of crop production, international trade, and crop prices. Although the GOL model provided the integrating framework, the climatologists were unaware, or had only very hazy conceptions of how the GOL model operated when they made their assessments. Similarly, the agronomists were not aware of the various aspects of the GOL model when they made their crop response predictions. Nevertheless, the GOL model served as an integrating device for the total project. Organizationally, this project represents a mix of scientific modeling and integration by leader.

Conclusion

To sum up, let us first consider those research efforts in which agricultural economists work with natural sciences and engineering. In my judgment, the modeling approach or integration by leader approach are more likely to provide a satisfactory environment in which agricultural economists may contribute. However, one should not presume that what seems to be a natural integrative role for agricultural economists will be automatically perceived as such by natural scientists and engineers. These disciplines also have competing macro models (ecosystems, energy accounting systems, etc.) with integrative potential and some melding of concepts may be required.

If social scientists, in addition to agricultural economists, are included in the research team, agricultural economists may again find their contribution greater under the modeling approach with participation, as far as possible, of all team members in the modeling effort. The economic modeling may serve to integrate the important elements of the natural sciences and engineering. In many contexts, however, there is an integrating task that is beyond economics. If the research has an implementation objective such as the drafting of legislation, it is important for those responsible for that part of the project to at least be somewhat familiar with the modeling process.

An alternative approach appealing to some agricultural economists in joint research involving other social scientists is negotiation among experts. Given the preferences and skills of the individuals involved and a limited time frame, this approach may provide a better organizational structure for interdisciplinary research than one involving modeling.

In this paper an attempt has been made to describe research processes involving more than one discipline. Substantial effort, together with some compromise, is required to prevent research projects with interdisciplinary objectives from becoming multidisciplinary. Although the potential contribution from agricultural economists working with other disciplines remains high, allocation of large segments of our professional resources to such activity should be done with caution. The gains from specialization are too high to be sacrificed casually; the opportunity costs of

doing interdisciplinary research may easily be underestimated. We should recall that the objective of the Association is to further the development of systematic knowledge of agricultural economics. A part of the development of that systematic knowledge requires working with other disciplines, and it is important that we do that part well.

Agricultural Trade: Protectionism, Policy, and the Tokyo/Geneva Negotiating Round

James P. Houck

If Shakespeare's Richard III had addressed Congress this summer, he might have opened his speech with the same line he uttered to start the drama that bears his name, "Now is the winter of our discontent." And Congress would have nodded in full agreement. The U.S. economy is tormented by persistent inflation, alarming energy shortages, and impending recession.

Major interest in trade and trade policy is focused on the fleecing we are experiencing at the hands of the Organization of Petroleum Exporting Countries (OPEC), our huge negative bilateral trade balance with Japan, and the sagging dollar. Not much front-page attention has been captured by the results of the Multilateral Trade Negotiations (MTN) which ended in April 1979, and whose implementing easily passed Congress in mid-July 1979. Yet the MTN is another important step in the evolution of the multilateral approach to world trade problems. Its implications for U.S. agricultural trade are central to this paper.

There are three main themes to follow. The first is a broad discussion of the role of agricultural trade in the world economy with some consideration of the U.S. position. The second is a rather brief look at the current trade policy/protectionism picture as it relates to trade negotiations. Third is an economic analysis of how the MTN will affect U.S. agricultural trade in the short run. Full documentation of the data and other general information used herein will not be attempted. The basic data are from well-known U.S. Department of Agriculture (USDA) sources and official publications of international agencies such as General Agreement on Tariffs and Trade (GATT), the United Nations, Organization for Cooperative and Economic Development (OCED), and the World Bank.

Invited address.

James P. Houck is a professor in the Department of Agricultural and Applied Economics at the University of Minnesota.

Research for this paper was partially supported by the Committee on Finance, U.S. Senate. Scientific Journal Series Paper No. 10,900, University of Minnesota Agricultural Experiment Station.

Agricultural Trade in Perspective

Since about 1950–54 (a benchmark period for this section), the volume of world production of all goods, agricultural and nonagricultural, has more than tripled. Since then, the volume of total world trade has more than quintupled. Consequently, the world as a whole is more dependent on and economically committed to trade than ever before.

Since 1950–54, the agricultural part of total trade has nearly tripled in volume. This trade growth has significantly outpaced the expansion in world agricultural production which has increased about 75% to 80%. Thus, nations of the world also are more dependent upon one another than ever before for food, fiber, and agricultural raw materials. However, agricultural trade has fallen from about 30% of total world trade value in 1950–54, to approximately 15% today.

Three main reasons lie behind this phenomenon. First is the pervasive tendency for farm production to grow more slowly than industrial production. This reflects the role food and fiber play in human life and the fact that these products are still generated by natural, biological processes, not mechanical and chemical ones. The second reason is that the unit values (prices) of agricultural products moving in trade have generally fallen relative to other primary products such as minerals and fuels since 1950–54 while staying approximately constant relative to manufactures. Third, complex barriers and impediments to agricultural trade have been erected over the years via national policies. These barriers do not have exact counterparts in the industrial sectors.

Composition of World Agricultural Trade and the U.S. Position

Since 1950–54, the composition of world agricultural trade has changed gradually. Food and feed products have grown from 45% of the total to almost 70% today. The major growth items have been oilseeds, feed grains, and livestock products (mainly meat). The effects of rising international affluence, the emergence of several centrally planned nations as feed and food importers, and the increasing food-deficit status of many less-developed nations have fueled this trend.

Agricultural raw materials have dwindled in relative importance from 29% in 1950–54 to about 11% today. The major items in this category display relatively stagnant markets. They are natural fibers, tobacco, and rubber. The gradual substitution of synthetic for natural materials is a major reason behind these slower growth rates.

As world markets for farm products have evolved in the past twenty-five years, the U.S. role has become larger and larger. Much of this growth is because trade demand has grown and shifted toward products in which the United States has unquestioned comparative advantage, such as grains and oilseeds. The relative decline in the value of several agricultural exporters' currencies (including the U.S. dollar) has helped to increase world demand for farm exports. But important supply factors also have been at work. For example, developments in mechanical and biological crop production technology have enhanced the natural efficiency of the United States in temperate-zone food and feed grains. Similarly, the evolution of U.S. agricultural policy during the past fifteen to twenty years has reflected the vital role exports play in generating farm income by keeping major U.S. farm exports competitive in world markets.

The net result is that the United States now accounts for about 16% or 17% of all world agricultural exports compared with about 12% in 1950–54. Our farm product imports from the rest of the world have grown much less rapidly. Consequently, the U.S. share as an agricultural importer has fallen. Our imports now account for about 8% of world agricultural trade. This is down from about 28% in 1950–54. Yet, we are still a major agricultural importing nation—behind only West Germany and Japan.

Export Products and Markets

Table 1 is a comparative profile of U.S. agricultural exports in 1953/54 and 1977/78. Note the relative growth in today's three largest categories, oilseeds (mainly soybeans), feed grains (mainly corn), and wheat. This group has virtually doubled in importance since the early 1950s with all the relative growth coming from oilseeds and feed grains. These "big ticket" commodities now represent almost two-thirds of U.S. farm exports.

Some traditional, politically important crops like tobacco and cotton have lost ground, and the myriad items in the "other" category stayed constant in proportion to the total. Many such as citrus, rice, and almonds have grown in export sales and are politically important because their production is concentrated in rather small geographic areas.

Overall, the volume of U.S. agricultural exports has almost quadrupled while farm output has increased by only 54% since 1950–54. (Oilseed and grain export volumes have grown over this period at annual rates of 10% and 7%, respectively.) Thus, a much larger share of U.S. output is being exported now than twenty-five years ago. In fact, only about 10% of cash recipts from farming came from exports in 1950–54. Now it is about 24%.

Today the bulk of U.S. agricultural export sales are for hard currencies. Only about 6% are under special government programs. Variously termed, "food for peace," "food aid," "P.L. 480," or "concessional exports," these sales have steadily dwindled in relative importance since the late 1950s and early 1960s. In the early days of Public Law 480 (the Agricultural Trade Development and Assistance Act of 1954), concessional shipments accounted for 25% to 40% of the value of our export

Table 1. Profile of U.S. Agricultural Exports, 1953/54 and 1977/78

Item	1953/54 ($3 billion)		1977/78 ($27 billion)	
	(%)			
Oilseeds and products	11	32	27	62
Feed grains	7		21	
Wheat	14		14	
Tobacco and cotton	35		11	
Livestock products	15		9	
Other	18		18	
Total	100		100	

trade, averaging about 30% in 1954–60. These special sales to food-short, politically friendly nations were very important for wheat, rice, soybean oil, cotton, tobacco, and nonfat dry milk. The nearly constant annual dollar appropriation for such sales has forced both export volume and relative importance downward since the early 1960s.

Over the past twenty-five years, the destinations of U.S. farm exports have altered to some extent but not dramatically. Changes occur slowly in the worldwide distribution of wealth, basic agricultural efficiency, the international network of farm and trade policies, and other factors influencing the direction and composition of trade flows.

The five leading buyers of U.S. agricultural exports in 1950–54 were, in order, Japan, United Kingdom, West Germany, Canada, and the Netherlands, together taking 45% of all U.S. agricultural exports. In 1977/78, the top five, in order, were Japan, the Netherlands, West Germany, Canada, and the Soviet Union (the U.K. was seventh, behind Korea). The top five in 1977/78 also accounted for 45% of all sales. Thus, at the top of the heap, no major realignments occurred with the important exception of the recent emergence of the USSR as a major market. Moreover, the nine-nation European Community (EC-9) can be viewed for most trade policy purposes as a single market. Today, it dominates all destinations, accounting for about 25%-30% of U.S. agricultural exports. Japan takes about 15%. (Incidentally, OPEC now takes 7% of the U.S. farm exports, a marked increase from very small quantities and values throughout the 1950s and 1960s.)

U.S. Agricultural Imports in Perspective

Although the dollar value of U.S. agricultural imports has more than doubled since 1950–54, the physical volume has increased by only 50%. Many tropical items do not compete with domestic farm output. These commodities (officially called complementary imports) such as coffee, tea, bananas, rubber, and cocoa now are about 40% of the total agricultural import bill, down from 60% in 1950–54. The balance is competitive at least to some extent with domestic production. Major items in this category (officially called supplementary imports) are beef, sugar, dairy products, wine, fruits, and vegetables. Of all food consumed in the United States, imports have accounted for a relatively constant 9% to 12% share in recent times.

The following list shows how imports shared in the U.S. consumption of some important items in 1976/77.

Coffee, tea, cocoa, bananas	100%
Fish	57%
Wool	50%
Sugar	43%
Fats and oils	10%
Red meat	7%
Fresh fruit (not bananas)	6%
Fresh Vegetables	6%
Dairy products	2%

Some interesting changes have occurred in the mix of imports. These are illustrated in the profile of competitive (supplementary) agricultural imports over the twenty-five year period, table 2. We now import relatively more meat, fruits and vegetables, and dairy products than we did in 1950–54. The growth in demand for hamburger meat (the principal import), the increasingly competitive supplies of off-season fruits and vegetables from Latin America, and the growth in sales of cheeses of all types are behind these increases. The inroads of synthetic fibers and the slow growth in domestic textile manufacturing caused the relative drop in wool imports. Slow demand growth and well-protected domestic production led to the relative drop in sugar's position among our major farm imports.

For competitive products, the five leading

Table 2. Profile of U.S. Imports of Supplementary Agricultural Products, 1950/54 and 1977/78

Item	1950/54 Average ($1.9 billion)	1977/78 ($7.3 billion)
	(%)

Total	100	100

suppliers in 1977/78, with 38% of the total, were the Philippines, Canada, Mexico, Australia, and New Zealand.

Balance of Payments and Exchange Rates

The strong contribution that agricultural trade makes to the troubled U.S. balance of payments is well-known and needs little elaboration here. The typical measure of agriculture's net contribution is the value difference between annual agricultural exports and imports. Currently this measure is running at approximately $10–12 billion annually and has been consistently positive since 1960. If competitive farm imports only are considered in this calculation, the agricultural sector has, with only two exceptions (1936 and 1940), contributed positively to the nation's annual trade balance back at least as far as 1900.

The recent fall in the value of the U.S. dollar relative to some other currencies is a much-discussed topic with implications for agricultural trade but also extending far beyond it. The fall in the dollar's value makes our farm exports look relatively cheaper to buyers in nations whose currencies are appreciating, such as Japan, Germany, Switzerland, etc. If domestic demand in such nations can respond to lower relative prices of farm imports, consumption (hence imports) will be stimulated.

Yet U.S. farm exports have not increased to the extent that the casual observer might suppose because currency devaluation relative to the yen and the mark also has occurred for other major agricultural exporters. Hence, the U.S. market share has not boomed partly because the U.S. dollar has not fallen much or at all relative to the currencies of Canada, Australia, Brazil, and Argentina—our major competitors for world markets. In addition, farm product prices in many large import markets do not fall (or rise) in response to world market changes. Insulating trade policies in the EC-9, Japan, and elsewhere keep internal prices of many key commodities clearly detached from world levels.

National Policy and Protection

Natural differences among lands and people are powerful forces shaping the direction, magnitude, and composition of agricultural trade. The world's agricultural trade flows approach those suggested by the pure theory of international trade and the concept of comparative advantage. Yet, major distortions away from the theoretical model are evident. These result mainly from trade policies and other decisions by national governments. For agricultural products, these policies and decisions are almost always extensions of domestic agricultural and food policies. Agricultural trade policy reflects and supports fundamental commitments made by governments to domestic farmers, food industries, and (occasionally) consumers.

Barriers to agricultural trade are extremely difficult to negotiate internationally. Any change in these barriers toward more liberal trade usually undermines some national farm or food policies by making them either more costly or administratively difficult to operate. Furthermore, no nation has ever shown much willingness to negotiate the structure or terms of its own internal agricultural policy. Although they are imperfect and inconsistent everywhere, existing agricultural policies and programs have been slowly and painfully constructed. They are not altered or put aside lightly.

These rigidities are reinforced by traditional trade negotiating processes. The four major parties in worldwide agricultural (and industrial) trade are the United States, Japan, the EC-9, and Canada. If agricultural trade agreements of consequence are to be reached, one or more of these four must be involved. Each has a complex domestic agricultural policy which carries over into its trade policy in ways which severely restrict its ability to negotiate broadly on agricultural trade. Moreover, the historical tendency to treat agricultural negotiations in a separate package, largely isolated from industrial agreements adds even more rigidity to the picture.

Let us consider some important elements of food and agricultural policies in Japan, the EC-9, and Canada, insofar as agricultural trade is concerned. This will set the stage for the subsequent examination of the major MTN agreements on tariffs and quotas.

Japan

Year in and year out, Japan is the United States' largest agricultural trade customer despite a basically trade-restrictive agricultural and food policy. This is because the Japanese economy is wealthy and diversified.

Approximately 24% of Japan's 114 million people live in farm households (Sanderson, OECD 1974b). Most Japanese farms are operated as family units, but 90% of them are part-time farms. The average farm size is about 2.5 acres. Only about 6% of Japan's farms are more than 5 acres in size.

Two foundation stones of Japan's agricultural policy are rice and self-sufficiency. Rice accounts for about 35% of farm output and 33% to 34% of the total caloric intake of the people. Rice prices at the farm are supported at levels several times higher than world prices. This has far-reaching effects on all of Japan's agriculture. Input use for other crops and livestock must compete with rice. Hence, the impact of the artificially high rice price spreads throughout the agriculture and food economy creating protectionist pressures virtually everywhere.

Although dependent on foreign suppliers for food and other raw materials, Japan still maintains a strong commitment to as much self-sufficiency in food as practicable. Bitter past experience fosters this commitment. Japan is about 72% self-sufficient in all foods; this includes 100% in rice, more than 90% in vegetables and eggs, more than 80% in milk, meat, and fruit, 40% in feeds, and less than 10% in wheat and soybeans. Japanese consumers devote an average 25%–27% of their consumption expenditures to food.

Because Japan is densely populated and has only 15%–16% of its land suitable for agriculture, this rather high degree of self-sufficiency and its distribution among commodities reflect a protective agricultural policy. Much of the pressure for and support of protective policies on behalf of Japan's farmers, at the expense of consumers and taxpayers, can be traced to the special characteristics of that nation's political life as it relates to agriculture (Sanderson, Houck). By any standard, Japan's farmers are well-organized and well-situated for political action. With the generally reliable support of the Ministry of Agriculture, Forestry, and Fisheries, the various farm organizations press for and obtain economic protection on a broad front, including trade.

To implement policy decisions, Japan uses straightforward methods of controlling food imports, namely government procurement (e.g., wheat), tariffs (e.g., poultry), and quotas (e.g., beef and citrus). The allocation of quotas is handled in several ways. Generally, the quotas are parceled out to private companies, farmer coops and their affiliates, or to quasi-governmental agencies.

In addition to these formal means of control, Japan's food distribution system also forms an informal import barrier. Most food products are distributed to consumers through long chains of intermediaries closely bound to traditional (domestic) sources of supply. Thus, it can be reasonably difficult to export food products to Japan even if there are no formal barriers to entry.

The European Community (EC-9)

For all its anomalies and inconsistencies the Common Agricultural Policy (CAP) is a joint Community policy (OECD 1974a). In fact, an official publication of the EC-9 Commission observes that the CAP "was introduced in 1962 and has unfortunately remained the only real joint Community policy" (European Communities, p. 5). Without some common farm and food policy, it is unlikely that the original six-nation Common Market could have been founded initially or could remain intact today. Therefore, it is not surprising that European government officials and political leaders will do nothing in international forums and agencies to seriously undercut the fragile CAP from the outside. There are plenty of internal forces shredding its fabric from day to day.

Prior to the formation of the original Common Market, each member nation had its own complex and generally protectionist agricultural policy to which it was strongly committed. The only feasible way in the 1960s that a mutually acceptable policy, insuring substantial self-reliance in food and agricultural raw materials, could be formed was through high common prices and no direct production controls. Such a policy could be sustained only by a thoroughly protective trade policy. There simply was no other workable pathway to agreement. Even today, no apparent alternative exists except to continually repair and repatch the original scheme. Powerful farm organizations, a widespread desire for food self-reliance, the general prosperity of the Community, and the existence of chronic pockets of low farm income add rigidity to the system, effectively precluding a substantial revamping.

High rates of self-sufficiency in grains, dairy, meats, fruits, and vegetables are protected through the CAP by high internal price

guarantees. Arrived at politically, guaranteed farm prices are maintained within the EC-9 via (*a*) market intervention by government agencies for surplus products and (*b*) import controls for deficit commodities. Most of the CAP's bizarre complexities boil down to these two fundamental ideas.

When surplus production occurs, it is acquired and stored for future disposition or exported with whatever subsidy is needed to sell it abroad. For deficit products, the main import controls are (*a*) the well-known variable levies (the difference between internal, guaranteed "target" or "threshold" prices and world market prices c.i.f. Europe), (*b*) other tariffs, special adjustable levies, and some quotas. Since these measures are extensions of domestic policy, they are extremely difficult, if not impossible, to negotiate internationally under current conditions.

Because each nation in the EC-9 still maintains its own currency and much financial independence, the CAP price targets and support levels are expressed in "units of account," an artificial Community-wide accounting device. If the relative values of members' currencies are constant, "unit of account" prices can reflect market harmony throughout the Community. However, the modern floating system of international exchange rates has allowed relative currency values to fluctuate, causing "unit of account" prices to rise and fall as they are translated into specific currencies. This, in turn, spawned a complex layer of border tax adjustments which are applied to intra-Community trade in farm products. Even though the Community is now moving toward a more stable monetary system, there are still separate exchange rates among European currencies applied only to agricultural trade. This adds a baffling new tangle of complexity to the CAP. It clearly narrows the short-run ability of the Commission to negotiate internationally by further weakening the CAP's cohesiveness and undermining its basic organizing principle.

Canada

Among the developed nations, Canada occupies a unique position in the U.S. agricultural trade picture. Canada is a leading export customer for U.S. farm products and an important source of our agricultural imports. In 1977/78, Canada was the fourth leading buyer of U.S. farm exports. (Two of the three nations ahead of Canada are inside the EC-9; Japan is the third.) Similarly, Canada is our third leading source of farm imports, exceeded in 1977/78 by only Brazil and Mexico.

Like the United States, Canada's leading agricultural export customers are the EC-9 and Japan. The United States now ranks third having recently been overtaken by Japan. We buy approximately 16% of Canada's total farm exports. On the other hand, the United States currently supplies more than half of Canada's agricultural purchases.

Much of this large trade flow is due to the proximity and vast geographical size of both nations. When not excluded by trade barriers, many products can move across a long international border more economically than they can within either nation. This happens when forces of localized comparative advantage in production and marketing are not overcome by national trade policies. Trade statistics reflect this idea. They show that U.S.-Canada farm trade is very diversified among products flowing in both directions.

Broadly speaking, Canada and the United States face similar conditions domestically and in their trading relations. For example, both nations rely on agricultural trade to contribute positively to their international balance of payments. However, the agricultural export/import ratio for Canada is typically somewhat smaller than that for the United States (1.2 for Canada in 1977 as compared with 1.7 for the United States). In addition, 70% to 75% of Canada's agricultural exports are grains, feeds, and oilseed products—for the United States it is about 65%. Consequently, like the United States, Canada's trade policy and domestic farm policy are dominated by the fostering of exports and the management of grain production and inventories. The institutions and the extent of direct involvement by the government differ markedly between the two nations and among commodities. However, the problems are clearly similar.

A parallel also exists on the import side. The Agricultural Stabilization Board of Canada has the responsibility to stabilize prices and "assist the industry in realizing fair return . . ." (OECD 1973, p. 29). Under legislation, the board must support the prices of various commodities at not less than 90% of the previous five-year average market or base price with appropriate additional consideration for cash cost increases. When imports of

stabilized or supported products interfere with this policy, quota and tariff measures are readily available to Canadian authorities on a commodity-by-commodity basis. Hence, domestic agricultural policy decisions about farm prices and incomes tend to control Canadian trade policy toward imports.

If agricultural trade between the United States and Canada were as free as between our own individual states (no tariffs or quotas), it is unlikely that vast changes would occur in the basic location of production or in trade patterns. It certainly would be nothing comparable to adjustments that would occur in Japan or Europe under free agricultural trade. Consequently, the scope for trade negotiations with Canada is related not to fundamental differences in social philosophy, geography, or economic structure, but to modest differences in agricultural resources, farm support systems, and the natural tendency for an economical flow of many products to occur back and forth across a long, shared border.

International Trends in Protectionism

Going beyond the well-established network of formal trade policy, there is substantial agreement that trade protectionism is growing, even in the face of expanding trade and falling tariffs. Nontariff trade barriers of many varieties dominate this discussion. Such barriers have a long history in agricultural trade. Hillman has recently published an extensive study on this topic. He builds the case that such trade-stifling barriers (both official and unofficial) are becoming more pervasive and more effective. Middleton also documents the importance of nontariff barriers and their key role in trade negotiations. Krauss argues that this "new protectionism" is a direct result of social processes and the welfare state.

Nontariff trade barriers are difficult to negotiate internationally because they are either (*a*) official extensions of nonnegotiable domestic policies, (*b*) outside the basic purview of traditional multilateral and bilateral negotiating schemes, or (*c*) applied unofficially or covertly from deep within modern government bureaucracies. Reidel, in trying to document the current concern about nontariff protectionism, such as quotas, licensing schemes, variable duties, writes:

> On the surface, it is not at all clear that we are presently facing a 'rising tide of protectionism' as so many have declared. The available evidence is mixed. But what is occurring below the surface? This is the most disquieting aspect of the current situation, particularly because it is so difficult to monitor these developments. (p. 15)

Much of the problem in monitoring protectionism today stems from its unofficial character. Reidel also ponders:

> Because of the secrecy that surrounds unofficial arrangements to restrain trade, there is no reliable way of monitoring these actions or assessing their significance. . . . Are these reported cases [of unofficial arrangements] no more than the tip of an evergrowing iceberg? (pp. 6–7)

The basic objectives and final results of the Tokyo/Geneva MTN Round, discussed next, reflect a serious effort to manage and possibly reduce the effects of nontariff trade barriers in both industrial and agricultural trade.

The Tokyo/Geneva Round in Brief

The official chronology shows that the seventy-nine month Tokyo/Geneva Round, concluded in April 1979, was the lengthiest formal trade negotiation in GATT history. The previous recordholder was the 1963–67 Kennedy Round, which lasted fifty-four months. The five GATT negotiating sessions before the Kennedy Round were comparatively short because tariff cuts and tariff bindings were the only major issues. Nontariff trade barriers were largely bypassed.

Agricultural trade issues have formed a large part of the recent negotiations. As mentioned earlier, such discussions are not completed quickly or easily. In addition, both the Kennedy Round and the Tokyo/Geneva Round produced some rather delicate changes in the basic legal and institutional framework of the GATT itself. Also, difficult negotiations on codes of conduct through which the agreement is implemented in practice and through which nontariff barriers are attacked were conducted.

The Legacy of the Kennedy Round

As in the Tokyo/Geneva Round, official statements were continually advanced in the Kennedy Round about the crucial importance of agriculture from the U.S. viewpoint. Here,

as quoted by Schnittker, is a typical example from a 1963 speech by Christian A. Herter, the U.S. Chief Negotiator for the Kennedy Round. "It is, of course, the firm position of my government that negotiations must include agricultural products. This means that my government will not be prepared to conclude the negotiations until equitable tariff and trade arrangements have been developed for agricultural products." However, major breakthroughs in agricultural trade negotiations simply did not materialize in the Kennedy Round. Those familiar with its history know that the major parties were simply too far apart and too inflexible within their own domestic policy constraints to maneuver toward anything new. At the 1967 conclusion of the Kennedy Round, the political commitment for substantive agricultural agreements was deemed to have been satisfied in two main ways (USDA 1967). First, an International Grains Arrangement was signed. It was an outgrowth of previous International Wheat Agreements and contained a Food Aid Convention and an ill-fated, price-fixing trade convention for wheat. Second, a set of tariff cuts and bindings was concluded for agricultural products whose trade coverage, at that time, was $866 million on the U.S. export side and $860 million on the import side. (Incidentally, at 1978/79 price levels, these trade coverage values would now approximate $2.0 billion. This can be compared with trade coverage values in the $3.0–4.0 billion range now being discussed in connection with current agreements.)

Herter's statement, quoted above, is remarkably similar to our official stance in the Tokyo/Geneva Round, which is buttressed by similar language in the Trade Act of 1974, authorizing U.S. participation in the round (U.S. Congress 1975). As with the Kennedy Round, agricultural agreements were again difficult to arrange and the final results are modest.

Major Agricultural Participants in the Tokyo/Geneva Round

Under negotiating procedures evolved in GATT since 1947, multilateral tariff and trade concessions for commodities and industrial sectors occur only when two or more of the leading trading nations in the relevant products are able to agree on the main terms of a settlement. Then other interested parties can join in and, by their participation, round out a multilateral package in which all GATT members may share.

In the Tokyo/Geneva Round, much as with the Kennedy Round, center stage in the agricultural negotiations was occupied by the United States, the European Community, and Japan. (Though important in earlier rounds, the United Kingdom is now submerged within the EC-9.) Other important nations on the inner fringe, next to the "big three," are Canada, Mexico, Brazil, Argentina, and Australia. These few nations form the pool from which pairs and other combinations must be drawn for any significant dealing to occur.

Results of the Tokyo/Geneva Round

The objectives of the round were set out in the so-called Tokyo Declaration of September 1973, which formally opened the negotiations (U.S. Congress 1975). Much has been published on the general objectives and the extent to which they were achieved as the negotiations unfolded (U.S. Department of State; USDA 1979; U.S. Congress 1979 a, b; Livernash; Twigs; Golt). However, three main categories of agricultural agreements can be identified from the economist's point of view.

First are the specific tariff and trade barrier agreements similar to those which have been the core of previous rounds. These were achieved within the traditional bilateral "offer and request" framework. Second are the behavioral codes, the most important of which for agriculture are the "export subsidies/countervailing duty" code and the "standards" code. The former seeks to tighten international responsibility and restraint insofar as export subsidies and retaliation are concerned; the latter is designed to reduce the use of various standards, product certification, and testing as barriers to trade. Third are international agreements for consultations on dairy products, beef, and general agricultural policy. These agreements have no substantive economic provisions.

Evaluation of the economic effects of the new codes and the international consultative agreements is completely subjective at this time. Their potential value lies in their ability to reduce and help manage trade conflicts. Interest groups and individuals, public and private, are now having their say about this, and they disagree. However, it is possible to estimate the net economic effects of the new tariff

and quota agreements with some standard tools of economic analysis. That is the subject of the balance of this paper.

Economic Analysis of the MTN Agreements for Agricultural Tariffs and Quotas

In the negotiations, three main bilateral packages with Japan, EC-9, and Canada were achieved. In addition, lesser agreements involving about thirty other nations were signed covering both tariff and nontariff items. On the export side, we will look at the three main packages separately and then consider the others as a single group. On the import side, we will consider U.S. agricultural concessions as a group.

The Method

The method used to calculate new trade values resulting from tariff changes comes from partial equilibrium analysis. For any given product, let

$$(1) \qquad I = C - S,$$

where I is volume of imports, C is volume of domestic consumption, S is volume of domestic production. Then, if P is the domestic price observed at the import level,

$$(2) \qquad \frac{\partial I}{\partial P} = \frac{\partial C}{\partial P} + \frac{\partial S}{\partial P}.$$

Then, by making appropriate multiplications and divisions, equation (2) can be restated in a general elasticity form as follows:

$$(3) \quad \frac{\partial I}{\partial P}\,\frac{P}{I} = \left[\frac{\partial D}{\partial P}\,\frac{P}{D}\right]\frac{D}{I} - \left[\frac{\partial S}{\partial P}\,\frac{P}{S}\right]\frac{S}{I}, \text{ or}$$

$$(4) \qquad E_I = E_D(D/I) - E_S(S/I),$$

where E_I is price elasticity of import demand, E_D is price elasticity of domestic demand, E_S is price elasticity of domestic supply. For purposes of this analysis, E_S was taken to be equal to zero in all cases. This rules out specific consideration of domestic supply response or stock adjustments to changed prices as tariffs change. Thus,

$$(5) \qquad E_I = E_D\,(D/I).$$

The import demand elasticity is the domestic demand elasticity (obtained from various empirical research studies) weighted by the ratio of consumption to imports, this ratio being greater than or equal to 1.0.

Finally, the percentage change in imports (% ΔI) was calculated as

$$(6) \qquad (\%\ \Delta I) = E_I\,(\%\ \Delta P),$$

where (% ΔP) is the estimated percentage change in domestic price as the result of a specified tariff change. This assumes that these import demand shifts do not alter world FOB or c.i.f. prices—a plausible assumption in this context. To obtain the dollar value of "new" trade, the result of equation (6) was applied to the 1976 base trade figures, used by the office of the Special Trade Representation (STR) for negotiating purposes, on the assumption that the United States maintains its 1976 market share of all import markets.

The value of quota changes was estimated by assuming that the new specific quotas would be filled at current world price levels by U.S. suppliers. Both the tariff and quota analyses focus on the total adjustments as negotiated without considering the intermediate staging that will occur in their actual application beginning in 1980.

Japan

The U.S.-Japan settlement insofar as agriculture is concerned has three major components. First is a set of tariff bindings. Second is a series of tariff reductions granted by Japan on about sixty-seven listed categories of items, widely diversified. Third are increases in Japanese import quotas of a few tightly controlled items.

Tariff bindings. Tariff bindings covered some fourteen items whose 1976 base trade value is \$809 million. These bindings are scattered over a number of product groups. However, the "free" binding on soybeans alone accounts for \$770 million, or 95% of this total. It is impossible to calculate or predict the value of this trade concession. Most observers value this concession highly and feel that a similar "free" binding on soybeans obtained from the European Common Market during the 1962 Dillon Round, and sustained since then, has been partially responsible for that market's huge growth.

Tariff cuts. Excluding bound items, the new tariff reductions average 35% across the board. For purposes of analysis, the tariff reductions were assumed to exert downward

pressure on retail and wholesale prices inside Japan. The economic value of a tariff reduction occurs because the total market for the general product expands and because the market share of imported items grows due to their relative price reduction.

Table 3 summarizes the results of calculations on the trade effects of the negotiated tariff changes. They are to be viewed as approximations indicating relative magnitudes; they are not precise predictions because, among other things, they isolate only the effect of tariff changes.

Almost 40% of the estimated trade increase is concentrated in the pork market. The calculation assumes that imported pork actually will fall in relative price because of the negotiated settlement. However, Japanese imports of pork are also subject to a complex duty formula which resembles a variable import levy. Consequently, this part of the calculation could be nullified if the relative price of imported pork is not permitted to decrease despite the nominal tariff cut. The totals show that trade values increase by an estimated $92 million or about 21% of the base value of the covered items. Without pork, the $57 million increase represents 19% of the base value of covered items.

Quota increases. The U.S.-Japan settlement contained import quota relaxation for four commodities in which the United States has a sizable, direct interest: high-quality beef, oranges, orange juice, and grapefruit juice. Table 4 illustrates the current quotas, the full relaxation implied in the settlement, and the estimated trade value of the quota increases.

Japan summary. Estimated values of the

[b] Calculated at 30¢/lb.
[c] Calculated at $1.15/lb.
[d] Calculated at $3.00/lb.
[e] Calculated at $2.75/lb.
[f] Calculated at $3.00/lb. for 1.5 million lbs. and $2.50/lb. for 2.9 million lbs.

tariff changes and the quota adjustments by Japan are $215 million. To this must be added the unknown but possibly large future value of new tariff bindings, especially on soybeans. Another positive point about this agreement is that the quota adjustments do, in fact, reflect changes in significant nontariff barriers. The precedent-setting value of these concessions should not be minimized despite their relatively small dollar values.

The European Community (EC-9)

The EC-9 concession covers about $960 million worth of 1976 agricultural trade. About $19 million involves a "free" tariff binding on peanut imports, and $8 million reflects a tariff reclassification agreement for some poultry items. The balance, about $933 million, involves trade affected by tariff cuts and a new arrangement for high-quality beef.

EC-9 tariff cuts. The tariff concessions by EC-9 span about thirty products totaling $867 million in 1976 trade value. Their contribution to expanded trade is shown in table 3 with full tariff cuts assumed. The totals show that trade values increase by an estimated $102 million or about 12% of the value of covered items. None of the key products in the CAP are involved substantively.

High-quality beef concession. A new tariff line for high-quality restaurant and hotel beef will cover an informally agreed upon import volume of 10,000 metric tons (22.1 million lbs.) or less. The traditional variable levy system will not apply to this line. At a per-unit trade value of $3.00 per pound, this EC-9 concession will approximate $66 million in new trade, table 4.

EC-9 summary. The EC-9 settlement shows an estimated $102 million tariff-related trade increase and $66 million in new beef trade for a total of $168 million. The new trade value of the tariff category reclassification in poultry is uncertain at this time as is the future value of the "free" peanut tariff binding.

Canada

Canada's agricultural trade concessions to the United States involve mainly the reduction and binding of existing tariffs. The 1976 trade coverage is $423 million, of which $413 million is accounted for by commodities for which tariffs were reduced. Almost $10 million reflects official binding of "currently applied" tariffs on prepared cereal foods. (These "currently applied" tariffs are approximately 40% lower than the official book rates.) Less than a million is accounted for by Canada's agreement to open the importation of canned turkey for "general licensing."

Table 3 shows estimated trade values of the proposed settlement with Canada. The total new trade value is estimated at $56 million. On the $413 million coverage base, this is a 13.6% trade gain strictly due to the tariff cuts.

Other Nations

The United States reached MTN tariff and access agreements with about thirty other nations or groups of nations acting together. These agreements cover tariff bindings and reductions as well as some adjustments in nontariff trade barriers. Their annual new trade value is $24 million.

Tariff bindings. Approximately sixty individual tariff bindings were achieved on products exported by the United States. Twenty nations offered these bindings with a total trade coverage of almost $450 million, 59% being concentrated in soybeans and soybean oil. They represent no new trade but do represent insurance against future duty increases.

Tariff reductions. Approximately ninety individual tariff reductions were achieved with eighteen nations on a wide variety of U.S. agricultural exports. These negotiated duty cuts vary from large to very small. The 1976 trade coverage of these tariff agreements is approximately $47 million. The estimated value of new trade generated by these tariff cuts taken together is only $9.0 million, table 3.

Nontariff barriers. About fifteen individual new agreements on nontariff trade barriers are in hand. They include quota increases, licensing procedure changes, and bindings on import-mixing regulations. These are important enough to warrant separate consideration.

U.S. Agricultural Import Concessions

There are two major categories of specific trade concessions offered by the United States. First and most important is an enlargement and rearrangement of Section 22 import quotas on cheese. The second is a wide variety of tariff reductions on agricultural imports ranging from wool to canned pineapple. In this section, estimates are presented for the dairy import concession and for as many of the others as feasible. Their total new trade value is calculated at $106 million.

Dairy imports. The proposed MTN agreement on dairy imports enlarges the quotas on foreign cheese, eliminates the current "price break" system, and brings all "price break" cheeses under the new quotas. If the new quota system had been in effect last year, approximately 15,000 metric tons of additional cheese could have been imported into the United States on an annual basis. This is the equivalent of 275–300 million additional pounds of milk on the domestic market, approximately 0.25% of total annual U.S. milk production. It also represents slightly less than 0.9% of total U.S. cheese production on an annual basis.

This potential increase in imports could depress milk prices by an estimated 5.4¢ per hundredweight (cwt) at the farm level (USDA 1975; Buxton and Fallert). Such a price decrease would happen only if nothing else changed and if cheddar cheese prices were more than 1¢ or 2¢ above support levels so that the downward adjustment actually could occur. If not, government purchases would prevent the price from falling. Taking the 1978 level of milk output as a basis, the cost of this trade concession to U.S. dairy farmers is $66 million. This is about 0.5% of the farm value of milk production in 1978.

Other MTN agricutural concessions. No other MTN concessions in agriculture approach the value of the cheese import quota agreement. For the most part these other concessions are tariff reductions across a wide spectrum of products. Those susceptible to analysis are shown in table 5.

The coconut oil concession involves elimination of the current duty of 1¢ per pound. Lamb tariffs are to be cut from 1.7¢ to 0.5¢ per pound. Tariffs on apparel wool are to be reduced by 60%. The canned pineapple tariff will go from 3% to 1% ad valorem. The tobacco concession involves tariff cuts on various cigars and cigar tobaccos. On canned beef, the duty cut is from 7.5% to 3.0% ad valorem. The barley concession reduces the tariff from 7.5¢ per bushel to 5.0¢.

The United States also agreed to cut tariffs on several products covered by the Meat Im-

Table 5. Value of Miscellaneous MTN Tariff Concessions Offered by the United States

Item	Import Value (1976)	New Import Value	Change
	--- ($ million) -----		(+)
Coconut oil	179	187	8
Lamb	21	29	8
Wool	54	60	6
Canned pineapple	68	73	5
Tobacco products	36	41	5
Cooked beef	68	73	5
Barley	53	56	3
Total			40

port Law of 1964 and Section 22 import quotas. Since the quotas themselves were not adjusted, estimates were not calculated for "new" trade. Items in this group include meat (mainly beef), butter, cream, and two specific staple lengths of cotton. Cheese tariffs will be cut 20%–25% as the new quota system is put into place.

Concluding Comments

In the Tokyo/Geneva Round, the United States placed high priority upon achieving improvements in agricultural trade through MTN agreements. As with previous rounds, major breakthroughs in protectionist agricultural trade policies were not obtained, even though the Tokyo/Geneva Round lasted five and one-half years. However, a series of agreements were achieved that should modestly enhance the highly favorable balance of trade exhibited by U.S. agriculture. Changes in some nontariff trade barriers achieved in the Tokyo/Geneva Round may establish extremely valuable precedents for future trade negotiations. Moreover, tariffs on some important U.S. exports to major markets were bound against future increases. The consultative commodity agreements, the new behavioral codes, and the GATT framework changes also negotiated at the Tokyo/Geneva Round were not emphasized in this paper.

The three major packages negotiated with Japan, the European Economic Community (EC-9), and Canada will enhance annual U.S. agricultural exports by an estimated $215 million, $168 million, and $56 million, respectively. A series of agreements with some thirty additional nations will add $24 million for an overall total of $463 million annually. This is approximately 2.1% of the 1976 base trade figures used throughout the report and by the Office of the Special Trade Representative.

In addition, tariff bindings were obtained on products whose exports totaled $1,278 million in 1976. About 80% of this total is accounted for by a "free" binding on soybeans conceded by Japan and by other tariff bindings on soybeans and their products offered by five other nations.

On the agricultural import side, the United States has made a significant quota adjustment for dairy products (cheese) and a series of tariff reductions for other products. The value of these concessions in terms of increased agricultural imports is approximately $106 million annually. Thus, these concessions will increase agricultural imports by about 1.0% over the 1976 base trade figures.

The net change in overall agricultural trade due to the MTN agreements is an increase of $357 million in 1976 terms. A plausible estimate of this annual value in 1979 terms is about $400 million. Making a further adjustment for value added, this increase in trade corresponds to the annual value of sales of about 6,500 average-sized farms in the United States. No one can argue that the MTN was a bonanza for U.S. agriculture, but the results are not to be ignored either.

The Dynamics of Supply: Retrospect and Prospect

Marc Nerlove

"... Per altra via, per altri porti
verrai a piaggia, non qui per
passare ..."

Dante Alighieri, *Inferno*, Canto III, vv. 91–92

It is, I think, safe to say that there are few topics of greater current interest than the agricultural production and food supply problems in low income and developing economies. In the preface to the proceedings of a recent conference on "Distortions of Agricultural Incentives," Schultz (1978) wrote:

> The biological constraints on potential food production have been substantially reduced by advances in agricultural research and by the availability of additional capital. But it has become increasingly evident that the adoption of the research contributions and efficient allocation of the additional capital are being seriously thwarted by the distortion of agricultural incentives. (vii)

I also concur in Schultz's belief that (1978)

> Farmers the world over, in dealing with costs, returns, and risks, are calculating economic agents. Within their small individual, allocative domain they are fine-tuning entrepreneurs, tuning so subtly that many experts fail to see how efficient they are. . . . (p. 4)

Often costs and returns which individual farmers confront are expressible in terms of market prices, although the risks they face are usually not so easily quantifiable. Whether such market forces, however, impinge directly and visibly on individual farm entrepreneurs, it will nonetheless be true, if we accept the presupposition of optimizing behavior, that shadow prices and opportunity costs are crucial determinants of agricultural supply. It follows that responses to changing "prices" for outputs and inputs, whether made visible by markets, must be a key element in our attempt to understand the agricultural production and food supply problems in low income and developing economies, as well as in the highly efficient and productive agricultural sectors of the developed and high income countries of the world

In what follows I examine what has been done on the problem of measuring agricultural supply response since the publication of my own work on the subject more than two decades ago (1956, 1958). Much of this work, that is available in English and done up to about 1976, has been exhaustively summarized by Askari and Cummings (1976, 1977), on whom I principally rely. Although many useful and interesting modifications have been made, particularly in applications to dynamically complex production processes, such as those for perennial crops and livestock, and to the study of agricultural supply response in developing economies, the adjustment and expectational models which were used in my own work remain basic in most of what has subsequently been done. In a lecture delivered in 1970 to the World Congress of the Econometric Society and later published (1972), I pointed out the ad hoc nature of most distributed lag formulations used in empirical

---

Kellogg 50th Anniversary Lecture.

Marc Nerlove is a professor in the Department of Economics at Northwestern University.

This lecture was written during Nerlove's tenure as a scholar-in-residence at the Bellagio Study and Conference Center of the Rockefeller Foundation and while a Fellow of the John Simon Guggenheim Memorial Foundation. The author is indebted to Rockefeller and Guggenheim Foundations for the environment in which, and the werewithal with which, to pursue this endeavor. Neither foundation is, of course, responsible for the opinions expressed.

The author also gratefully acknowledges many helpful conversations with colleagues at the Bellagio Center, John W. Mellor, and Uma Lele. The discussion of perennial crops at the end of sect. 3 draws on correspondence with M. J. Hartley of the World Bank. The author's deepest intellectual debt is to T. W. Schultz and D. Gale Johnson who have, over the years since his initial work on the subject, continued to shape and influence his ideas concerning agricultural supply response. The author's errors are his own. He also should like to take this opportunity to thank B. F. Stanton and the Executive Board of the American Agricultural Economics Association for the honor and opportunity offered to him in their invitation to present this lecture.

econometrics, including those resulting from the models used in my work on supply, and entered a plea for the development and implementation of "econometrically relevant" dynamic models of optimizing behavior.

It is easiest to see the need for such dynamic models in the case of production processes which are biologically of relatively long duration, such as those for perennials and livestock; moreover, the biological structure can be used, in the first instance disregarding the other durable inputs, to determine the dynamic structure (Carvalho 1972; Nerlove, Grether, Carvalho 1979, pp. 327–53). It should be emphasized, however, that the same arguments apply to any processes involving durable inputs, including structures, implements, and improvements to land, and it is less easy to develop appropriate models which capture essential dynamic features in these cases. Following a brief review of what has been done on the problem of measuring agricultural supply response, I turn to the question of how to make distributed lag formulations less ad hoc, in the sense of being based on dynamic optimizing behavior, specifically within the context of livestock and perennials.

This discussion does not fully resolve the dynamic problems involved in studying agricultural supply response in the context of a developed economy; moreover it does not touch at all on the essential dynamics of supply response in developing economies. Below, I suggest that to understand these dynamics it is essential to consider the causes of changes in the agricultural sector, the complex of forces set in motion by technological improvement, public investment in infrastructure and the development of markets, and the differential abilities of economic agents to deal with the resulting disequilibria. In most developing economies the agricultural sector is so large and so central to the whole process of economic growth and demographic change, that supply response cannot be treated as an isolated phenomenon. Moreover, in these economies, markets, at least as we know them in developed economies, may be poorly organized or may not exist at all; it follows that the relevant "prices" motivating producer behavior may be difficult, or impossible, to observe directly. Many of the trade-offs in the allocation of resources may take place within individual farm households or between these households and relatively isolated labor or product markets. Traditional methods of aggregative time-series analysis of supply cannot even begin to capture these kinds of responses.

Finally, I attempt to draw some general conclusions about the data and analytical methods needed to push forward the frontiers of our knowledge of the dynamics of supply in a complex and developing world.

Retrospect

In their exhaustive survey of the English language literature on agricultural supply analysis, Askari and Cummings (1976), take note of more than 600 estimates of supply response to price. The studies surveyed deal, for the most part, with annual food crops in developed countries or in areas for which reasonably good price date exist, e.g., South and East Asia. A number of studies surveyed cover nonfood annual crops such as fibers and tobacco, semiperennials such as sugar, perennials such as cocoa, coffee, tea, and rubber, and livestock and livestock products. The last group are all for developed countries for which livestock data are relatively complete. Although many of the studies, particularly those dealing with perennials, introduce important modifications and extensions, the basic model employed in most is the formulation I advanced some years ago (1956, 1958). Stripped to its essentials, this model for an annual crop consists of three equations:

$$A_t - A_{t-1} = \gamma(A^*_t - A_{t-1}), \tag{1}$$

$$P^*_t - P^*_{t-1} = \beta(P_{t-1} - P^*_{t-1}), \tag{2}$$

$$A^*_t = a_0 + a_1 P^*_t + a_2 Z_t + U_t, \tag{3}$$

where A_t is actual area under cultivation in t; P_t, actual price of the crop per unit in t; A^*_t, "desired" or equilibrium area to be under cultivation in t; p^*_t, "expected normal" price in t for subsequent future periods; Z_t, other observed, presumably exogenous, factors; u_t, unobserved, "latent" factors affecting area under cultivation in t; and β and γ are "coefficients of expectation and adjustment" reflecting the responses of expectations to observed prices and observed areas under cultivation to changes in equilibrium areas.

The statistical problems of estimating a model such as (1)–(3), particularly of identifying relevant observed exogenous variables, not subject to expectational lags, and problems due to serially correlated disturbances

are well-known. In addition, the use of area cultivated, one input in the production process to represent planned output, the problem of choosing the relevant price or prices, and other issues of specification, such as the inclusion of expected yields, weather conditions, and price and yield variances to take account of elements of risk, have been widely discussed in the literature.

Important modifications of the basic model have been made in connection with its application to cereals and basic food crops in developing countries. These commodities are at least partly consumed on the farms on which they are grown so that a key question becomes the response of marketed surplus to price. Among the studies of particular interest are those of Raj Krishna (1963, 1965) for rice and wheat in the Punjab, of Behrman (1966, 1968) for rice and other food crops in Thailand, and of Nowshirvani (1968) for a number of food grains in various regions of India. An important point made in these studies is the need to take into account the income elasticity of consumption within the farm household. Nowshirvani (1968, 1971) shows also, in a model involving both food grains and strictly cash crops and a farm-household utility function expressing risk aversion, that stabilization of food prices may sometimes lead to a reduction in supply. Askari and Cummings (1976, pp. 52–162) discuss a large number of such studies, including some for food grains in developed economies. Some of the investigations also introduced prices of other factors, size of farm, and variables related to irrigation, tenancy status, health, and so forth.

Using their collection of elasticities, Askari and Cummings (1976, pp. 342–82) attempt to get at some of the factors which might explain variations in supply response to price across regions and commodities, finding that higher income levels and larger farm sizes, availability of irrigation and reduced yield variability, greater literacy levels, and ownership as opposed to tenant-status, all increase responsiveness to variation in output prices.

I return below to some of the problems I see in these applications of the basic supply response model on a crop-by-crop basis in developing economies in which substantial changes are occurring in the availability of new varieties and of inputs other than land and labor, and in which major improvements in infrastructure are taking place.

Applications of the basic model have also been made to various nonfood annual crops such as cotton, jute, and tobacco. (See Askari and Cummings 1976, pp. 163–218.) Perhaps the most interesting applications and modifications of the basic model, however, are in connection with perennial crops. Such crops, once planted, yield a flow of output, continuously or discretely, over a period of years. Many are tree crops, which must mature several years after planting before any output is forthcoming, and for which thereafter yields are dependent upon the age of the tree and may also depend upon other inputs. In the earliest studies of perennials, the vintage or effect of the age distribution of the stock has been noted, and the decisions to plant new stock or cull older trees have been viewed as investment decisions under uncertainty, at least with respect to product prices, if not also input prices or prices of crops which might compete for land or labor. Moreover, the decision to harvest from a given stock at any particular time may also reflect opportunity costs or labor costs during and immediately surrounding the harvest period.

A number of difficulties arise in connection with the study of many perennial crops in developing countries. First, except in rare instances, continuous information over time is lacking on new plantings and current age structure, although such information may be available irregularly. This means that a key variable in the analysis, namely the age distribution of the stock, may have to be determined within the supply model itself, i.e., inferred from a time series of actual output (Hartley). Second, government intervention in the marketing of perennial crops is widespread. One effect, for example, in the case of Ghanaian cocoa, is to lead to smuggling of significant amounts of output. The existence of marketing boards which create substantial spreads between prices paid to producers and the prices at which the crop is sold and which hold large stocks of the commodity in question may also lead to significant problems in formulating appropriate models of expectation formation (Bacha). Third, as indicated above, there is frequently an imperfect relation between output and the stock of the perennial, since the existence of alternative uses of other inputs and variable prices and yields makes the decision not to harvest, or to harvest only partially, a viable option. Depletion of the stock may vary not only because of culling, but also because of the differential effects of

weather and disease. Finally, technical change in the form of improved varieties introduces a new element of uncertainty especially in view of the long-time horizon.

Notable among the studies of perennials are those of Bateman (1965a, b, 1968), Behrman (1968b) and Stern (1965a) on Ghanaian cocoa; Behrman (1969), and Stern (1965b) and Chan (1967) on Malaysian rubber; and by Arak (1967, 1968, 1969) and Bacha on coffee. Most of these studies utilize stock adjustment models and price expectation formation models similar to (1) and (2) above, but adapted to the long lags involved between planting and the emergence of output. Stocks are inferred from a sequence of outputs so that the models quickly become rather complicated, especially when a competitive relation between several perennial crops is considered. Wickens and Greenfield have been critical of previous investigations for neglecting the important distinction between investment and harvesting decisions and have attempted to estimate a more complex model for Brazilian coffee. The most elegant work to date on perennials is that of French and Matthews on U.S. asparagus (a perennial crop with a bearing life of ten to fifteen years). Their model distinguishes between the quantity of produce and bearing acreage, new plant, and removals of old plants. It must be recognized, however, that the data available are greatly superior for this crop than for most perennials important in developing countries.

Livestock and livestock products have been studied mainly for developed economies. The most common approach has been to employ some variant of the adjustment model (1) applied to a measure of "capital stock." In the case of milk, for example, in which production is continuous, seasonal factors have been introduced. Various combinations of current and lagged prices are used but rarely has much specific attention been devoted to the problem of expectations formation. A large number of studies are summarized by Askari and Cummings (1976, pp. 299–341) notable among which are Halvorson, Gardner, and Gardner and Walker on milk, Dean and Heady on hogs, and Jones, and Jarvis (1969, 1974) on beef. My own work with Carvalho and Grether, and Carvalho is discussed below since it is of a rather different character than the aforementioned studies.

While Jarvis (1969, 1974) did attempt to estimate a specifically capital-theoretic model, he was handicapped by lack of data on births and had to reconstruct them from herd size, slaughter, and deaths. Mascolo had similar problems in his study of the Brazilian cattle industry in which, however, he attempts to follow the lines of Nerlove, Grether, and Carvalho; and Carvalho.

Despite the greater complexity of perennials and livestock in a dynamic sense, there does not appear to have been an attempt to go beyond an essentially static formulation of the demand for the stock from which output is produced. Dynamic considerations are introduced through fixed, biologically determined lags together with ad hoc stock adjustment and/or price expectation formation models, such as (1) and (2), originally used in the study of animal crops. In the next section, I address myself to this issue and show how more econometrically relevant dynamic models can be constructed for livestock and perennials under certain simplifying assumptions. Many of the same arguments can be made with respect to annual crops if long-lived capital equipment, structures, or land improvements are significantly involved in production. In the section following the next, I take up the far more serious difficulties encountered in the study of agricultural supply response within the kind of dynamic setting encountered in a developing economy in which the agricultural sector is concurrently being transformed from traditional to modern.

Distributed Lag Models of Supply Response Based on Dynamic Optimization Behavior

The basic supply response model discussed in the preceding section incorporates dynamic elements in two different ways: First, a distinction is made between a long-run equilibrium position toward which producers are assumed to be moving and their current position. The former is determined on the basis of a static theory of optimization, in this case the standard microeconomic theory of the firm and the assumption that the exogenous variables of the problem, in this case mainly prices, are given once and for all. Elsewhere (1972, p. 225), I have called this the assumption of static, or stationary, expectations. The important point is that whatever these expectations are and however they are formed, the concept of a long-run equilibrium solution to the optimization problem is well-defined only if it can be assumed that the values of the

exogenous variables expected in the future are unchanging; it does not matter if the constant future value of each variable differs from its current value, as indeed it plausibly will. Having a well-defined notion of a long-run equilibrium position then permits us to examine the question of why producers are currently at a position different from that equilibrium. At this point the discussion usually becomes vague; one can argue in various ways (Nerlove 1972, pp. 228–31), but perhaps the most common approach is through the introduction of adjustment costs. Rarely, however, are models explicitly introducing these costs formulated or the rationale for such costs carefully examined. (The literature up to about 1970 is surveyed and two models of investment behavior incorporating both separable and nonseparable adjustment costs are discussed in Nerlove 1972, pp. 231–41; see also Nerlove, Grether, Carvalho, pp. 317–20.) The dynamic element in the basic supply response models is introduced at this point without a formal theory by the simple ad hoc assumption that each period, if we are dealing with discrete time, a fraction of the difference between the current position and the long-run equilibrium is eliminated, i.e., equation (1) above.

In the next section, I argue that the matter of adjustment to equilibrium, if indeed equilibrium is an appropriate concept, in the agricultural sector of a developing economy in the process of transformation is far too important to be treated in such an ad hoc manner. The simple adjustment process assumed in the basic supply response model is undoubtedly also inadequate to describe the dynamics of supply in a developed economy in which technical change is occurring at a rapid, if uneven, rate, and in which the demands for agricultural outputs and the supplies of inputs are subject to substantial shifts. In the case of perennials and livestock, however, there is no need to introduce an ad hoc adjustment model since the intrinsic biology of the production process already provides most of the essential dynamic structure.

The second way in which dynamic elements are incorporated in the basic supply response model is through a description of expectation formation, e.g., the adaptive expectations generated by equation (2), in which expected "normal" prices are revised each period in proportion to the difference between last period's observed price and the previous expectation. Above, I argued that static, or stationary, expectations are necessary to make the concept of a long-run equilibrium meaningful; the adaptive expectations model does not violate this principle, since it is not solely next period's price to which P^*_t refers but "normal" price, i.e., an average price expected to prevail in all future periods. The argument that farmers rationally should respond, not to the best forecast they can make of next period's price, but rather to some average or "normal" level, rests intuitively on the idea that there are costs of adjustment. However, virtually any plausible model one can construct, with costs of rapid adjustment of, say, a durable factor of production, will generally involve response to prices in many future periods although the weights which attach to the more distant future will usually be less than to the near future. Moreover, unless the optimization problem has a specific form, it will generally be nonoptimal to behave as if one were responding to a point estimate of each future value. (Theil; see also the discussion in Nerlove, Grether, Carvalho, pp. 334–37.) When the optimization problem is of this specific form, however, we say that there exist certainty equivalents to the uncertain future values of the variables to which response is occurring. Such certainty equivalents are the conditional expectations of the variables to which they refer; they are minimum-mean-square-error forecasts based on the information available up to the time the forecast is made and taking into account the structure of the system generating the data. Muth (1961) has termed such forecasts "rational expectations."

Apart from whether they are certainty equivalents, when are adaptive expectations rational in the sense of being conditional expectations? Muth (1960) provided an early answer to this question which I later generalized (1967). For a simple unobserved-components model of the time series of, say, prices, it can be shown that the minimum-mean-square-error forecast for next period and for every future period is the same exponentially weighted moving average of past values (Nerlove, Grether, Carvalho, pp. 320–23). In general, several endogenous variables, such as prices and quantities, will be determined by a series of structural relationships, such as supply and demand functions, reflecting the behavior and expectations of different groups of economic agents, such as farmers and consumers. In this case, the behavior of farmers who respond to

conditional expectations of an endogenous variable, such as price which is determined in the market by the equilibrium of supply and demand, cannot be characterized so simply; generally the distributed lag relationships will contain parameters of the structural system, as well as parameters reflecting the serial properties of the structural disturbances. These relationships among the structural parameters and the characterizations of the conditional expectations of endogenous variables imply certain restrictions on the form of the minimum-mean-square-error forecasts of future variables.

Time-series modeling and forecasting is a complex subject of considerable current interest. Much of the recent literature leads away from the structural equation approach of traditional econometrics. Single and multiple time-series models are formulated in terms of fairly simple moving-average autoregressive processes (ARMA processes) involving relatively few parameters (Nerlove, Grether, Carvalho, pp. 103–46). If the exogenous variables of a structural system are expressible in terms of ARMA processes, or if their effects can be removed prior to analysis, then under certain conditions, the final form of a structural equation system can be reduced to one in which each endogenous variable is expressible in terms of an ARMA process, which, however, may be relatively complex and involve restrictions across the various representations (Zellner and Palm; Wallis). A simple supply and demand example is contained in my recent book with Grether and Carvalho (pp. 302–308). There, we call conditional expectations, or minimum-mean-square-error forecasts, based on univariate or multivariate time-series analysis neglecting such restrictions as may arise from the simultaneous determination of several endogenous variables with a structural system, quasirational expectations. Such forecasts are easy to obtain by formulating and estimating relatively simple univariate or multivariate time-series models (a univariate model being one in which only information on the past of the series itself is used, whereas a multivariate model allows the information contained in the past values of related series to be used in estimation and forecasting). If we assume the economic agents, whose behavior we are attempting to describe, are aware of the underlying structure, quasi-rational expectations offer an approximation to fully rational expectations and a far less arbitrary, less ad hoc, approach to expectation formation than the adaptive expectations used in the basic supply response model. In general, however, such forecasts will not be the same for different future periods, i.e., they will not represent static or stationary expectations in the sense defined above.

If, then, we reject the adaptive expectations model, and, with it, the proposition that farmers respond to the expectation of some average of prices in all future periods, we must also dispense with the notion that farmers are adjusting toward a well-defined, long-run equilibrium in each period, because this equilibrium is well-defined only for stationary expectations. I hasten to add that this does not mean stationary equilibria are totally irrelevant in the analysis of agricultural supply response; indeed, a long-run equilibrium with stationary expectations may characterize traditional agriculture in countries prior to development and may approximate the final position of farmers after response to a one-time major shock. This, however, is not dynamics but comparative statics. As I have argued elsewhere (1972), an econometrically relevant dynamic theory would characterize response paths of economic agents who are optimizing their behavior under dynamic conditions and forming expectations of the future on the basis of all information available to them. Such a theory would not, in general, involve the notion of a long-run equilibrium toward which adjustment is being made nor simple forms of stationary expectations. Formulation of models based on this principle is not an easy task, nor may you think it worth the effort when you have seen the example of a recent attempt to model the U.S. cattle industry, to a brief sketch of which I now turn.

A simplified model of the U.S. cattle industry was developed and estimated by Carvalho; a modified version of this model is presented and reestimated in the final chapter of Nerlove, Grether, Carvalho pp. 327–53). Neither the market for feed nor the milk sector are considered explicitly, although these markets impinge on the cattle market through the costs of inputs and the prices of beef, especially utility beef and veal, which come in large part from the dairy sector. The reproductive herd consists of cows, heifers older than eighteen months, and bulls. The latter are neglected. We assume the production of young animals to be proportional to the size of the reproductive herd and than one-half of these are males

which are castrated to become steers. The optimal decision concerning heifers is whether (*a*) to slaughter, (*b*) to place on feed, (*c*) to add to the reproductive herd, or (*d*) to breed, in which case the heifer becomes a cow by definition. In the case of a steer, however, there are only two choices: (*a*) to slaughter now, or (*b*) to keep on feed. Cows may be (*a*) kept in the reproductive herd, (*b*) placed on feed, or (*c*) sold for slaughter. Additions to the stock of cows occur through the addition of newly bred heifers; subtractions occur through the sale of cows for slaughter or natural mortality. (The latter is small and we neglect it.) Because there are biologically determined lags between the time a cow can be bred and the time her offspring can be slaughtered, added to the reproductive herd, or placed on feed, and because there are intrinsic costs of aging which make it unprofitable to hold an animal forever, there is a natural dynamic structure in this problem: What the producer does now will affect the constraints under which he operates for some time into the future, but not forever; therefore his current decisions must reflect what he now expects conditions will be in relevant future periods; but, because the lags involved are finite and animals cannot be held forever, the indefinite future does not matter. The same dynamic characteristics also apply in the case of perennial crops. When long-lived capital is involved in a production process, then, in principle, the distant future is involved in current decision making, but, if the future is discounted and if capital depreciates, in practice only the near future will matter.

In the empirical example reported in Nerlove, Grether, Carvalho (pp. 338–53), we choose calendar quarters as our observational unit. Specifically: the gestation period is nine months or three quarters; we assume births are proportional to the stock of cows in the reproductive herd and that one-half of all births are male; bulls are neglected and we assume that an animal is not considered as added to the stock of heifers or steers on feed nor to the reproductive herd until nine more months have passed. The decision variables each period are numbers of (*a*) steers to be sold, (*b*) heifers to be sold, (*c*) heifers to be bred, i.e., placed in the reproductive herd, and (*d*) cows from the reproductive herd to be sold for slaughter. Given prices for steers, heifers, and cows, gross revenues are a linear function of the numbers sold in each category provided we assume, as a first approximation, that price is independent of age; however, in our formulation we also introduced quadratic terms reflecting "aging costs" for each of the three categories, so that longer retention of an animal results in a lower "net" receipt. The decision variables are conditioned by the stocks of steers and heifers on feed, by the size of the reproductive herd, and by births nine months ago. The decision variables and conditional variables are constrained by a set of linear identities expressing our assumptions about the nature of the lags involved. In addition to aging costs, we assume quadratic costs for maintaining animals on feed or in the reproductive herd, different for steers, heifers, and cows, and an additional quadratic cost for maintaining calves each period prior to the time at which they can be allocated to one of the stocks or slaughtered. We also assume a "breeding" cost over and above the cost of maintaining a cow in the reproductive herd. Feeding costs plus aging costs are assumed to reflect variations with age both in the ability of an animal to transform feed into flesh and the decreasing value, *ceteris paribus*, of older animals. We assume that the cattle producer makes his choice so as to maximize the expected discounted present value of future net revenues from sales of steers, heifers, and cows to some finite, but distant horizon (retirement), subject to uncertain future sales prices but known constant aging, feeding, breeding, and maintenance costs and a constant rate of discount. Because of the structure of the problem, the finiteness of the horizon, in fact, turns out not to matter.

Because our objective function is quadratic in the decision variables and the uncertain prices and since all the constraints among these variables are linear (see Nerlove, Grether, Carvalho, pp. 335–37), there exist certainly equivalents for the unknown future prices, namely their conditional expectations at decision time, given past values of these variables, which, in the present problem, we assume are all the information at the disposal of the cattle producer. (In a more complete and complex model we might also wish to consider demands for various types of cattle as well as the market for feed and other inputs; in this case the distinction between rational and quasirational expectations would become important.) The existence of certainty equivalents means we can replace prices by their conditional expectations and proceed as if we were dealing with a problem of decision mak-

ing under certainty. The problem as formulated is now a relatively simple dynamic programming problem which, if numerically specified, could be solved by standard methods. However, as we have set the problem up, it is not numerically specified: the discount rate and aging, feeding, and maintenance costs are all behavioral or technological parameters, or some combination thereof, to be determined by estimating the model. What equations do we estimate? Presumably one each for each of the four decifion variables: The stocks of steers and heifers, the size of the reproductive herd, and new gross investment, i.e., the number of heifers added to the reproductive herd. Alternatively, equations determining any four equivalent variables related to the foregoing by the identities referred to above may be estimated. To find these equations, we must solve the dynamic programming problem algebraically in the usual recursive manner, backwards from the end of the horizon; the solution will generally differ depending on the number of periods to go to the end of the horizon; however, because of the nature of the lags involved, the solutions "stabilize" after a certain number of periods back. The number of periods differ for the different variables: It is only one quarter for steers, but five periods for heifers and additions to the reproductive herd, and four periods for cows. (See Nerlove, Grether, Carvalho, pp. 345–66, for an intuitive explanation.) When we say the solution stabilizes we mean that it is the same after, say, six periods as it is after five. A stable solution equation thus characterizes current producer behavior and provides a basis for estimation.

The characteristics of the stable solutions are as follows: The "own-demand for the stock of steers" depends upon the current price of steers in relation to the price expected next period and the size of the reproductive herd four periods ago. The "own-demand for the stock of heifers" depends on the current price of heifers in relation to the expected prices, one, two, five, six, and seven periods from now, the current price of cows in relation to the expected prices one through four periods from now, the expected prices of steers five, six, and seven periods from now, and the current and past four values of the size of the reproductive herd. Similarly, gross additions to the reproductive herd and the own-demand for the stock of cows depend on the current and expected future prices of heifers and cows, and the expected future prices of steers, and certain past stock variables. If we now formulate time-series models, in principle multivariate but possibly univariate, in order to obtain quasi-rational expectations as minimum-mean-square-error forecasts, the latter may now be substituted for the unknown conditional expectations of future prices. In this way, implicit distributed lag relationships are obtained; however, it should be emphasized that the behavioral relationships deduced in this manner do not explicitly involve any distributed lags. If the exogenous variables which drive the system, in this case the prices of steers, heifers, and cows were suddenly to become fixed at certain levels and thereby cease to follow the time-series models we had estimated for them, but cattle producers, implausibly, continued to assume that they did, the system would proceed over time to an equilibrium solution in which all variables remained unchanged forevermore. The same equilibrium would be reached, although the path to it would be different, if the same levels of prices were announced and believed with certainty. But this equilibrium is only implicit in the dynamic structure; it does not, in any sense, correspond to a long-run equilibrium position which is continually changing and toward which cattle producers are continually adjusting.

Although it is undoubtedly grossly oversimplified as a model of U.S. cattle production, we have estimated the model partially for the period 1944–69, using quarterly data. The results are reported in Carvalho and modified results in Nerlove, Grether, Carvalho (pp. 348–53). The reader is referred there for the empirical detail. My discussion here serves primarily to illustrate how econometrically relevant dynamic models of behavior can be constructed on the basis of optimizing behavior without recourse to the many arbitrary or ad hoc assumptions. Some of the latter must, of necessity, remain in any practical formulation, the most crucial of these being the assumptions necessary to obtain a problem in which relatively simple certainty equivalents exist.

In the absence of substantial technical change and/or rapid developments in intrastructure or markets, such as frequently characterize agriculture in developing countries, perennial crops are also susceptible to analyses similar to the one described above for livestock, but certain features of perennials

make the existence of relatively simple certainty equivalents doubtful.

Both because of the longer time horizon involved and a number of other characteristics, the analysis of supply response for perennial crops is likely to be more difficult than for livestock. First, the decision to plant such a crop is normally made far in advance of the expectation of any output. Even after output is forthcoming, the yield typically varies over the lifetime of the plant reaching a peak some years after initial output, maintaining a roughly constant level for a number of years, and then beginning a slow decline to eventually uneconomic levels. The pattern of yield may be varied somewhat by other inputs, but more importantly by choice of variety. During the initial phase of no output, and sometimes even beyond this period, the perennial may be interplanted with other crops. Second, whereas in the case of annuals the decision to harvest or not usually represents an insignificant aspect of supply response (but see Nerlove, 1958, pp. 112–21), harvesting costs typically represents a major part of the costs of production in the case of a perennial, so that knowledge of the age-distribution and yield profile of the existing stock of plants provides only an upper bound to potential output. Third, the stock of plants may be depleted over time not only by deliberate action of the producer to cull unproductive plants in the older age groups, to replant or replace existing plants with higher yielding varieties, or to plant alternative crops, but also by the differential effects of weather and disease. One cannot deduce the age distribution of the stock from a knowledge of past plantings alone. Moreover, the effects of poor weather or disease upon yields may be spread over a number of years.

As in the case of livestock, it is possible to formulate a dynamic programming model which can take into account the main features of perennial production. Apart from data limitations, which are typically very serious in the case of most perennials (Hartley), the chief difficulties appear to be the nonlinear constraint introduced by the bounding of harvested output by potential output and the additional uncertainty, beyond the uncertainty of future prices and costs, of yields due to weather and disease, but, more important, also as to the introduction of new plant material with highers yields. For example, in the case of rubber, research in Malaysia on the agronomy of natural rubber in the past twenty-five years has led to a more than threefold increase in commercial yields as new clonal materials have replaced previously unselected seedlings or inferior stock. I will return to the question of how new technology affects the dynamics of supply in the next section, but note here that its possibly discontinuous nature and uncertainty regarding when a new variety or new material may be available introduces a whole new dimension in the case of a long-lived perennial which is not present in the case of an annual crop. Unless harvests are normally well below potential always, a very implausible circumstance since one could not then explain why so much of the crop had been planted in the first place, the nonlinear boundary condition in itself would preclude the formulation of a dynamic optimization model having single-valued certainty equivalents. Even approximate certainty equivalents would be ruled out in this case (Malinvaud). The discontinuous nature and uncertain timing of technological change and the effects of weather and disease on yields would also seem to rule out single-valued certainty equivalents. Without such certainty equivalents, the dynamic programming model formulated and solved as if future prices, costs, and yields were known with certainty no longer represents a structure into which we can introduce quasi-rational or rational expectations based on time series of past prices, costs, and yields. No doubt, as additional work on perennials is undertaken, these issues will be resolved initially in an ad hoc manner with different analysts concentrating on different aspects of the problem.

Supply Response during Agricultural Transformation

In *Transforming Traditional Agriculture*, Schultz argued that farmers in traditional agricultural settings, while they may differ for reasons of schooling, health, and experience in their ability to perceive, interpret, and respond to new events as these impinge on their farm enterprises, do in fact allocate the limited resources at their disposal in a highly efficient manner. But within a traditional agricultural setting few adjustments are required and those which do occur are typically not large.

One can imagine an agricultural sector in which no changes in technology, infrastruc-

ture, markets, and so forth, have occurred for a long time. Under such "stationary" conditions, farmers may be poor, uneducated, and slow to perceive or respond to change. They may, nonetheless, be in virtually perfect adjustment to their environment and attain an efficient allocation of resources. In the case of a largely subsistence agriculture there may be few price signals to which to respond. Efficient allocation of resources largely consists then of proper allocation of time, land, and whatever limited physical capital exists in various household activities which include, not only farming, but other types of household production and consumption, the rearing of children, and such limited gross investment in human and physical capital as may be necessary to maintain existing stocks. If farmers have limited needs for goods they themselves cannot produce and limited opportunities for off-farm employment, markets and the infrastructure of communications and transport may be poorly developed or virtually nonexistent. In this case, one can learn very little about potential supply response to price or other changes by observing past behavior. One might infer little supply response to prices observed in central markets, for example, simply because such prices are largely irrelevant to the allocation problems which these farm households resolve.

Even when farmers sell a substantial fraction of their output of certain crops and buy other goods they need, fluctuations in market prices may induce little response simply because such changes are due to weather or other temporary factors which have little long-term significance for the allocative decisions being made.

Schultz (1975) puts the matter well and succinctly:

> Farm people who have lived for generations with essentially the same resources tend to approximate the economic equilibrium of the stationary state. When the productive arts remain virtually constant over many years farm people know from long experience what their own effort can get out of the land and equipment. In allocating the resources at their disposal, in choosing a combination of crops, in deciding on how and when to cultivate, plant, water, and harvest, and with what combination of tools to use with draft animals and simple field equipment—these choices all embody a fine regard for marginal costs and returns. These farm people also know from experience the value of their household production possibilities; in allocating their own time along with material goods within the domain of the household, they too are finely attuned to marginal costs and returns. Furthermore, children acquire the skills that are worthwhile from their parents as children have for generations under circumstances where formal schooling has little economic value. (pp. 831–2)

It is doubtful whether such a stationary state now exists or has ever existed, although it may have been approximated in certain times and places (a point made very clearly by Schultz, 1964). In modern agriculture, or in an agricultural sector in the course of modernization, constant changes are occurring. These changes are typically large, frequently discontinuous, and require major reallocation of resources both within the agricultural sector and between agriculture and the rest of the economy. Moreover, more often than not, these changes are not reflected in "visible" prices, although in market-oriented economies major shifts in the demand for various agricultural commodities or in the supply of inputs used in agricultural production do take the form of price changes. In the supply response studies discussed earlier in this paper, and, indeed, in my discussion of models of response based on dynamic optimization, I tacitly assumed that "visible" prices convey all of the information to which farmers find it necessary to respond. This is certainly not true even in recent times in a highly developed economy such as we have in the United States.

In the last fifty years we have experienced two major changes in U.S. agriculture, as well as, of course, a continuing sequence of lesser changes due to shifts in demand and supply and ongoing agricultural research. The first of these was the development and spread of hybrid corn, so well documented by Griliches. While it may be true that the differential spread of hybrid corn in the U.S. can be explained in terms of differing costs and returns and farmers' perceptions of these differences, such a formulation is not particularly useful in understanding the complex of forces related to the supply of research and discovery which brought about the change and which governed its rate of spread. On the other hand, the second major change, the remarkable fall in the cost of nitrogen fertilizer, which took place in the 1950s and early 1960s and which resulted in a significant increase in the optimal amount of such fertilizer applied to a variety of crops, was essentially a price phenomenon. Yet, as I think is shown by the studies of Huffman (1972, 1974, 1977), the changes which took place cannot be explained dynamically solely

in terms of relative prices. There is virtually nothing in the production process for corn, for example, which would have prevented an almost instantaneous complete adjustment, yet the adjustment did take time and the speed with which it occurred varied substantially in different parts of the Corn Belt. Using county data for the period 1959–64, during which prices of nitrogen relative to corn fell about 25%, Huffman computes a partial adjustment coefficient showing actual changes during the five-year period as a fraction of the changes by county necessary to achieve an optimum as determined from a production function for corn estimates from agronomic data. His major finding is that the speed of adjustment varies systematically across counties with respect to average levels of extension services provided, farmers' education, and farm size. One could not have predicted such results on the basis of the type of dynamic model discussed in the preceding section of this paper. If the production function is shifting and not completely known by producers, processing and dissemination of information and its incorporation into the optimization process constitute a more important part of the dynamics of supply than the issues we have raised thus far.

Two additional points are worth making in this connection: The research process, especially in the United States, has become institutionalized to such a degree that it and farmers' continuing responses to the wide range of new opportunities constantly opening up to them have become a central characteristic of the dynamics of supply in modern agriculture. Second, developments in the industries supplying inputs to agriculture are not unrelated to other types of research, such as the continued development of new varieties of plants which use fertilizer and water more effectively or lend themselves more readily to mechanized cultivation and/or harvesting. The impact of the fall in fertilizer prices would have been far less without the hybrid varieties, and, conversely, the profitability of the new varieties would have been less great with higher fertilizer prices.

What lessons does the U.S. experience hold for understanding agricultural supply response in developing countries today? I return to the theme on which I touched at the very beginning of this paper: To understand the essential dynamics of supply in developing economies, we must consider the causes of change in the agricultural sector, the complex of forces set in motion by technological improvement, public investment in infrastructure and public health, the development of markets, and the differential abilities of economic agents to deal with disequilibria. From what I know of agriculture in developing countries, I would suggest several major sources of change in agriculture during modernization:

(*a*) As investments are made in better communications, transportation, and other types of infrastructure, there are greater opportunities for markets of all kinds to develop. In consequence, price signals are likely to become more important, not less, as farm people become less isolated. Moreover, the markets and prices which are important in understanding the dynamics of supply are not limited to product markets and prices. Clearly, inputs such as fertilizer, farm implememts, herbicides and insecticides, better seeds, and so forth, are increasingly purchased and used. But labor markets also develop more fully and farm people begin to respond to opportunities for off-farm employment, part-time, seasonal, and permanent. The impact of changes in the labor market on supply response may be at least as great as the impact of changing product prices.

(*b*) The process of technical change in agriculture accelerates and becomes increasingly institutionalized and indigenous. Improvements in varieties of plants and animals and in the other inputs which are necessary to make these varieties more productive become an increasing source of supply response. The dynamics of supply under these circumstances can be understood only by understanding the determinants and manner of adoption of new agricultural technology and how it comes to be produced on a continuing basis. The so-called "green revolution," the rapid adoption of new, highly productive wheat varieties by the small, financially poor, uneducated farmers of the Punjab is perhaps somewhat misleading in this connection. To be sure, this event, and others like it the world over, and the development of international agricultural research centers, have had a major impact on supply. Continued change, however, is likely to rest more on a series of smaller, less dramatic developments, the perception of which will require improvements in the abilities of farm people to adapt to maintained disequilibria. Improvements in rural educational facilities, especially literacy and extension services, and

in other infrastructures such as facilities for irrigation, drainage, and other forms of water control, must play an important role in these developments. Many of these require major public investments, but the ability and willingness of farm people to take advantage of the increased availability of educational and extension services or the public provision of certain types of infrastructure can come about only through changes in the nature of private investment, especially in human capital but also in on-farm physical capital.

(*c*) Demographic change which accompanies the process of agricultural transformation and economic development is a crucial element in agricultural supply response. To an important extent these changes are initiated by improvements in public health which result in sharply decreased mortality, particularly infant and child mortality, and in control and/or eradication of debilitating diseases which make human labor less productive than it would otherwise be. However, many of the demographic changes which occur have their roots in the individual decisions of farm people to make greater investments in human capital in the form of greater education and better nutrition for their children and to have fewer children, as other forms of saving and provision for old age become available, as labor markets improve, and as there is an increased awareness of opportunities outside of the agricultural sector. Such demographic changes alter the nature of agricultural production, lead to increased use of nontraditional inputs, and to a greater reliance on markets, and thus alter the nature of supply response to prices and other factors.

(*d*) Naturally, the role of government in this process is important, and there are many areas in which, and points at which, government intervention is both necessary and desirable. But this should not be allowed to obscure the fact that governments are continually tempted to intervene when they should not and in ways which may seriously impede agricultural development and distort the incentives and signals which prices provide in modern agriculture. Marketing boards which supposedly regularize the flow of product from producer to market or stabilize extreme price fluctuations frequently hold down the prices producers receive; protection of domestic industry, such as fertilizer, serves to make more costly the things that farm people buy; taken together, serious consequences may follow, as the infamous case of rice production in Thailand serves to indicate.

While all of these arguments suggest that increased production is more dependent upon factors other than price, they do not mean, as Johnson has so cogently pointed out (pp. 210–13), that prices do not matter very much and that they can be used to accomplish other goals and objectives. As he says:

> Prices do matter. Prices affect decisions made by farmers—how much fertilizer to use, how to allocate this land and labor among crops and whether it pays to invest in tube wells or in improvements or irrigation systems. But prices also matter to others who have direct relationship to agriculture—research institutions, producers of farm inputs, credit agencies, and extension agents. Where the price of fertilizer is five to ten times the price of grain, there is little point in research institutions undertaking research on methods of applying fertilizer or on crop varieties that will give a significant response to fertilizer. Firms will be reluctant to produce farm inputs for which demand is restricted by low farm-product prices. Similarly, the supply of credit—as well as the demand for it—is affected by farm output prices.
>
> If there is continuing investment in research resulting in a flow of new varieties, new methods of protecting plants from diseases, insects and rodents, investments and improvements in irrigation, and readily available supplies of modern inputs at reasonable prices, increase in [product] prices will evoke much larger increases in output than if some or all of these conditions are not met. . . . But this in no way implies that prices are not important. (pp. 211–12)

Because of the inevitable tendency of governments to interfere with markets and prices, however, the problems of untangling supply responses are made doubly difficult. In the short run price uncertainties may be reduced by such interventions, but reduced uncertainty is not at all clear in the long run. Uncertainties with respect to the behavior of government may be far greater than uncertainties with respect to the behavior of weather and markets. Supply response occurs in a complex and interrelated system of which government is one element. Prices and other factors such as those discussed above affect not only farm people but also numerous institutions related to agriculture and agricultural development. The dynamics of supply in developing nations and in agriculture in the process of transformation cannot be fully understood without taking these complex interrelationships into account. It is doubtful whether studies based on historical relationships of the output of a single crop, or the area devoted to its cultivation, in rela-

tion to past prices can shed much light on these issues or even on the role and importance of prices and markets.

Prospect

Since the publication of my own work on the subject—eons ago it now seems to me—there have been numerous well-done studies of supply response to price in both developed and developing countries. Real interest, however, centers on the dynamics of supply in agricultural sectors undergoing the transformation from traditional to modern agriculture. In this paper, I have emphasized the simplistic and relatively ad hoc nature of the basic model I used so long ago to study the response of U.S. farmers to price in the production of corn, cotton, and wheat in the period prior to the introduction of price supports and acreage allotments. It is inadequate, despite the many ingenious modifications and additions others have made to it, either to model dynamic optimization in response to changing prices or to understand the true nature of dynamic supply response in the context of a developing economy.

To overcome the first sort of inadequacy is a challenging intellectual problem from both a theoretical and an econometric point of view. I have, perhaps, dwelt overly long on some of the ways in which distributed lag models of supply response based on dynamic optimization under uncertainty can be developed for livestock and perennial crops. In defense, I plead current involvement in research on these problems, rather than a sense of their importance relative to the second group of difficulties I have discussed here. Given a sufficiently adequate data base and enough intellectual effort and ingenuity, I am confident that the former can be satisfactorily resolved.

The inadequacy of the basic supply response model to disentangle the forces shaping agricultural supply in the context of a developing economy is far more serious. We are lacking both the necessary theoretical and econometric tools and the basic data. To be sure there exist time series data and other information in scattered instances for individual crops in particular areas which make it possible to do the more standard types of analysis with or without modifications along the lines suggested in my discussion of livestock and perennials. Along these lines perennials, so important to the economies of many developing countries, appear to offer the greatest opportunities for fruitful research. But, at best, such studies can yield only a partial and limited understanding of the dynamics of supply in developing countries. These dynamics are the result of a complex interaction of household and economy, which extends beyond the demographic-economic interactions I discussed in an earlier paper (1974). A variety of institutions, markets, and other phenomena must be related to one another in a process which extends over both time and space. Neither the data nor the theory are at hand in any very complete form.

What hope have we then for understanding the dynamics of agricultural supply in developing nations and what are the prospects for fruitful research? Notwithstanding my pessimism about the current state of affairs, I am optimistic with respect to the future. Economists have become increasingly involved in the collection and analysis of basic data at the microlevel of household or firm by special surveys or using census instruments. More often than not surveys are the only way to collect information on household time allocation, adoption of modern agricultural practices, fertility, and labor force participation, and, for firms, on expectations, plans, and realizations. The last decade has witnessed a resurgence of interest in the "new home economics" and the development of new theoretical and analytical tools which can be applied equally to farm households in developing nations. New econometric techniques for the analysis of microdata, particularly categorical data from surveys, are being adapted from earlier uses in biostatistics and sociometrics (e.g., Nerlove and Press; Koenig, Nerlove, Oudiz). We can, by special surveys and these methods of analysis, gain considerable insight into many of the basic phenomena underlying supply response in transitional and developing agriculture, particularly with respect to the adoption of new techniques and the demographic-economic interactions at the microlevel which are so crucial. The tangled web of the effects of government interventions, investments in infrastructure and the development of markets may be less susceptible to purely econometric analysis, but considerable progress can be made in understanding these phenomena by in-depth case studies and clear, if simple, economic reasoning. Sophisticated econometric techniques and high-powered

economic theory are complementary, not antithetical, to case studies and common sense.

Inflation, Agriculture, and the Food Economy
(G. Edward Schuh, University of Minnesota, Chairperson)

Commodity Programs and Inflation

J. B. Penn

Inflation has been identified by many as the nation's number one economic problem. And that makes the theme of this plenary session—inflation and its pervasiveness in agriculture and the food system—especially timely. Unfortunately (and perhaps inexcusably), we have woefully little rigorous analysis of the subject to allow comprehensive assessment of impacts. We can, then, hardly be prescriptive. The role of the agricultural commodity programs in the performance of the national economy and their contribution to the persistent inflation is complex. The complexity has grown in this decade with the increased interdependence of the agricultural sector and the national economy.

This paper identifies and explores the major considerations necessary for full and complete analysis of the costs and benefits of these programs to society, especially the inflationary impacts. I will discuss the impacts of inflation on the agricultural sector and the commodity programs, the role of commodity programs in affecting the national price level, the mechanism by which agricultural prices are transmitted through the economic system, and some issues and research areas important to future public policy decisions.

Background and Current Setting

Agriculture has a dual role in inflation—it is both perpetrator and victim. And, of course, the distributive impacts are ever present; seldom are the groups that benefit from (cause) inflation the ones most immediately victimized by it. But everyone is eventually victimized by inflation. So, why this paradox? Why do people urge their special interest, such as the commodity programs, when short-term gains must surely be overtaken and hugely outweighed by long-run adversities?

Expectations and Self-Interest

We have seen another curious paradox in recent public opinion polls of the national mood. Most individuals feel they are doing well and have bright prospects. Yet, they feel that the country is in poor shape and has an uncertain future.

This split personality of the American public exhibits an incongruity between personal and national expectations which cannot exist forever. Individuals eventually will cease to prosper if the nation ceases to prosper.

This apparent irrationality may well derive from the subject of this session, inflation. It is directly related to the subject of this paper: the farm commodity programs, part of a growing concern over special interests versus the national interest.

A popular phrase, the "Me-First" decade (or generation) is used to characterize our present situation: one where people focus so closely on their own economic position that the national interests become blurred. This condition is not only condoned but supported by public policy. Such selfishness is most evident in efforts to control inflation. The public tells the opinion pollers that inflation is the nation's number one economic problem. Further, all agree that the most strenuous effort should be made to halt inflation, so long as the burden falls on someone else. The cry of the me-firsters is loudest when any attempt is made to rationalize federal programs—with a view toward improving efficiency and eliminating duplication—or to reduce the deficit of the federal budget. Such attempts inevitably run into one or another of the special interest groups.

When inflation becomes the perceived norm, the incongruity between personal and national expectations may not be so incongruous after all. Most people have found ways to beat the system. Some buy land or homes or other things that appreciate more rapidly than the cost of living. Government and private

---

J. B. Penn is Deputy Administrator for Economics; Economics, Statistics and Cooperatives Service, U.S. Department of Agriculture.

sector workers have succeeded in getting their wages, salaries, and pensions indexed to the cost of living.

Does individual progress really go hand in hand with national deterioration? A positive response may unfortunately be the logical one. As individuals, we are earning more money and increasing our material levels of well-being, while at the same time, the country is losing ground. The national economy becomes less and less competitive with those of other nations (evidence the growing sentiment for protectionism). It becomes increasingly vulnerable to the actions of other nations, as the recent OPEC oil price increases have demonstrated.

Personal hopes, in the long run, must come into accord with national expectations. But, not the least of the evils of inflation is that it keeps postponing the day of reckoning. It keeps advancing the time when Americans must finally come to grips with the problem.

Old Paradigm of Commodity Programs

The commodity programs were inaugurated to alleviate low farm incomes experienced in the twenties. The income problem emerged as per capita incomes in the nonfarm economy rose to levels such that the demand for food became inelastic. Consumers could purchase all the food they needed. But, the farm sector productive capacity was far in excess of that needed to meet domestic and foreign requirements. The excess production brought sharply lower commodity prices and the resulting farm incomes were much lower than incomes in the nonfarm sector.

The initial programs were considered temporary, but the resource disequilibrium in agriculture was severe. Resource adjustment was much too slow for the problem to be quickly eliminated. Low incomes persisted and the programs have been continued, even to this day. Only in atypical periods, such as wartime and the recent 1973–75 period, have the programs been shelved.

These programs have incorporated a variety of methods to secure farm incomes at politically acceptable levels. For over three decades, the preoccupation was with supporting commodity prices. Maintaining prices above market clearing (equilibrium) levels proved to have many undesirable side effects. Uneconomic production was encouraged and consumption was discouraged. Surpluses, of course, accumulated. These results necessitated production control, and various means, usually involving some form of limiting the land input, were used. By the end of the sixties, price support loans, direct purchases, marketing quotas and orders, set-asides, diversion, acreage allotments, direct payments, and some other methods had all been used at various times to increase commodity prices and farm incomes. It all amounted to high costs for increasing farm incomes.

New Paradigm of Commodity Programs

The incomes problem in agriculture had seemingly become eternal as we entered the seventies. Huge commodity surpluses were in government stockpiles, vast acreages of cropland were idle, and the income transfers to the farm sector were large and growing. But, largely unnoticed, the needed sectoral resource (especially labor) adjustment had been slowly occurring over the years (Schuh). The resource disequilibrium was becoming less pronounced even though the symptoms lingered. And, just when the problem appeared to be most severe—the largest proportion of the cropland acreage capacity ever, almost one-fifth, was idle in 1972—a convergence of events produced a dramatic economic upheaval. Evidently, the sector was nearing relative resource equilibrium when the upheaval occurred.

The economic environment for agriculture is a much different one today than before the upheaval. Perhaps the most significant difference is the greatly increased importance of international markets. These now absorb one-third of the value of domestic production and the physical output from one acre of every three. While the incomes problem is no longer paramount in the new setting, equally serious problems have emerged. The instability of commodity prices and farm incomes is perhaps the major problem confronting the sector today. The potential instability is greatly increased by the international markets. They have added the foreign counterpart to the domestic sources of uncertainty and instability such as weather aberrations and economic and political vacillations.

The instability problem is made much more severe by the structural changes that have occurred in the farm sector over the years. Farmers, once able to endure periods of depressed economic conditions because of their

relatively low fixed costs and little use of industrial inputs, are unable to do so today. The cost structure of most farm businesses is significantly different today. Annual debt service and fixed-cost commitments must be met. Additionally, almost 60% of the annual production inputs are purchased, most from the nonfarm sector. The prices of many of these inputs have risen rapidly in this decade, even though unit costs (reflecting productivity) may have been rising less rapidly. This is an important source of cost-push inflation and is in stark contrast with former times when few inputs were purchased from the nonfarm sector and at much more stable prices.

Even though the structure of the farm sector was changing markedly, the basic structure of the commodity programs remained largely unchanged at the beginning of this decade. However, some modifications had been effected over the years to incorporate greater economic rationality. Further modifications have been made in the seventies, at least for the major crop commodities: commodity-by-commodity production restraints were discarded in 1970 in favor of constraining the total plant capacity; full separation of the price support and income support (direct payments) approaches, begun in the mid-sixties, was achieved in 1973; and, in 1977, the antiquated acreage allotment system was abandoned, downward flexibility for the price supports was adopted, additional commodities (rice and peanuts) were brought into the general program framework, and provisions for a price-stabilizing grain reserve were adopted. Direct purchase programs, market orders, import restrictions, and other programs, however, continue to be operated for some major and several minor commodities.

Perhaps the most significant change has been the separation of the price support and income support functions of these programs. This resulted from recognition of the distortions arising from holding commodity prices above market clearing levels, not the least of which was the reduced competitiveness of U.S. commodities in export markets. This separation was completed in the 1973 Farm Bill when the target price-deficiency payment scheme was adopted. This program allowed the price supports to be set at relatively low levels, generally below the market prices, thus largely avoiding the distortions. Deficiency payments now provide the income support formerly provided through price supports. Direct payments, of course, can also contribute to inflationary pressures in the economy, even though prices are not immediately affected.

Transmission of Inflation

An important aspect of the role of commodity programs in inflation is the way in which commodity prices are passed through the economic system. The prices of many agricultural commodities seldom enter directly into determination of the composite national price level. Rather, as raw materials, they influence, to varying degrees and after lags of varying lengths, the prices of final (consumer) products which do enter directly into determination of the national price level. Agricultural commodities may be sold directly to consumers (e.g., fruits and vegetables) and, in this case, their prices are consumer prices; used as raw materials for manufacture of finished food products (e.g., wheat for bread), hence are reflected indirectly through the food component of the consumer price index (CPI);[1] used as raw materials for industrial products (e.g., soybean oil for paints and varnishes) and are also subsequently reflected indirectly in the appropriate category of the CPI; and sold for export, priced in the international commodity markets, thus are not reflected directly in the national price level, but influence the level of domestic prices.

The relative proportion of products sold directly to consumers and their importance in total food expenditures is small—valued at $3.5 billion or 1.5% of total food expenditures.

The prices of commodities that serve as raw material for food products are indirectly reflected in the food component of the CPI. The food component at present has a weight of 18% of the CPI, indicating that this proportion of total consumer expenditures is for food at home (12%) and away from home (6%).

As the primary linkage of commodity prices to the national price level, hence inflation, is through retail food prices, it is instructive to look at the relative importance of commodity prices in food prices. Some notion of this may be gained by examining food expenditures (price times quantity). The farm value of commodities in 1978 comprised 26% of total expenditures and 32% of expenditures for

[1] The all-food component of the CPI also reflects prices for food products that do not have a domestic farm origin. These include imported foods, fish and nonalcoholic beverages.

domestically produced farm foods (excludes imported foods, fish, and nonalcoholic beverages). Thus, the value of farm commodities in total domestic food expenditures comprises only about one-third, meaning that the remaining two-thirds are accounted for by nonfood inputs.

The food manufacturing and distribution sector—performing the functions of transforming domestic raw farm products into finished foods—contributes about twice as much to food costs as do commodities. Thus, labor, energy, packaging, advertising, and profits have about twice as much impact (through food prices) as raw commodity prices on the national price level. Of these, labor (wage rates) is by far the largest, accounting for about one-half of the marketing bill. Food containers and packaging materials are the second largest, followed by rail and truck transportation.

An increasingly important factor in food price inflation is the large service component (an added product attribute). This is a response to changing consumer preferences arising from demographic and age distribution shifts, the changing role of women, income growth, and other factors characteristic of our population.

Illustrating the relative impacts of commodity price changes, a 10% increase in all commodity prices, *ceteris paribus,* would increase short-run food prices about 3.3%. Likewise, a 10% increase in retail food prices would add about 1.8% to the inflation rate. The extent and rapidity of raw material price impacts on retail prices depend, of course, on the mix of commodity price increases (reflecting their relative importance) and on the ability of firms at each stage in the food system to pass through the price increases to the next stage, a function of their market power.

With this background, I now turn to examining the commodity programs, first as a victim, then as a perpetrator of inflation.

Inflation Impacts on Commodity Programs

There is a circularity in inflation and agriculture, both in terms of price transmission and in the formation of expectations that perpetuate inflation. Price increases are soon incorporated into decisionmakers' expectations; they become the perceived norm. These inflation expectations are in part self-fulfilling; they create demands for greater economic protection. As each group attempts to beat the system, to protect their self-interest, they seek enhancement of the commodity programs to protect them against inflation. The interest groups press their demands upon the Executive Branch and the Congress. Often they are successful: decisions are frequently taken in a micro-context and another incremental contribution is made to perpetuating the expected inflation.

Inflation affects the farm sector in the short run through the costs of inputs. As noted above, 60% of the annual production inputs are purchased from the nonfarm sector. The prices of these inputs are largely determined by forces in the nonfarm economy. Cost increases are quickly reflected in these input prices and the imperfect structure of the inputs industries means these are quickly passed on to farmers.

The major long-run effect of inflation is perhaps in the way it affects the prices of fixed assets, primarily land for agricultural purposes. The effect is especially pronounced for farmers who have purchased land in this decade, when the average annual price increase has been 12 %. The result is, of course, increased cost of production, further creating incentives to seek enhancement of the commodity programs to reduce the risk associated with the large investment.

The inflation-induced production cost increases also affect the cost of operating the commodity programs. An obvious example is the milk price support program which indexes the level of support to the formula-determined parity price. The milk price support was $4.28 per hundredweight in 1969; today, it is $10.76, an increase of 151% for an average annual increase of 15%.

There are adverse impacts of inflation on agriculture other than the commodity programs. These are treated in the other papers and are outside the scope of this discussion.

Commodity Program Impacts on Inflation

There is little doubt that the commodity programs, to the extent they are successful in achieving their purpose, contribute to inflation. And, they do so in a number of ways other than a direct increase in prices.

The programs serve to reduce the economic risk associated with the production of a specific commodity. They limit the downside risk on price, enabling farmers to increase

their financial leverage and encouraging lenders to lend more. This increased leverage and capital availability allows farmers to bid up the price of assets, especially land. Related, the programs also serve to influence farmers' long-term expectation about the profitability of production. More positive expectations are factors encouraging expanded asset acquisition, again usually resulting in increased asset prices.

To the extent that the programs lead (rather than lag) production cost increases, they serve to widen the cost-price spread, at least temporarily. This, in turn, stimulates greater use of inputs and expanded asset acquisition. However, the long-run average cost eventually will increase and any advantage from the wider spread is eliminated. The increased demand for inputs will result in increased input prices, especially for those products in the most heavily concentrated markets. The cumulative cost increases (land and other inputs) from these effects become reflected in the long-run average cost and subsequently in higher product prices. But, the higher long-run average cost creates new demands for enhancement of the commodity programs and the cycle starts again.

The commodity programs also may produce other secondary impacts as they influence the CPI. The federal budget today approaches $505 billion, of which some $160 billion (32%) is for federal programs that are directly or indirectly indexed to the CPI (i.e., the benefits of outlays are tied to the "cost of living" as measured by the CPI). These include such programs as social security, supplemental security income, military and civilian government employee retirement programs, the food stamp program, and the like. Although not direct, a reasonable rule of thumb for measuring the second-round impact is that each 1% increase in the CPI increases federal budget outlays by $1.0 billion to $1.5 billion.

A commodity price-food price-CPI increase has even more far-reaching impacts. About 23 million (23.7%) of the total labor force of 97 million workers are unionized and most have contracts with cost of living adjustments tied to the CPI. Thus, wage increases follow price increases. And, this is not limited only to unionized workers. Nonunion workers frequently follow the lead of the unions, emulating their wage demands. Thus, there is some "demonstration effect" with varying time lags. Wage increases are, of course, eventually reflected in the prices of the final products and the general price level. Many of these products are agricultural production inputs. The higher prices result in higher production costs for farmers. This full-circle transmission of commodity price increases gives rise to the so-called "ratchet effect": the eventual increased costs are largely inflexible downward while commodity prices are not. This produces another well-known condition, the "cost-price squeeze."

The capitalization of the commodity program benefits into land and other fixed asset prices also may produce a short-run inflationary effect. However, the longer-term effect of this capitalization may be much more serious as it affects entry, exit, and the structure of the farm sector.

Although the payments programs are less inflationary than price supports, they can have an adverse inflationary effect. To the extent inflation is demand-pull, the transfer payments to the farm sector undoubtedly increase this pressure. And, to the extent the payments increase the budget deficit, there are inflation impacts through debt service and impacts that can extend even to the value of the dollar in international currency markets. These are the little explored areas in assessments of commodity program impacts.

In addition to the price support-loan and payments programs, other commodity programs such as federal market orders also contribute to inflation, if only in a small way (Dobson and Salathe, Jamison). While they do stabilize prices, they also do so at somewhat higher than competitive levels.

Food Prices and Inflation—A Historical Perspective

The supply and demand conditions underlying price formation for commodities are affected by many factors that serve to cause price volatility. These sources derive from domestic weather and natural phenomena (diseases, pests) and, much more important since the early seventies, from world weather and world economic and political events.

A review of the historical role of commodity prices/food prices in inflation indicates that in eighteen of the twenty-nine years since 1949 food prices contributed less than one percentage point to the overall rate of inflation (table 1). In twenty-two of those years, food prices

Table 1. Contribution of Food Prices to Inflation

Year	CPI Food	Change in CPI Food	Contribution to All-Item CPI[a]	All-Item CPI	Change in All-Item CPI	Increase in All-Item CPI Accounted for by Food[b]
			%

Source: Salathe and Boehm.
[a] The change in the CPI for food multiplied by its relative weight in the all-item CPI. The relative weight of food in the all-item CPI was 0.33 from 1950 through 1962, 0.22 from 1963 through 1965, 0.23 from 1966 through 1977 and 0.18 in 1978.
[b] Column 3 divided by annual change in the all-item CPI.

increased at a slower annual rate than the rate of inflation in the general economy. Food prices actually declined in four years, while the CPI has declined only once since 1949 (in 1955).

Food prices have increased 185% since 1950. Up to 1967, the increase was relatively slow; the average annual increase was 2.5%. Since then, however, the rate has accelerated, to an annual average rate of more than 7% (9% since 1972). The two largest year-to-year changes occurred in 1973 and 1974 when retail food prices increased 14% each year.

Future year-to-year increases in food prices will reflect more closely the underlying rate of inflation in the nonfarm economy, evidencing the importance of the nonfarm inputs and services in producing finished food products. However, significant aberrations will still come from short-run disruptions in the supply of and demand for raw farm commodities.

Issues and Research Areas

The overriding public policy issue is, of course, the elimination of the underlying causes of inflation in the national economy. Successful courses of action to achieve this have eluded policy makers since the late sixties, and no immediate solution is in sight. However, significantly slowing the rate of inflation will require a concerted effort across the entire economy, a lockstep approach to policy actions with few exceptions to special interest groups. There will be overriding social concerns that merit exceptions, but the means by which these concerns are treated will re-

quire close scrutiny to minimize economic distortions.

Research Areas

The major research need is the same one that Schuh noted in 1976: a greater understanding of how domestic agriculture and the national economy fit into a rapidly changing interdependent world. There is a great need for consideration of the farm sector-food system-macroeconomy relationships. The information from greater quantification and understanding of the relationships is a sorely needed input for public policy decision making. A primary area for research treatment is comprehensive analysis of macroeconomic impacts on the farm sector and food systems and, in turn, the impacts of these sectors on the macroeconomy. This is amply illustrated by the inflation issue.

The development of such research would enable more complete analysis of benefits, costs, and distributive impacts of the agricultural programs. More explicit considerations of the indirect and secondary consequences (alluded to above) could alter the estimated net benefits and policy conclusions about the programs. It could also suggest means by which the programs could be structurally improved.

There is a heightened awareness of the role of macroeconomic policies in determining the structure of the farm sector. Improved understanding of the sector-macroeconomy interdependencies and linkages could help identify and clarify often unrecognized policy impacts on farms by size, type, geographic location, form of business organization, and the like.

As inflation persists, questions about how particular groups will fare and about the role of particular programs under varying rates of inflation will become more frequent. Our present knowledge base for responding to these and related questions is inadequate.

Inflation and Productivity

Vernon W. Ruttan

Inflation and productivity are the most persistent economic problems confronting the U.S. economy. Both represent a serious threat to the position of the United States in the world economy and in world polity. Both are serious obstacles to achievement of a degree of equity in the quality of life which has come to be taken as a major goal of domestic economic policy. The central thesis of this paper is the dialectical interaction between inflation and productivity. Inflation dampens productivity growth and slower productivity growth contributes to inflation.

The National Economy

The rate of inflation has risen gradually from 2% per year or less in the 1950s and early 1960s, to the 4%–6% range in the late 1960s and early 1970s, and to the 6%–10% range in the mid- and late 1970s (fig. 1). The inability of the old macroeconomics to provide effective and acceptable guides to economic policy has induced the emergence of a new "rational expectations" approach to economic policy. The operating hypothesis of this school is that, in the presence of a public which is continually trying to outguess the government, monetary and fiscal policy interventions in response to cyclical changes in economic indicators can only assure continued high rates of both inflation and unemployment.

The leading exponents of the rational expectations school, barricaded behind the portals of the Federal Reserve Bank of Minneapolis, prescribe a policy of gradually slowing money growth and reducing the federal deficit. The approach must, they insist, be sufficiently gradual to avoid pathological withdrawal symptoms—but of sufficient magnitude and consistency to lead to expectations on the part of consumers, labor, and business that the policy will be continued (Federal Reserve Bank of Minneapolis 1978, 1979; Lucas and Sargent).

Concern about lagging productivity in the American economy is of somewhat more recent vintage than concern about inflation. Changes in the rate of inflation can be measured in terms of directly observed ratios that are more apparent to the individual consumer and producer than the implicit gross national product (GNP) deflator—the cost of a market basket at the grocery store relative to a weekly or monthly paycheck or by the prices paid for farm inputs relative to the prices received for farm production. Productivity is a somewhat more abstract—even arcane—concept. It is measured in terms of changes in a physical input-output ratio, such as change in output per unit of labor or in terms of changes in output per unit of total input. Its impact on the individual worker, on the firm, or on the total economy often is obscured by more transient sources of change. It must be interpreted to the citizen and to policy makers by a special breed of technicians—the growth accountants—who have not yet been able to agree on how productivity should be measured.

It is clear that the rate of productivity growth has declined in the private nonfarm sectors of the American economy (fig. 2). The Council of Economic Advisors noted in its 1979 report, "Between 1948 and 1965 (labor) productivity growth in the private non-farm sector averaged 2.6 percent per year. . . . Since 1973, private non-farm productivity growth has averaged less than 1.0 percent per year" (p. 67). A number of factors have been identified as accounting for a measurable share of the decline in productivity: (*a*) reduction in the rate of growth in capital investment per worker; (*b*) exhaustion of the backlog of technological knowledge that had emerged during the depression and World War II; (*c*) demographic changes in the labor force, particularly the increase in younger workers and women; (*d*) increased regulation to reduce the disposal of residuals into the environment and to pro-

tect the health and safety of the labor force; and (*e*) increases in illegal activity (Denison 1978).

What is the impact of inflation on productivity? Friedman, in his Nobel lecture, argues that inflation leads to inefficiency, because it makes market prices a less efficient system for coordinating economic activity. Its impact is particularly corrosive on the functioning of capital markets. It contributes to a decline in the rate of savings and to the distortion of investment patterns. A consequence of inflation which appears to have been overlooked is the erosion of the capacity of public sector institutions to provide the services needed to enhance productivity in the private sector. Edward Denison (letter), our most careful analyst of the sources of productivity growth, after reviewing the literature on the effects of inflation on productivity, concludes "that inflation impairs productivity seems certain. But I have no idea how much it may have done so from 1973 to 1976."

What is the impact of the decline in productivity on inflation? Clearly, an economy in which labor productivity is increasing at 1.0% per year can provide its citizens with smaller annual increases in real income than an economy in which labor productivity is rising at between 2.0% and 3.0% per year. If labor,

Figure 2. Productivity measures 1950–78

management, and government come to accept productivity growth in the 1.0% range as "normal," there is no reason why low productivity should represent a source of inflation.

However, if workers expect real wage increments in the 3.0% range—on top of wage adjustments necessary to compensate for anticipated inflation—a decline in the rate of growth in productivity can represent a significant source of inflation. The importance of lagging productivity as a source of inflation, particularly in the short run when structural rigidities impose severe limitations on the flexibility of prices and wages, will depend on how expectations about both productivity and inflation enter into the complex economic and political bargaining among workers, management, and government.

The rational expectations school would presumably argue that in the presence of correct and consistent policy with respect to money supply, budget deficit, and exchange rates, any inflationary impact of a downward shift in the rate of productivity growth would be temporary. In a world characterized by substantial structural rigidity, I would expect that a continuation of the low productivity growth rates of the last several years will lead to intensified stress between workers, management, and consumers over the partitioning of the limited growth dividends that become available.

The Agricultural Sector

The same general forces that have operated to influence productivity growth and inflation in the national economy have also impinged on the agricultural sector.

Some intuitive insight regarding the short-run effects of inflation on the agricultural sector may be generated by examining the behavior of the series on prices received by farmers for commodities, prices paid by farmers for inputs, and the "parity" index. In general the index of prices received rises more rapidly than the index of prices paid during very rapid inflation. However, when the general price level is rising at a more moderate rate, prices paid tend to rise more rapidly than prices received.

The only rigorous empirical examination of the effects of inflation on prices received and paid by farmers with which I am familiar is the series of papers by Luther Tweeten and his associate of Oklahoma State University (Tweeten and Griffin). Tweeten's empirical estimates indicate that the effect of a 1% increase in the general price level is to raise the index of prices paid by farmers by 1% and to leave the prices received by farmers essentially unchanged. I personally have some difficulty accepting Tweeten's result that a 1% increase in the general price level has almost no effect on prices received. He arrives at this conclusion by an estimate that the increase in farm level demand that would otherwise be generated by inflation is approximately offset by increases in the cost of marketing services associated with inflation, leaving prices at the farm level essentially unchanged.

While the impact of inflation on current account is negative, the impact on capital account remains ambiguous. No one has, to my knowledge, successfully separated the impact (*a*) of land productivity increasing biological technology; (*b*) of labor productivity increasing mechanical technology; (*c*) of competition between agricultural and nonagricultural uses for land; and (*d*) of general inflation on changes in the price of land. The most successful efforts to untangle these interrelated forces have been made in a series of papers by Melichar (1978a, b). Conventional wisdom, based on comparisons of the increase in farm land prices with increases in farm operators' income, suggests a decline in the return earned from land ownership. Melichar points out, however, that during the 1950–70 period a combination of productivity growth, farm price programs, and changing land/labor and capital/labor ratios modified the historical relationship between land prices and farm operator income. During this period the rate of return to land ownership, even on current account, increased substantially. Since 1970, however, agriculture has experienced a land market boom in which anticipated capital gains have been used to finance current cash flow requirements. And the ratio of debt service costs to earnings on farm assets have exceeded the heights that preceded the land market crash of the early 1920s.

The high debt service to earnings ratio would not be particularly serious if real and nominal interest rates were still in the traditional 4%–6% range. With nominal interest rates averaging near 12%, a modest decline in the rate of cash flow can have very serious repercussions in the farm real estate market. The only thing that would be worse than continued inflation would be deflation! A major source of uncertainty for those who must do outlook work is whether the same set of political forces will be generated to validate inflated

land market prices again in the early 1980s as in the mid-1970s.

Productivity growth in the agricultural sector, measured in either partial (i.e., labor) or multifactor terms, continues at a more rapid rate than in the private nonfarm sector (fig. 2). I do not know why the difference continues. Given the adjustments that have occurred in the agricultural sector of the 1920–70 period, I would have expected greater convergence. I would also have expected the level of capital intensity that has emerged in the agricultural sector, significantly higher than in the industrial sector, to act as a factor dampening productivity growth.

Several hypotheses commend themselves to further investigation. Ben-Zion and I have shown that investment in research and development (R&D) in the private nonagricultural sector is quite responsive to economic fluctuations. The supply of technology to the agricultural sector may be less influenced by fluctuations in economic activity than in the industrial sector. Public sector research and development remains the primary source of agricultural technology, particularly the biological technology which has expanded the capacity of crops and animals to respond to higher levels of industrial inputs. The demand for technological change in agriculture continues to be driven by the product market and land market treadmill phenomenon.

The continued high rate of productivity growth in the agricultural sector cannot obscure, however, the fact that the rate of productivity growth in agriculture has slowed down over the last decade. While debate over measurement and the dating of turning points continues, I see no way to interpret the data plotted in figure 2 other than to conclude that the rate of productivity growth in agriculture has fallen below the level that prevailed over the first two decades after World War II. It may not be a coincidence that the timing of the decline coincides with the rapid expansion of agricultural exports in the late 1960s (Schuh).

Some Emerging Issues

In the closing sections of this paper I address three additional issues related to productivity in American agriculture. First, I raise the question of whether American agriculture is as productive today as we have become accustomed to believe. Second, I raise the question of whether we are continuing to make the investments required to release the technical constraints on agricultural productivity. Third, I raise some questions about the institutional constraints on productivity growth in American agriculture.

How Efficient Is American Agriculture?

In 1947, Schultz argued that the agriculture of the United States "did not come anywhere near meeting the standard of efficiency set by the American economy" (p. 646). A few years later, Byron Shaw, then Director of U.S. Department of Agriculture's (USDA) Agricultural Research Service, called attention to the narrowing gap between crop yield and livestock efficiency ratios realized by farmers and the results obtained from experiments and performance tests.

These concerns were largely forgotten in the 1950s and the 1960s. American agriculture was the wonder of the world—capable of meeting the food and fiber demands of the American economy, of filling the gap arising from rapid population growth in the developing countries, and of meeting the demand for feed-grain-based livestock production in Western Europe, Japan, and in the higher income socialist countries. By the mid-1970s, however, we were again being confronted with a new series of challenges regarding both the technical and institutional efficiency of the system of agricultural production that had emerged in the United States over the last half century.

Comparative historical evidence suggests that the capacity of the American agricultural system to meet domestic and foreign food and fiber requirements has been based at least as much on slow growth of demand for agricultural commodities by American consumers as on high rates of productivity growth. Output per hectare of a number of individual crops, maize in particular, is high relative to other countries. But average agricultural output per hectare of cropland remains low relative to the levels that prevail in many other developed and developing countries. The rate of growth of agricultural output since 1950 has averaged little more than 1.7% per year—well below the 2%–4% "modern" growth rates achieved by many developed and developing countries.

The serious issues confronting U.S. agricultural performance in the future are (*a*) whether the U.S. agricultural research system is main-

taining its capacity to support productivity growth, and (*b*) whether the institutional constraints which condition the structure of American agriculture are becoming an increasing burden on productivity growth.

How Strong is the Scientific and Technical Basis for Agricultural Productivity Growth?

This question, like the previous one, is not easily answered. Clearly, research at the state agricultural experiment stations and related institutions within the U.S. Department of Agriculture and in the private sector has failed during the 1970s to maintain the momentum for growth that characterized the 1950s or 1960s or that was expected at the time of the joint Department of Agriculture-State Experiment Station study of research needs in the 1970s (USDA). Research budgets have shown no real growth when measured against growth in the GNP deflator and have declined when measured against an index of costs of scientific manpower. Research expenditure, as a percentage of sales, has declined sharply for field crops, declined modestly for horticultural crops, and has risen significantly for livestock. And the mission of the agricultural research system has been broadened to include a range of environmental and consumer protection and enhancement roles that did not exist a decade and a half ago.

Agricultural research is clearly undervalued in the United States. Marginal rates of return in the range of 25%–50% per year have been estimated for a large number of commodities and for the research system as a whole (Evenson, Waggoner, Ruttan). Rates of return in this range induce a warm glow of self-satisfaction in the hearts of agricultural research administrators. When taken seriously they indicate substantial underinvestment in agricultural research.

Several hypotheses can be suggested for the failure to push research investment closer to an equilibrium. At the state level, the spillover of the impact of research on productivity into other states, estimated to be in the 50% range, seems clearly to be a factor limiting state expenditures on agricultural research. At the federal level, it seems apparent that the slippage in research support has been at least in part a result of the expediency of budget making in an inflationary environment rather than a conscious decision to cut back on either public or private investment in agricultural research. At the federal level, the substitution of a bureaucratic objective function for a social welfare function also appears to play a significant role. While productivity growth leading to a relative decline in the price of farm output can result in both higher net income to farmers and lower food costs to consumers, it also, under the price programs that have prevailed since the 1930s, imposes budget costs on the U.S. Treasury. The effect is to translate a social benefit into cost when viewed narrowly from the Office of Budget and Management or the Office of the Secretary of Agriculture. A rate of productivity growth just sufficient to keep commodity prices from rising is preferable from a bureaucratic perspective to the higher rate of productivity growth that would optimize the social rate of return to agricultural research.

Institutional Constraints on Productivity Growth

In addition to these built-in biases toward underinvestment in agricultural research, there have been a number of institutional changes in the economy which appear to have a negative impact both on the productivity of our agricultural research effort, as measured by the rates of return to agricultural research, and on the productivity of the agricultural sector, as measured by the rate of productivity growth.

We have, during the years since World War II, erected an incentive structure in American agriculture that has induced inefficient substitution of material inputs (capital and operating expenses) for land and labor. The constraints imposed on land use during most of the 1950s and 1960s led to excessive substitution of chemical inputs for land. The tendency was reinforced by institutional factors that failed to communicate the externalities resulting from increased levels of chemical inputs in terms of costs to farm producers. By the mid-1960s, the set of inefficient incentives for chemical-land substitution was supplemented by a tax policy that has had the effect of inducing inefficient substitution of capital for labor. We also have built a set of institutional constraints that impinge on the productive use of agricultural resources. One of the more obvious cases is the impact of market regulation on the shift of milk production from low- to high-cost locations. Efforts to manage more efficiently the spillover costs of chemical technology are in some cases having a sub-

stantial negative impact on R&D productivity, particularly in the pesticide, herbicide, and animal drug fields.

Perspective

In closing, I would like to come back to the issue of the interaction between productivity and inflation. During the half-century between 1920 and 1970, the focusing device that directed productivity growth in American agriculture was the declining real price of energy. The declining prices of energy induced the substitutions of mechanical power for animal power and labor, and substitution of yield-increasing and yield-protection chemical technology for land (Hayami and Ruttan; Binswanger and Ruttan).

Since the early 1970s, the price of energy has risen relative to most other inputs. I do not know whether energy prices will continue to rise relative to other inputs during the coming decades. However, it is very difficult for me to believe that they will decline as during the 1920–70 period. This means that the focusing device for scientific and technical effort that we have relied on for more than half a century is obsolete. A new focusing device will have to be found.

This leads me to anticipate a period of relatively slow growth in total productivity. In many respects the next several decades could parallel the lag in productivity in U.S. agriculture between 1895 and 1925. At that time, the closing of the land frontier induced a new land-saving biological and chemical technology. During the next decade I expect that we will be devoting increasing effort to the search for new energy-saving technologies.

What does this mean for the American economy? It means that it is unlikely that the economy can depend, as it has in the recent past, on productivity growth in the agricultural sector to dampen the impact of inflation on food prices (Schuh). If in addition to slow productivity growth, export demand remains strong, the effect of competition between foreign and domestic consumers on food prices will become more intense. The U.S. economy is past the era when transfer of resources from the agricultural to the nonagricultural sector, through either the labor market or the product market, can significantly enhance national productivity growth. And the nation may find great difficulty, if efficient new sources of productivity growth in agriculture are not found, in avoiding substantial resource transfers from the nonagricultural to the agricultural sector. The signals that such a transfer is under way will be masked for a considerable period by the slow growth of domestic demand for farm products, the large share of production that now moves into export, and the heavy absorption of grain production by the domestic livestock sector.

The Distributional Consequences of Recent Inflation

K. L. Robinson

Income redistribution is an inevitable by-product of inflation, simply because all prices do not move upward at the same rate. The most recent period of accelerated inflation in the United States, that is the period beginning in 1972 and continuing up to the present time, has been characterized by extremely diverse changes in income within agriculture because the prices for different commodities have peaked at different times and have risen by widely varying amounts. Income redistribution also has occurred because factor price ratios have changed. Appreciation in land values has redistributed income from new entrants to those retiring from agriculture. Debtors clearly have gained relative to creditors. But I do not propose to dwell on these more obvious effects of inflation. Instead, I intend to focus on those aspects of recent inflation that appear to be somewhat unique or different from what we have experienced in the past. I shall begin with an analysis of interregional income transfers resulting from the widely divergent changes in commodity prices that have occurred since 1971. I shall turn next to the effect of recent inflation on income inequality within agriculture, that is on what may be referred to as the "Pareto" distribution of income. Third, I will examine the possible long-term consequences of recent changes in relative factor prices; and finally, I will comment briefly on the distribution effects of changes in food prices.

Regional Effects

Few generalizations can be made about the distributional consequences of recent inflation because of the diversity of price movements. Gains and losses among farmers have been associated with their product mix, when they sold or priced their output, their dependence on purchased feed, and when they began farming. Some regions clearly have gained much more than others and this in turn has influenced relative rates of inflation in land values.

It is difficult to sort out the effects of general inflation from other factors which have contributed to the erratic behavior of farm prices since 1971. There is no simple way in which this diversity in price behavior can be expressed, but one can highlight the differences by noting the range over which major commodity prices have moved since 1970–71 and in what year prices peaked. The peak season average price for wheat (which occurred in 1974) was more than three times the average price prevailing in 1970–71 (table 1); at the other extreme, the peak increase in the price of eggs over the same period was only 66%. These figures do not take into account the changes in prices that have occurred since 1978.

The diversity in price behavior, especially between grains and livestock products, is striking. Grain prices peaked earlier and at much higher levels relative to 1970–71 than livestock prices. This had the effect of redistributing income within agriculture. Grain producers gained relative to grain feeders in the mid-1970s. The aggregate net income of farmers in North Dakota, to take the most extreme case, more than quadrupled between the early and mid-1970s. But in states that rely on purchased feed, such as New York, the aggregate net income of farmers actually declined during this period.

Maximum changes in aggregate net farm income for each state were calculated for the period 1971–78 in order to obtain some indication of relative gains which farmers in different areas have experienced during the recent period of accelerated inflation. Maximum gains calculated as a percentage of aggregate net farm income in 1970–78 ranged from less than 50% in most of the northeastern states (with the exception of Maine) to over 200% in North

---

K. L. Robinson is a professor of agricultural economics, Cornell University.

[b] Excluding Maine.

and South Dakota, Washington, Oregon, Arizona, and Illinois.

Wide differences also exist among states in the rate at which land prices have appreciated. As one would expect, states in which incomes have gone up the most also tend to have experienced larger increases in land prices. Based on a superficial examination of the state data, it appeared that a first difference analysis relating maximum changes in net farm income to changes in land values would produce interesting results. But the R^2 value turned out to be relatively low, thus indicating that only a small part of interstate differences in the behavior of land prices since 1971 can be attributed to relative rates of change in farm incomes. In a few regions, there was consistency among states in the relationship between changes in income and land prices, but not in others.

States which exhibited reasonably uniform behavior were grouped together and the percentage changes in both land values and net farm income were then calculated. Regions were omitted in which there was considerable variation among states in the behavior of land prices and incomes. In the West, for example, land values have gone up much less in California than they have in Oregon, Washington or Idaho. Substantial differences also can be observed within the Mountain states and among those that make up the "Old Cotton South."

Percentage increases in land values from 1971 to 1978 were approximately equal to the maximum increase in net farm income for the group of states chosen to represent the Great Plains (table 2). A similar relationship prevailed in the southeastern states, but in the Corn Belt land prices rose almost 50% more than the maximum increase in farm incomes. The divergence between the maximum increase in land values and net farm income was even greater in the Northeast. Land values more than doubled in that area between 1971 and 1978, but this occurred despite a very modest increase in net farm income. Nonfarm demand for land obviously has played an important role in accelerating inflation in land prices since 1971, and perhaps more so in the Northeast than in the Midwest or the Great Plains.

Income Inequality

One can be reasonably confident in concluding that recent inflation has contributed to a greater degree of income inequality among regions and types of farms, but it is less certain what effect it has had on the incomes of those operating large as compared to small-scale or medium-sized farms. Inflation has made our statistics relating to farm sizes (which are based mainly on gross sales categories) almost meaningless (Stanton). Inflation also has added to the difficulties one encounters in attempting to compare the distribution of income over time. We know that gains in income are correlated with gross farm sales, but we do not know precisely how much of the recent increase in net income on large farms is attributable to inflation and how much to other factors. Again, differences in product mix affect the distribution. Large farms producing wheat, corn and soybeans probably increased

their share of total income during the mid-1970s, but not all large farms produce grains. Many of them specialize in the production of commodities whose prices have risen much less than the overall rate of inflation. Over the period from 1971 to 1978, for example, the incomes of cattle ranchers, feed lot operators, poultrymen and many of those producing vegetables for processing lagged behind. At the same time, those at the lower end of the income distribution, regardless of their product mix, were receiving more income from off-farm sources. Thus, it is not clear that the "Pareto" distribution of income has, in fact, been altered significantly as a result of recent inflation although it is possible this has occurred.

The most recent period of inflation has been accompanied by exceptionally large seasonal changes in prices. Increased volatility in prices may be attributable in part to more speculative trading on the part of those who have become disenchanted with the stock market and are turning to commodity markets in an attempt to "beat inflation." One of the by-products of increased volatility in prices has been to afford opportunities for exceptional gains to those who have been either very astute or lucky in the time they chose to sell or price their crop. The timing of transactions has become a critical management decision. Optimum timing of wheat sales in 1978–79, for example, could have added as much as $2 per bushel to a farmer's return. Soybeans is another crop in which timing of sales has been especially important. The 1979 July futures price, for example, has ranged from around $6 to over $8.50 per bushel.

I have no information which would enable me to determine what types of farmers have been most successful in timing their sales, but my guess is that the larger farmers who are well-financed and have relatively modest debts have been more successful in exploiting seasonal price changes than have small farmers and new entrants. The former have access to more information and can afford to hold their crop in anticipation of a rise in prices later in the season or even in subsequent years. Thus, my hypothesis is that recent inflation has widened income differentials among farmers producing similar products (mainly grains) and that these differences are associated with management skills related to the timing of sales or transactions on the futures markets.

Relative Changes in Factor Prices

The distribution effects of changes in relative factor prices or costs are even more difficult to identify than those associated with changes in product prices. One of the obvious differences between the most recent period of inflation and those experienced earlier is the relative rise in the price of energy and petrochemicals, including nitrogen fertilizer. Farmers who use abnormally large amounts of energy, such as those who depend on deep wells for irrigation, obviously will be disadvantaged in the future relative to those who rely on natural rainfall or gravity irrigation. Those farming soils with low inherent productivity and no livestock also may find their relative advantage declining as a result of the rise in the cost of nutrients. But thus far, these changes in the cost of energy and petroleum-based products have had little impact on the regional distribution of income.

Since my interest is in attempting to identify what is unique about recent inflation, I chose to compare changes that occurred during this period with those that took place during earlier periods of inflation. Two earlier periods were selected for comparative purposes: the first was the period from 1940 to 1949 during which the rate of inflation was more nearly comparable to what we have experienced recently; the second was from 1960 to 1969 when inflation was proceeding at a much slower rate.

Three price series or index numbers were selected to represent changes in the prices of the major factors or inputs in agriculture (land, farm wage rates and an index of tractor and farm machinery prices). The percentage change in price that occurred in each of the three periods of inflation was then calculated. These percentage changes in factor prices were divided by the percentage change in industrial wholesale prices in order to form a ratio which shows the relative change in factor prices which took place during each period of inflation. The index of industrial wholesale prices was chosen as the denominator or deflator because it is broadly based and is a reasonable indicator of the underlying rate of inflation for the economy as a whole. The percentage increase in farm prices during each period was also divided by the percentage change in industrial wholesale prices to determine what changes may have occurred in the overall terms of trade of farm products.

Table 3. Relative Price Changes in Three Periods of Inflation

Period of Inflation	Percentage Change in Industrial Wholesale Prices	Ratio of Change in Each Index to Industrial Wholesale Prices: All Farm Products	Farm Land	Farm Wage Rates	Tractors and Farm Machinery
1940–49	+71	2.1	1.6	3.3	1.1
1960–69	+11	1.1	6.0	5.5	3.0
1971–78	+84	1.0	1.8	1.0	1.3

Source: Calculated from data in *Agricultural Statistics*, 1952, 1967, and 1978, and the *Economic Report of the President*, Jan. 1979.

The results of these calculations are shown in table 3.

The increase in average farm prices between 1971 and 1978 was about equal to the increase in industrial wholesale prices over the same period. In this respect, the recent period of inflation differs substantially from the 1940s. During the earlier period, farm prices rose much more than industrial prices.

Machinery prices have risen more than industrial prices since 1971, but this should not be considered unusual since it is consistent with what happened in the 1940s and 1960s. In fact machinery prices rose more relative to both industrial and farm prices in the 1960s than they have since 1971.

Average farm wage rates increased no more rapidly than industrial prices between 1971 and 1978. In the 1960s, the increase in farm wage rates was 5.5 times the percentage increase in industrial prices. If recent trends persist, there will be less incentive to substitute capital for labor over the next few years than there was in the 1960s.

As everyone is aware, land values have gone up relative to both farm and wholesale prices. But this is not a new phenomenon. Land prices actually rose more relative to farm product prices in the 1960s than they did between 1971 and 1978.

An increase in land prices relative to the prices of farm products has important long-run distributional consequences. It changes the distribution of returns among factors, increasing the proportion which flows to land and decreasing the proportion which goes to reward labor and management. It also distorts decision making, rewarding those who are successful in land speculation relative to those who are simply good farm managers. Returns from appreciation in land have exceeded returns from farming in recent years as Breimyer and others have pointed out.

Inflation in land values also may serve to widen income differentials among farms. Established farmers and those already more financially secure in the community can generally outbid new entrants for whatever land becomes available, thus tending to reinforce existing income inequalities.

If inflation persists, an increasing proportion of the land is likely to be owned by those who have no interest in actually farming the land. Since land is looked upon as a hedge against inflation, few will want to sell it. Wherever possible, it will be passed on within the family. But many of those who inherit land will elect to rent it rather than to farm it. This will lead to further separation of land ownership from farm operation.

Separating or divorcing land management from farm management, while inconsistent with the Jeffersonian ideal, need not be disastrous for agriculture provided those who own the land are content with a modest current return on their investment and take a long-term interest in preserving the land. Many farms are now being rented for less than a farmer would have to pay if he owned the land. Furthermore, by divorcing ownership from farm management, the real estate tax burden, which has become of increasing concern to farmers as land values have risen, would be shifted to those who want to speculate in land.

It is not too soon for agricultural economists to begin thinking more seriously about alternative institutional arrangements that would encourage good land management and make it possible for those with limited capital to enter farming. This is precisely what the British tried to do in the late 19th century with their tenure reform laws. The aim was to protect the rights of tenants, to reward them for any improvements they made on the land, and to encourage practices that would maintain the long-term productivity of the land. In the past we have tried to solve the problem of entry

into agriculture by liberalizing credit. This has had the effect of reinforcing inflation in land prices. We should now consider the possibility of creating new institutions that will enable those with limited capital to become farmers and let those who have the capital and want to speculate in land to pay the taxes and carry the costs of land ownership.

Distributional Effects of Inflation in Food Prices

In contrast to their behavior in the 1960s, food prices have risen more than other items in the Consumer Price Index (CPI) since 1971. Gains from higher food prices have been shared by farmers and middlemen. Because food expenditures absorb a higher percentage of the income of families at the lower end of the income scale than those at the upper end, this transfer of income through higher food prices is equivalent to a regressive sales tax. Furthermore, since much of the meat, fruits and vegetables purchased by low income families is produced on farms with sales in excess of $100,000 per year, one might argue that the transfer of income associated with recent inflation in food prices has been socially undesirable.

The poor obviously have been compelled to pay more for food, but the incomes of the "poorest of the poor," or at least those participating in the Food Stamp program and those receiving Social Security benefits, are now indexed to take account of inflation. Food stamp benefits are adjusted semi-annually in accordance with changes in the cost of a market basket which includes foods typically consumed by low income households. Social Security benefits, likewise, are now raised automatically each year and, in fact, have gone up more than the Consumer Price Index since 1971. Thus it is probably fair to conclude that those most adversely affected by rising food prices are families whose incomes are just above the poverty line or those who elect for a variety of reasons not to participate in the Food Stamp program. With increasing indexation, including mandated increases in minimum wages and higher medicaid payments, the social consequences of inflation in food prices are less serious now than they would have been five or ten years ago.

Conclusions

Few generalizations can legitimately be made about the distributional consequences of recent inflation. Income has been redistributed within and between agriculture and the rest of society, but in ways that can be described with only slight exaggeration as capricious. Commodity prices have behaved erratically in response to a multitude of exogenous forces, including poor crops in the Soviet Union, drought and a short growing season in the U.S. in 1974, the entry of China into the world market on a much larger scale, a freeze in Florida, too much or too little rain in California, and a poor soybean crop in Brazil. Differences in the timing and magnitude of changes in commodity prices have produced wide fluctuations in farm incomes and unequal benefits among producers. Gains in real income were concentrated chiefly among grain producers in the mid-1970s, but subsequently those selling cotton, citrus and other fruits also benefited. More recently, incomes have been redistributed from consumers to livestock producers, not because of inflation, but mainly because the liquidation phase of the cattle cycle has ended.

Existing inequalities in income within agriculture probably have been reinforced by rising land prices and the ability of farmers with secure financial resources to hold commodities and to take advantage of abnormally large intra- as well as inter-seasonal fluctuations in prices. But not all those operating large farms have gained since many produce commodities whose prices during much of the past seven years have gone up less than the overall rate of inflation. This includes producers of eggs, fed beef and a number of vegetables sold for processing. Small-scale and part-time farmers have benefited as much from increasing off-farm income as they have from higher farm prices.

Income also has been redistributed among factors of production and between generations. Most, if not all, of the benefits from rising commodity prices have been capitalized into the value of farm land. This is nothing new, but the effects have been far from uniform among states.

Farm wage rates have risen less than the price of machinery, energy and fertilizer since 1972 which is a marked change from what happened in the 1940s and again in the 1960s. This reversal of past trends has not had much

effect as yet in altering factor combinations, but it is likely to do so in the future.

Finally, indexation of transfer payments, mainly Food Stamp and Social Security benefits, has reduced the potential adverse social consequences of rising food prices. This also has made it more difficult to determine precisely who wins and who loses from inflation. Some of the old rules about who benefits from inflation still apply. Debtors and those who bought land some years ago clearly have gained relative to creditors and new entrants into farming. But with more widespread indexation, even of private pension plans, and increasing public subsidies for medical care, housing and possibly home heating for the poor and elderly, the victims of inflation are less obvious.

Inflation, Agriculture, and the Food Economy: Discussion

Wallace Barr

Our economy, of all economies in the world, should have the capacity for flexibility and dynamism beyond most others to achieve the basic economic goals of full employment, price stability, and economic growth. But, increasingly it appears our economic system lacks the adaptability and capacity to generate change. One reason for inflation being at, or near, the forefront as an economic problem is that we may have set our sights for economic growth, economic equality, and full employment at unrealistic levels. Our promises have led to highly stimulative monetary and fiscal policies. Combined with excessive regulation, they have resulted in an acceleration in the rate of inflation.

Our words and motives are contradictory. Baughman, in a recent speech, said that, "all too often we—

"Talk economic growth but act to restrict production;

"Talk free markets but act to restrict competition;

"Talk price stability but pass laws that directly raise prices;

"Talk full employment but pass laws and impose regulations that directly increase unemployment;

"Aspire to be rich but act to denigrate savings and investments;

"Label inflation public enemy number one but fail to attack it from all quarters." (March, 1979)

Each of the authors has lamented the acceleration in the annual rate of inflation. They have provided a useful basis for looking at some of the impacts and the relationships of inflation to productivity and food costs (Ruttan), commodity programs (Penn), and farm income distribution (Robinson). Little was said about the courses of action to contain inflation.

In light of this situation, I focus my discussion on some policies which have some potential to effectively reduce the annual rate of inflation.

Wallace Barr is an agricultural economist with the cooperative extension service at Ohio State University.

Policy Directions

If we want to design a policy to reduce the rate of inflation we must deal with two basic and highly interrelated questions. The first question is "What rate of inflation is desired?" or "What rate of inflation is tolerable?" The second is "What policy tools, or mix of tools, might best achieve the desired goals?"

A few limitations are in order. It is quite apparent there is too little research on inflation. But there is frequently a shortage of research. Any public policy initiated to combat inflation interacts with factors influencing the welfare of the private sector. The public and private forces can be complementary. But inflation containment policies are sure to conflict with the objectives of some group. Thus, we get into the emotional portion of the policy process in how and what tradeoffs will be made.

High employment levels, economic growth, economic equality, and price stability are all appropriate economic goals. But goals should be set at achievable levels. Each needs to be considered in light of other important goals—not irrespective of the effects on other goals.

The policies suggested below to influence the rate of inflation are just that—suggested. There is neither time nor the inclination to look at all the options or to exhaustively analyze them. Absent are specific magnitudes.

Balance the Budget

The most popular prescription, although not universally acceptable, is to balance the budget. In the legislative process, this policy carries a lower priority than tax reductions and additional spending to meet needs deemed

important. Though a balanced budget may not be absolutely essential to contain inflation, it merits major consideration due to the realities of today's political-economic climate.

The budget could be balanced by increasing revenues while slowing the rise in spending, or by cutting expenditures while maintaining or slightly cutting revenues. A compromise would be to at least halt the increase in spending. Following a series of large deficits it is encouraging that budgets are being subjected to critical review in an effort to lower budget deficits.

The major inflation containment impacts would be (*a*) reduced government employment and purchases of goods and services making more available to the private sector slowing price increases, and (*b*) reduced government borrowing permitting private demand for financing at somewhat lower interest rates. The results of such policies should be to increase capital spending and improve productivity, moderate the rate of inflation, and improve competitiveness in world markets. The major obstacle to a balanced budget is that attainment will probably mean slower economic growth rates.

Slower Expansion of Money and Credit

Any list of inflation containment policies includes slowing the expansion of money and credit. The major reasons for placing a high priority on this course of action is that, in the long run, all that monetary policy can influence is the general price level. And it may be impossible to contain inflation if money and credit are allowed to expand rapidly.

What constitutes an appropriate monetary expansion policy is subject to much debate. But in the years since World War II, consumer prices have advanced about 290%, the stock of money (M_1) increased 320% and, production of all goods and services rose nearly 300%. Thus, monetary growth roughly comparable with growth in production can finance increases in the general level of prices.

In a historical perspective, Baughman (Jan. 1979) cites the five-year period of 1960–65 when annual inflation was 1.6% as measured by the gross national product deflator and production increased at an average annual rate of 4.7%. M_1 increased at an average annual rate of 3.1% and M_2 by 6.4%. Monetary growth, economic growth, and inflation rose and unemployment declined. However, unemployment at 5.5% was deemed unacceptable and stimulative monetary and fiscal policies were pursued.

During 1977 and 1978, the basic money supply or M_1 grew at an average of 8% and 9% for the broader measure M_2. In this period (1977–78), investment in new plant and equipment was inadequate to maintain growth in industrial capacity and/or improve productivity. In the past three months (April-June, 1979) Foldessy points out that M_1 has grown at an 11.1% annual rate and M_2 at 11.2%. These rates far exceed the federally announced long-term growth rate targets of 4.5% for M_1 and 8% for M_2.

From a historical perspective these recent monetary growth rates, if inflation is to be contained, are excessive. In the 1960–65 period moderate inflation and rapid economic growth occurred with a money growth rate of 3% and 6.5% for M_1 and M_2, respectively. If price stability and moderate economic growth are to be the goals, M_1 and M_2 at somewhat lower levels would be in order.

Change the Income Tax Structure

The structure of our income tax system may contribute to inflation (Brake). Many groups have the power to negotiate, arbitrate, or set their incomes. They recognize the need to obtain a 14% increase in wages to net 7% after the tax increase if they are in the 50% bracket. Or that a 7% increase in wages nets only 4% to 5% after taxes.

The loss of incentives from moving to a higher tax rate with a lowering of before tax purchasing power (due to inflation) results in people searching for tax shelters, or writeoffs, or taking more time off, and/or tax cheating. It may be a factor in our relatively low saving rate.

Brake (and others) suggest that indexing the tax structure has appeal because the system would then be neutral to inflation. Congress would increase or reduce taxes as various needs arose. The expected results of neutralizing the income tax structure should result in improvements in price stability and economic growth.

Reduce Bureaucrat Overhead

We worry about inflation but pass laws that increase prices. Examples include recent increases in minimum wages, farm income sup-

ports, and restrictions on some industrial imports.

A policy of reviewing and reconsidering laws and regulations directly influencing prices in light of our relatively high inflation rates should be encouraged. Some may need to be repealed; some may need to be revised to lessen the inflationary impact. The laws designed to restrict competition or to permit groups to raise or maintain prices are those that should be considered.

Laws and regulations should promote competition wherever feasible; not restrain it. Some regulations impose compliance costs that exceed the problems they intend to alleviate. The most noted current example is airline regulation. The deregulation of airline routes, fares, and services is restoring a large measure of competition to this industry. Airline deregulation is demonstrating that restoration of competition is more effective than government regulators. Deregulation of the trucking industry should provide similar benefits, thus helping to contain inflation.

Toward an Inflation Policy

The current state of affairs in this nation provides an improved opportunity to change directions if, in fact, we want to contain inflation. Instead of living with accelerating inflation rates we can decide between the options of (*a*) a gradual reductions approach or (*b*) a more rapid or "shock" approach.

The gradual or rational expectations approach mentioned by Ruttan prescribes a policy of gradually slowing money growth and reducing the federal deficits. The idea is to avoid withdrawal symptoms, but to be of sufficient magnitude and consistency to lead to expectations by consumers, labor, and business that the policy will be continued. The weakness of this approach is that the policies may be abandoned before accomplishing the goal of reducing the inflation rate.

Some people feel the longer it takes to control inflation the less probability the task will be accomplished. This gives rise to the "shock" approach of declaring inflation an emergency. This means calling for emergency measures to control inflation by a specific time, say 1982. The specific measures identified earlier can be adopted in a magnitude determined by Congress and encouraged by the administration to attain the desired monetary growth and employment levels deemed appropriate.

The compelling evidence is that we have an economy that is inflation prone. It inflates easily because we have built in both private and government stimuli to expansion, while our resources do not provide for as much expansion as they once did. Consumer and worker groups use their power to avoid being a victim and investors look for inflation havens.

Since inflation does not arise from a single cause a few grand actions cannot solve the problem. Monetary and fiscal policies are a part of the package of policies that will be required. So are laws and regulations that increase costs, reduce competition, and unduly enhance price. Encouraging freer trade, adjusting income tax laws to provide incentives to invest and to work, and developing a domestic policy to encourage industrial efficiency, including energy, will be helpful in reducing the annual rate of inflation.

Actions to decelerate inflation will be painful to most citizens. But it could be worse for our political-economic system to do nothing.

Inflation, Agriculture, and the Food Economy: Discussion

Dale M. Hoover

The topic for this session is so broad and the economic shocks of the past decade have been so numerous it is not surprising that the preceding papers have ranged over a wide territory. The participants have presented a number of intriguing hypotheses and some very interesting facts. I will present a brief overview of inflation taken from the three papers and from my own assessment. Then I will discuss specific issues from each of the papers and raise some questions about inflation not covered here or in the agricultural economics literature.

Almost everyone agrees that inflation can be said to have occurred if the consumer price index (CPI) increases persistently. However, there is great confusion about the cause of inflation. An Environmental Protection Agency rule may be called inflationary. So too Occupational Safety and Health Administration regulations, frosts, floods, freezes, and droughts, but calling the proximate causes of advances of the components of the CPI the sources of inflation is a mistake. We need to examine the increases in demand that stand behind the advances of specific prices. Taken in the long run, inflation is caused by an increase in the stock of money relative to the quantity of real cash balances that households and business wish to hold at a given level of prices.

In a period of monetary expansion, households and firms find their cash balances increased. They are moved into a state of disequilibrium. They will pass the shock along as they increase their purchases of goods and services. As the sellers of these goods and services transmit orders to replenish their inventories, the shock wave spreads. Producers will probably not identify the increase in demand as a monetary phenomenon unless they already hold an expectation of inflation. The adjustment process will move through the market until all prices have advanced more or less equally.

Now let us look at the microeconomics of inflation in the farm sector. Gardner's model of marketing margins can be used even though it was not designed for inflation analysis. When demand increases, the elasticity of supply for farm products will be less than the elasticity of supply of processing inputs in the short run. This leads to an increase in the price of farm products relative to the processed product and in the "farmer's share of the consumer's dollar." But after the demand changes have worked their way through the processing factor markets, there will be no reason to expect relative price changes. The farmer's share can be expected to fall back to its former level.

Farm input markets will feel the increase in demand and prices will advance. Following an additional lag, asset values will adjust in the direction of restoring the original price/earnings ratio but we need to go cautiously here. It has been widely observed that the real rate of interest—that is, the nominal rate less the rate of inflation—often falls in a period of a rising rate of inflation. This makes borrowing a good thing for those persons who correctly anticipate the rate of inflation. These forces together may impart capital gains from land ownership in the short run. These gains may provide the basis for another round of increases if land price increases confirm past expectations and become a source of new expectations about the future.

There are three more lags that need to be discussed, all in the public sector. Congress tends to write farm laws in absolute terms and only occasionally to build in an escalator clause with a lag. Market prices outrun support prices, but at any hint of market softness there will be pressures from farmers to increase support rates, if net farm incomes fall as input prices catch up. The second lag is in the budgets of not-for-profit organizations such as the land grant universities. Deans and

Dale M. Hoover is a professor and an assistant department head in the Department of Economics and Business at North Carolina State University.

chancellors are not as aggressive as labor union leaders in getting escalator clauses for their associates. This lag reduces the rate of discovery of new techniques and after a considerable period leads to a slowdown in the growth of productivity in the farm sector. The third, but shortest, public sector lag is between Social Security payments and food stamps on the one hand and inflation on the other. This lag is short because of indexing written into the laws. As a consequence, any real income decline that arises because of inflation, or as a result of an attempt to slow it, are concentrated on taxpayers and persons who face reduced employment during recessions.

Now to comments on the papers. While I agree with Penn that we need research on the impact of inflation on agriculture, I do not believe cost-push is a defensible theory of inflation. Appeals to sacrifice as a cure for inflation are not effective except in the shortest of runs and only then if they alter consumers' and producers' expectations. In the face of persistent and increasing inflation they are of no value. In fact, they may confuse the electorate about the locus of responsibility for inflation. If I can convince Penn that money is the primary cause of inflation I can simplify his life and remove some of his worries. The milk program is not inflationary as are neither price supports nor direct payments. Let the monetary authorities have the praise and blame for inflation and let the Economics, Statistics, and Cooperatives Service get on to other issues.

Robinson's review of commodity and input prices covers a period which included monetary inflation as well as the shocks of OPEC and the Russian shortfalls in wheat production. Unfortunately, he confounds the results of inflation with all of the other changes that occurred between 1971–78. Useful and interesting though his analysis is, it does not leave us with a clear impression of the separate impact of inflation as it is classically defined. His analysis of the income distributional impact of inflation is somewhat "cleaner" because national policy has not yet been extended to include "wheat stamps" to recompense poor people for the export boom.

His analyses of the changes in the prices of farm inputs, farm products, and wholesale goods utilize first differences and fairly short periods. As a result the reported changes are very dramatic, perhaps too much so. If the starting and ending indexes of land values are divided by the starting and ending indexes of wholesale prices, the figure for 1960–69 is 1.6. This indicates a 60% increase in the purchasing power of land over industrial goods. Robinson's ratio of first differences for this period is 6.0. Even at a lower amplitude, Robinson has called our attention to some real puzzles that deserve further analysis.

Even though everything depends on everything else in economics, I am not persuaded by Ruttan that there is an important causal force running from productivity to inflation. With inflation at or above 10% and productivity falling one or two percentage points, surely we can neglect productivity as an important determinant of inflation. Labor expectations about productivity may be important in setting the terms for bargaining, but do they loom large relative to secular and cyclical shifts in the real demand for products, technological change that affects the demand for workers, and the rate of inflation existing before the recent declines in productivity? If labor demands lead to an increase in the growth of the money stock, inflation may result. The money stock is still the first round cause of inflation even though there may be a political or public choice process that links labor expectations to price levels in a second round.

Ruttan has stressed an important impact of inflation on productivity through the budget process of public institutions but there is a question about the length of the lag. For example, I am not convinced there was no growth between 1895 and 1925. I believe productivity accountants should examine the changes in the biologic stock in the agricultural sector in that era; the level of nutrients available to crops from centuries of soil building activity, the stock of diseases, and the stock of insects are examples. If the flows from these sources were properly measured, would we still conclude that technology and research had not had any impact or would we conclude that they offset a decline in productivity that would otherwise have emerged? Similarly, was the recent decline in productivity growth due to an undermeasurement of the land stock in the era of diversion and an overmeasurement since 1972?

Ruttan also presents an interesting hypothesis about cheap energy having provided the focus for technological change. Stated in its most optimistic form the induced innovation hypothesis argues that there is considerable payoff to research wherever you are stimu-

lated to invest resources. If this is true, then could not the energy shock provide a stimulus for more technological change?

In thinking ahead to this session I reviewed a considerable amount of the literature and was depressed with how little I found that is useful to an understanding of inflation in the farming and food sector. None of the work on margins I came across formally treats inflation as a problem. Most of the papers that purport to analyze inflation's impact on agriculture use no macro-variables. They simply build in the historical drift in real product prices and then attribute the decline in real farm prices to inflation. An exception is the paper by Shei and Thompson. Why have not we worked on the micro-foundations of inflationary price changes in some way analogous to the labor-search foundations of unemployment or to the disequilibrium market analyses produced by other economists? Since inflation appears to be an important and persistent phenomenon this appears to be an area in which we should launch new studies.

Valuing Nonmarket Goods: Conceptual and Empirical Issues (Virgil Norton, University of Maryland, Chairperson)

Approaches to Measuring Public Goods Demands

A. Myrick Freeman, III

Although some public finance textbooks still teach that public goods demands cannot be measured, substantial progress has been made in developing and implementing techniques for measuring one form of public good—the benefits of improving environmental quality. This paper presents a brief review of the three major approaches to estimation of demands and benefits and a somewhat more detailed discussion of those techniques which are based on market interactions between public and private goods. The analysis is limited to those public goods which are arguments in individual utility functions. Public goods which are inputs in production processes for marketed goods—for example, air quality in agricultural production—affect cost, supply, and factor demand functions and through them affect one or more of the following: output prices, factor prices, and profits (quasi-rents). The benefits of increases in public goods supply can be measured in a conceptually straightforward manner from observable market data. See Freeman (1979a) for an elaboration.

Individual Demands for Public Goods

The first step is to outline a basic model of individual preference and demand which incorporates a public good such as environmental quality as an argument in the utility function. This will establish the basis for describing various approaches. The analysis is limited to only one individual so that the problem of consistent aggregation to market demand curves can be ignored. Assume a utility function of the following form:

$$(1) \qquad U = U(\mathbf{X},Q),$$

where $\mathbf{X}$ is a vector of private goods, $\mathbf{X} = (x_1, \ldots, x_i, \ldots, x_n)$, and Q is the level of environmental quality taken to be fixed to the individual. Maximizing utility subject to a budget constraint

$$\sum_i p_i x_i = M,$$

where M is money income, leads to a set of demand functions

$$(2) \qquad x_i = x_i(\mathbf{P},M,Q).$$

Note that in general it is possible that environmental quality could be an argument in private goods demand functions.

The dual to the utility maximization problem can be stated as follows: minimize expenditures $\left(\sum_i p_i x_i\right)$ subject to the constraint that utility as defined by (1) equal or exceed some stated level, say U^*. The solution to this problem gives the expenditure function

$$(3) \qquad E(\mathbf{P},Q,U^*) = M.$$

The derivative of the expenditure function with respect to any price gives the Hicks-compensated demand function for that good, i.e.,

$$(4) \qquad x^*_i = \partial E/\partial p_i = E_{p_i}(\mathbf{P},Q,U^*).$$

The compensating variation and equivalent variation measures of the welfare changes associated with changes in market price can be interpreted easily in terms of equation (3). Similarly, the derivative of (3) with respect to Q gives the Hicks-compensated inverse de-

---

A. Myrick Freeman, III, is a professor in the Department of Economics, Bowdoin College.

The author is grateful to V. Kerry Smith for a number of helpful discussions of various aspects of the paper.

mand function or marginal willingness to pay for environmental quality, $w^*(Q)$,

$$w^* = -\partial E/\partial Q = E_q(\mathbf{P},Q,U^*). \tag{5}$$

The benefit to the individual for a nonmarginal increase in Q is:

$$b = -\int_{Q_1}^{Q_2} E_q(\mathbf{P},Q,U^*)dQ. \tag{6}$$

The main question addressed in this paper is under what circumstances and by what techniques information on (5) or (6) can be obtained.

Empirical Approaches

One approach involves analyzing data from market transactions in goods and services related to various measures of environmental quality. Under certain circumstances, the demand for improvement in Q can be estimated from market data on the demand for goods and services which have substitute or complementary relationships with Q. Examples of these approaches include: the use of property value differentials; household expenditures on cleaning, maintenance, and repair of materials damaged by pollutants; and travel costs incurred to participate in outdoor recreation.

The second approach is simply to ask individuals, through surveys and direct questioning, what value they place on a specified change in Q or how much Q they would "purchase" at a given stated price. One well-known problem with this approach is the incentives individuals may have to give biased answers for strategic reasons. In addition to these strategic biases, there is some evidence that certain structural characteristics of surveys have the potential for biasing responses. For example, in order to make the questions seem realistic, some surveys have stated that the vehicle for repayment will be an increase in the sales tax, or a surcharge on electric utility bills. If the respondents have some attitudes concerning the chosen means of repayment, this could introduce vehicle bias into responses. Also, in many surveys the questioner announces a value and then adjusts it upward or downward in fixed increments depending on the response. The starting point can also introduce a bias.

It appears to be possible, however, to design survey questions so as to eliminate the incentives for biased response. The general approach is to design the survey instrument so as to minimize the occurrence of any linkage between a subject's response and either an actual repayment or an actual outcome. But devices to eliminate incentives for biased responses also have a second effect. They reduce the incentive to provide accurate responses. An accurate response is one which is consistent with the behavior that would be revealed if the good in question could actually be offered in a market. In the real world, an individual who takes an action inconsistent with his basic preferences, perhaps by mistake, incurs a cost or a loss of utility. In the purely hypothetical survey situation, there is no cost to being wrong, and therefore no incentive to undertake the mental effort to be accurate. The more hypothetical the situation posed to the individual; that is, the further removed the situation is from his normal everyday experience, the less likely is the answer to be accurate. This problem has not yet been addressed seriously.

Another problem with surveys has to do with perceptions and how to portray accurately the hypothetical situation to respondents. For example, if the purpose of the survey is to estimate the benefits of a specified water quality improvement, the questioner must find a way to describe the improved water quality accurately and in sufficient detail so that all respondents are reacting to similar perceptions of water quality improvement. Some of the best survey studies have combined photographs with descriptive textual material, e.g., Brookshire, Ives, and Schulze, and Randall, Ives, and Eastman. But there are limits to the ability of both words and pictures to convey effectively all of the aesthetic dimensions associated with Q.

In summary, at the theoretical level the problems of bias, accuracy, and perceptions must give one pause about the effectiveness of surveys in measuring willingness to pay. However at the practical level there is very little evidence concerning the seriousness or the magnitude of the errors introduced by these three problems. It would be useful to have comparative studies of benefit estimates derived by alternative techniques. Few of these have been done (Knetsch and Davis; Brookshire, d'Arge, Schulze). In the meantime, information derived from such surveys can be considered useful but not definitive.

A third approach is to place proposals which consist of alternative levels of Q and asso-

ciated tax increases to referendum vote. Under certain circumstances the outcome of the voting process will be consistent with, and therefore reveal information about, the underlying demand curve for improved Q. The outcome of a referendum in any one jurisdiction only reveals whether the proposed level of Q and the associated tax burden were preferable to the status quo for a majority of voters. However, if the outcomes of elections or referenda in a large number of jurisdictions are observed simultaneously, it can be assumed that they approximate the median preferences in each jurisdiction. Then each jurisdiction can be taken as a sample unit, and the data on the quantity of the good or service, price or tax share, and socioeconomic characteristics such as income, education, and occupation can be pooled and analyzed by multiple regression techniques to determine the relevant price and income elasticities of demand. Examples of this approach include Bergstrom and Goodman, and Borcherding and Deacon.

Where all costs are financed through taxes in the voting jurisdiction and all benefits accrue to residents, voting can yield unbiased information on demand and on the optimum provision of Q. But where some of the benefits accrue outside the region, voting behavior does not capture all of the relevant demand for Q. And where some of the costs are shifted out of the jurisdiction, voters are not responding to the true price; thus voting reveals information about only a limited (and not the most relevant) portion of the demand function.

Market Approaches

In this section a priori assumptions are used to impose certain restrictions on the form of individual utility and demand functions. Different types of restrictions have different implications for the measurability of public goods demands from market data. The first assumed restriction leads to a situation in which it is impossible to estimate the demand for Q from market data.

A Hopeless Case

Suppose that the utility function is strongly separable with Q as the single argument in one of the subsets. In other words,

$$U = V[u^a(\mathbf{X}_a) + u^b(\mathbf{X}_b) + u^c(Q)],$$

where $\mathbf{X}_a$ and $\mathbf{X}_b$ are subsets of marketable goods. Strong separability means that the marginal rates of substitution between any pair of goods in $\mathbf{X}$ are independent of Q. Changes in Q have no effect on marginal rates of substitution of any of the marketable goods. Q can be excluded as an argument in all of the market demand functions. Although changes in Q affect utility, they leave no record of this impact in the data on market transactions. Thus in principle it is not possible to estimate the demand for Q from observable market data on transactions in $\mathbf{X}$ when the utility function is strongly separable in Q.

Strong separability is a property of two of the most commonly used functional forms for utility functions—the Cobb-Douglas and the constant elasticity of substitution (CES). This can be seen by writing them in their log transformations. Separability may be a characteristic of an important class of benefits. For example, those amenities of the urban environment which are not directly associated with private goods consumption may be separable. The option value associated with the preservation of unique natural environments is also likely to be separable (Cicchetti and Freeman).

Weak Complementarity

For some forms of utility functions, the private goods demand functions do contain Q as arguments:

$$x_i = x_i(\mathbf{P}, Q, M). \tag{8}$$

Suppose that this system of demand equations has been estimated econometrically and that the system satisfies the Slutsky conditions for integrability. Is it then possible to integrate this system to solve for the underlying utility function and expenditure function? If the answer is yes, then it would be possible to compute public goods demand or willingness to pay functions from market data whenever private good demand functions had this form.

The answer is that in general it is not possible to solve completely for the utility and expenditure functions with the information given. Mathematically the result of the integration contains unknown terms which are themselves functions of Q and the constants of integration (Mäler, pp. 183–9). It is necessary to impose additional conditions on the problem in order to solve for the unknown terms and determine the constants of integration.

The additional conditions involve what Mäler has called "Weak Complementarity."

Weak complementarity is defined by Mäler to occur if when the quantity demanded of a private good x_i is zero, the marginal utility or marginal demand price of Q is zero. The weak complementarity assumption would seem to apply to a number of useful situations. For example, the marginal value of water quality in a particular lake could be assumed to be zero for those people who did not use the lake for recreation. The marginal value of air quality over a particular residential site would be zero for those who did not live at that site.

Since direct application of the weak complementarity method as described here would require the econometric estimation of complete systems of demand equations, it would appear to be of relatively limited practical significance. Fortunately the weak complementarity conditions also permit the estimation of the demand price for Q without solving for the underlying utility and expenditure functions. This latter method requires only information on the demand for x_i, the weakly complementary private good. When Q increases, the demand curve for x_i shifts out. Mäler (pp. 185–6) has shown that the benefit of the improved Q can be measured by the area between the old and new demand curves for x_i. In those cases where weak complementarity is not strictly true, i.e., when the willingness to pay for Q is positive even with zero x_i, then this area understates the true demand for Q.

If the analysis uses the Hicks-compensated demand curve for x_i, the area between the curves is an exact measure of the compensating variation measure of benefits. If an expression can be formulated for this area as a function of Q, the derivative of this function with respect to Q is the marginal demand price for Q. Typically what is known is an ordinary demand curve, not a Hicks-compensated demand curve. Willig has established conditions under which areas under ordinary demand curves can be taken to be close approximations of the precise compensating or equivalent variation measures. A straightforward extension of Willig's analysis shows that if the income elasticity of demand for x_i is constant over the range of variation, his conditions also apply to areas between ordinary demand curves. Thus for practical purposes, the technique described here can be applied to market data. (See Stevens for an example.) The primary empirical requirement for utilizing this technique is that we be able to obtain econometric estimates of the demand function for the private good as a function of Q as well as prices and income. This requires observations of the market for x_i under different quantities of Q. If Q has never changed, there is no possibility of identifying the partial relationship between Q and the demand for x_i.

Perfect Substitutes

Mäler (pp. 116–18) has shown that the partial derivative of the expenditure function with respect to Q is equal to the price of the private good times the marginal rate of substitution between it and Q. This would be a useful practical result if it were possible to derive simple expressions for the marginal rate of substitution.

Suppose the utility function is weakly separable and is of the following form:[1]

$$(9) \quad U = V\{u^a(\mathbf{X}_a), [cx_i^{-\rho} + (1 - c)Q^{-\rho}]^{-1/\rho}\},$$

(x_i is not in $\mathbf{X}_a$). Given the separability assumption, the marginal rate of substitution between x_i and Q is independent of the quantities in $\mathbf{X}_a$. Then the marginal willingness to pay is

$$w^* = -P_{x_i}\left(\frac{c}{1-c}\right)\left(\frac{Q}{x_i}\right)^{1/\sigma},$$

where σ is $\rho - 1$.

In general, to use this formulation, we need to know both the elasticity of substitution, σ, and "c." There is one special case where the expression reduces to a usable term. If x_i and Q are perfect substitutes in consumption, the elasticity of substitution between them is infinite, and the expression for the marginal demand price of Q reduces to $P_{x_i}r$, where r is the equivalence or substitution ratio between x_i and Q.[2] If perfect substitutability can be assumed, r (or c) should be computable from known or observable technical consumption data.

The perfect substitutability assumption lies behind the "defensive expenditures" technique for estimating benefits of pollution control. Defensive expenditures (or what Zeckhauser and Fisher call averting behaviors) are expenditures made to prevent or counteract the adverse effects of pollution. If de-

[1] The following discussion is based on Mäler, pp. 178–83.

[2] $r = c/(1 - c)$. For example, if $c = .75$, then $r = 3$. This means that one unit of Y is a perfect substitute for three units of x_i.

fensive expenditures are a perfect substitute for reductions in the level of pollution effects experienced, then an individual can effectively purchase the optimal amount of Q through defensive outlays. In practice, defensive outlays which would be perfect substitutes for Q would be rare. There is no such thing as a perfect defense. There are some disutilities associated with pollution that cannot be prevented by further spending. This is equivalent to saying that σ is less than infinite. Hence, changes in defensive outlays are likely to give underestimates of the true benefits of the changes in Q. Nevertheless, recognizing this limitation, analysis of changes in defensive outlays related to pollution could substantially narrow our range of ignorance about benefits.

Hedonic Prices

The techniques described so far have been developed for the case where the level of public good provision or environmental quality is fixed and the same for all individuals. Although this represents one polar extreme, it is not descriptive of all possible cases involving public goods or environmental quality. Individuals can choose the level of consumption of local public goods through their choice of a jurisdiction to reside in. Also there are important cases where individuals have some freedom to choose their effective consumption of environmental quality through their selection of a private goods consumption bundle. Where these choices are possible, information on public good demand is embedded in the prices and consumption levels for private goods. For example, if air quality varies across space in an urban area, individuals may choose their exposure to air pollution through their residential location decisions. Residential housing prices may include premiums and discounts for locations in clean or dirty areas. It may be possible to estimate the demand for clean air from the price differentials revealed in private markets. The demand function for Q is estimated through a two-step procedure in which first the implicit price of Q is estimated by the application of the hedonic price technique, and then the implicit prices are regressed against observed quantities to estimate the demand function itself.

The hedonic technique is a method for estimating the implicit prices of the characteristics which differentiate closely related products in a product class (Freeman 1979b). Let **X** represent a product or commodity class. Any unit of **X** can be completely described by a vector of its characteristics. Continuing with the housing example, let c_i represent the specific characteristics of a structure and its lot, and Y_j represent neighborhood characteristics such as quality of schools, and Q represent air quality. Then for any unit of **X**, say x_i,

$$(10) \quad P_{x_1} = P_x(c_{11}, \ldots, c_{1i}, \ldots, c_{1n}, Y_{11}, \ldots, Y_{1j}, \ldots, Y_{1m}, Q_1).$$

The function P_x is the hedonic or implicit price function for **X**. If P_x can be estimated from observations of the prices and characteristics of different models, the price of any model can be calculated from knowledge of its characteristics.

The implicit price of a characteristic can be found by differentiating the implicit price function with respect to that characteristic. This gives the increase in expenditure on **X** that is required to obtain a model with one more unit of that characteristic, *ceteris paribus*. If (10) is linear in the characteristics, then the implicit prices are constants for individuals. But if (10) is nonlinear, then the implicit price of an additional unit of a characteristic depends on the quantity of the characteristic being purchased, and perhaps on the levels of other characteristics, too. Linearity will occur only if consumers can "arbitrage" activities by untying and repackaging bundles of attributes (Rosen, pp. 37–38).

Under some circumstances it may be possible to use the information contained in the implicit price function to identify the demand relationship for a characteristic—even if the characteristic is a public good such as environmental quality. First assume that each individual purchases only one unit of **X**, or if he purchases more than one, they are identical models. Otherwise the individual facing a nonlinear hedonic price function might be observed to act upon two different implicit prices for the same characteristic. Also assume that the utility function is separable in **X** and its characteristics. This makes the marginal rate of substitution between any pair of characteristics independent of the consumption of any good other than **X**. Without separability, the demand for a characteristic would in fact be a function of the consumption levels of other goods; and the estimation of the second stage demand function would require addi-

tional price and quantity data beyond that derived from the hedonic price function.

For the i^{th} individual, the quantity, Q_i, is known by observation and its implicit price P_{Qi} is known from the implicit price function. Can individuals' marginal willingness to pay functions be identified from these observations? The answer depends on the circumstances of the case. If the implicit price function is linear in Q, then it is not possible to identify a demand curve for Q. The price observation is the same for all individuals. However the marginal implicit price can be interpreted as the marginal willingness to pay or marginal benefit for small changes in Q for each individual. If equation (10) is nonlinear, the ability to identify the demand curve depends on the specification of the underlying model (Freeman [1979a] and Rosen).

If inverse demand functions for individuals can be identified, benefits of changes in Q can be calculated by taking areas under the demand curves bounded by the old and new levels of Q. Since these are not income-compensated demand curves, the areas are approximations of the true compensating variation measure.

Values of Marine Recreational Fishing: Measurement and Impact of Measurement

Kenneth E. McConnell

There is a rich literature in economics dealing with the inefficiencies of the competitive allocation of open access resources. Economists working in the area of outdoor recreation have devised several methods for simulating market demand curves for estimating social benefits. Recreational fishing, most especially marine fishing, is one of those activities competing for the use of open access resources that requires the estimation of social benefit functions.

In the absence of good information about net social benefits for open access activities, decision makers tend to respond to measures which reflect the total level of economic activity. Decisions based on the level of economic activity can have rather severe consequences for nonmarket activities such as recreation. This bias is evident in the allocation of resources between marine recreational and commercial fishing. The history of fishery management in the United States, particularly on the East Coast, is almost exclusively that of commercial fishery management. The magnitude of commercial fishing is recorded in market transactions at harvesting, in processing and consumer levels, and by inputs such as vessel days at sea, fuel, and employment. However, for measures of the magnitude of recreational fishing, we have only the market value of inputs used in fishing such as boats, rods and reels, and other ancillary services. One result of relying on market data is to instill in policy makers the belief that fish are most valuably used in the commercial sector because only in that sector is the output sold on the market.

Economists can help improve resource allocation by applying their evaluation techniques to marine recreational fishing. In this paper, I report on two approaches to evaluation: the travel cost method (Dwyer, Kelly, Bowes) and the hedonic price method (Pollak and Wachter; Brown, Charbonneau, Hay; Bockstael and McConnell). The two approaches are similar in that they rely on observed behavior rather than responses to hypothetical questions. They differ in the extent to which they assume an individual can control his environment.

Economists view the efficient allocation of fish stocks between commercial and recreational fishing as the allocation which maximizes the present discounted value of recreational benefits plus commercial benefits, subject to a constraint on the biological growth of the fish stock. The solution to this problem yields a dynamic multiplier which can be interpreted as the user cost of catching fish. The optimal allocation between commercial and recreational use can be achieved by imposing a fee per unit of catch equal to the user cost. The user cost depends upon the discount rate, the response of catch to increased stock density, the response of commercial and recreational effort to increased catch, and the change in biomass growth caused by greater stock densities (for details, see McConnell and Sutinen). No economist would argue seriously that fisheries management requires simply the computation of user cost and the imposition of a fee per pound of fish landed equal to the user cost. Yet, the information required to calculate the user cost is central to decisions about fishery management, and can give direction to empirical work. In particular, we need to estimate how the value of recreational fishing responds to changing stock densities.

The Household Production Function

The value of fish allocated to the recreational sector can be determined from the recreationist's net benefit function as it depends

Contribution Number 1879 of the Rhode Island Agricultural Experiment Station. This paper was based on data gathered as part of a three-year study on recreational fishing funded by the National Marine Fisheries Service and the University of Rhode Island Sea Grant Program. The author appreciates the help of Nancy Bockstael whose ideas formed an integral part of this paper. He also wishes to thank Bill Ralph for help in all stages, and Jon Sutinen and T. J. Tyrell for valuable comments.

upon catch rates and trips.[1] To estimate this function, it is useful to adopt the household production function framework:

$$(1) \qquad x = x(\mathbf{w}_1),$$

where x is trips and $\mathbf{w}_1$ are inputs used to produce x, for example days, miles traveled.

$$(2) \qquad q = q(\mathbf{w}_2, S, \mathbf{a}),$$

where q is fish caught per trip, and $\mathbf{w}_2$ are inputs used to catch more fish per trip; for example, bait, time per trip, etc., S is the stock density of fish, and $\mathbf{a}$ is a set of attributes peculiar to the individual which affects production technology. S is a public input in the sense that it enters all anglers' production functions.

An individual's choices of trips and catch per trip can be viewed as if it were the result of a two-step maximization process. In the first step the individual minimizes $\mathbf{p}_1\mathbf{w}_1 + \mathbf{p}_2\mathbf{w}_2$, the cost of achieving x and q, where $\mathbf{p}_i$ is the price vector for inputs $\mathbf{w}_i$. The result is a cost function which depends on $\mathbf{p}_i$, x, q, $\mathbf{a}$, and S. It is assumed that S and $\mathbf{p}_i$ do not vary systematically across individuals. In the second step the user maximizes utility subject to costs of the consumption bundle not exceeding income, I.

The equilibrium conditions for this two-step process are:

$$(3) \qquad \begin{cases} f_x(x,q,I) = MC_x(x,q,\mathbf{a}) \\ f_q(x,q,I) = MC_q(x,q,\mathbf{a}), \end{cases}$$

where $f_x(\cdot)$ and $f_q(\cdot)$ are the marginal value functions for x and q, and $MC_x(\cdot)$ and $MC_q(\cdot)$ are the marginal cost functions for x and q. If the individual cannot adjust his catch rate, then $\partial q/\partial \mathbf{w}_2 \equiv 0$, and catch rates may be considered exogenous. Then (3) reduces to $f_x(x,q,I) = MC_x(x)$ which is simply the travel cost method if $MC_x(x)$ is independent of x.

In the following two sections applications of the travel cost and household production function approaches to data gathered from a survey of marine recreational fishing in Rhode Island are presented. The example pertains to fishing for winter flounder. As the reader will discern, the estimates presented are not conclusive. It is perhaps most useful to consider these empirical results as an example of how one might apply the two approaches.

The version of the household production function presented is based on the idea that fishermen can increase their catch rate per trip by spending more on bait and equipment. We assume, for a given individual, that the catch rate does not vary systematically with trips (i.e., the catch rate is constant across trips per year, except for a random component). The cost of increasing trips depends on the catch rate per trip. Thus, the higher the catch rate, the higher the marginal cost of a trip. Likewise, the marginal cost of the catch rate increases if there are more trips. Let t be the constant travel cost per trip, and let c_q be the constant cost of catching a fish. Then total costs per year are given by:

$$(4) \qquad C(x,q) = xt + xqc_q.$$

Observe that

$$\begin{aligned} \partial C/\partial x &= t + c_q q = MC_x(q) \\ \partial C/\partial q &= xc_q = MC_q(x). \end{aligned}$$

Hence, though the marginal cost of x is independent of x, it depends on q, and similarly for the marginal cost of q.

To complete the system, we assume that the demand functions can be approximated by linear forms, so that (3) can be written:

$$(5) \qquad \begin{cases} x = a_0 + a_1 p_x + a_2 p_q + a_3 z_1 + \theta_1 \\ q = b_0 + b_1 p_x + b_2 p_q + b_3 z_2 + \theta_2, \end{cases}$$

where the z_j are exogenous variables and θ_j are disturbances. Here p_q and p_x are the equilibrium marginal costs and marginal values of x and q. Substituting the marginal costs as given in (4) for p_x and p_q, we have

$$(6) \qquad \begin{cases} x = a_0 + a_1(t + qc_q) + a_2(xc_q) + a_3 z_1 + \theta_1 \\ q = b_0 + b_1(t + qc_q) + b_2(xc_q) + b_3 z_2 + \theta_2. \end{cases}$$

This system can be estimated by nonlinear two stage least squares (Kelejian), though the efficiency can be improved by using nonlinear 3SLS.

To compute social value from (5) and (4), we solve for the marginal values as a function of x and q. Suppressing the exogenous variables and the disturbances into the constant term and solving (5) for p_x and p_q, we have:

$$(7) \qquad \begin{bmatrix} p_x \\ p_q \end{bmatrix} = \begin{bmatrix} a_1 & a_2 \\ b_1 & b_2 \end{bmatrix}^{-1} \begin{bmatrix} x - a_0 \\ q - b_0 \end{bmatrix} = \begin{bmatrix} \gamma_0 \\ \beta_0 \end{bmatrix} + \begin{bmatrix} \gamma_1 & \gamma_2 \\ \gamma_2 & \beta_2 \end{bmatrix} \begin{bmatrix} x \\ q \end{bmatrix}.$$

By assuming that $\partial x/\partial p_q = \partial q/\partial p_x (b_1 = a_2)$,

[1] This section is an application of the ideas on the household production function presented in Bockstael and McConnell.

we can write the total value associated with x and q as a line integral from (0,0) to (x^*,q^*) (Burt and Brewer). Let this path be denoted Q. Then

$$(8)\ \text{Total value} = \int_Q f_x(x,q)dx + f_q(x,q)dq.$$

The net social value is given by the line integral

$$(9)\ \text{Net Value} = \int_Q [f_x(x,q) - MC_x(q)]dx + [f_q(x,q) - MC_q(x)]dq.$$

Symmetry is assured by definition in the cost function, but it must be imposed on the demand function. Imposing symmetry is equivalent to assuming that the income elasticities are equal for trips and catch rate.[2] This approximation we assume to hold locally.

Symmetry lets us express benefits as a path-independent line integral. Thus,

$$(10)\ \text{Net value} = \gamma_0 x + \gamma_1 x^2 + 2\gamma_2 xq + \beta_0 q + \beta_2 q^2 - tx - xqc_q.$$

For estimation purposes, (6) is rewritten with observation indexes

$$(11)\ \begin{cases} x_i = a_0 + a_1(t_i + c_{qi}q_i) \\ q_i = b_0 + b_1(t_i + c_{qi}q_i) \end{cases} \begin{aligned} &+ a_2(x_i c_{qi}) + a_3 z_{1i} + \theta_{1i} \\ &+ b_2(x_i c_{qi}) + b_3 z_{2i} + \theta_{2i}. \end{aligned}$$

The exogenous variables are z_1, z_2, t, and c_q. The nonlinear 2SLS procedure calls for estimating $t + c_q q$ and xc_q as polynomial functions of the exogenous variables in the first stage; in the second stage the predicted values of $t + c_q q$ and xc_q are used as instruments on the right hand side of (11). In the application here, z_1 is years of experience fishing and z_2 is the number of rod and reel combinations owned.

Table 1 presents preliminary results of the estimation procedure. These results are suggestive rather than final.[3] The equations were estimated with only fifty-six observations, perhaps accounting for the low t-values. More efficiency could also be achieved by accounting for the correlation between errors for the two equations. Consumer's surplus was computed on the basis of mean values of independent variables from equation (10). For a representative fisherman seeking winter flounder, consumer's surplus was computed to be $515.

The Travel Cost Approach

An alternative to the household production function is to assume that anglers cannot vary their catch rates. The result is a single equation system where the catch rate is exogenous. However, it is still an argument of the demand function because individual attributes such as rods and reels make catch rates vary across individuals. To use the travel cost approach we estimate with OLS

$$(12)\quad x_i = r_0 + r_1 t_i + r_2 q_i + r_3 E_i + \epsilon_i$$

where t_i is the cost of taking another trip, q_i is the catch per trip, E_i is the experience of angler in number of years fished, and ϵ_i is the random error term. This specification is fairly close to the spirit of the one given in table 1. The OLS results for equation (12) are

$$(13)\quad x_i = 7.1 - \underset{(2.58)}{.085t_i} + \underset{(.14)}{.015q_i} + \underset{(.42)}{.012E_i} \qquad \bar{R}^2 = .11 \quad n = 56,$$

where t-statistics are in parentheses. Obviously this equation leaves something to be desired in terms of explanatory power and significance of variables. It is worth noting that r_1 changed little with specifications involving different independent variables.

Consumer's surplus in the single equation case is computed as the area under the demand curve and above the cost line. For mean values of independent variables, consumer's surplus is $233. Although equation (13) is statistically weak, the estimate of consumer's surplus is robust because of the stability of the slope of the demand curve for specifications with other independent variables.

In addition to substantial uncertainty about coefficients of the equations, there are two reasons why the household production function estimates more consumer's surplus. First, the quality variable is complementary to trips, and to the extent that cost of quality and the

[2] Testing this assumption is quite difficult. Estimates of the coefficients on income variables in trip demand equations tend to be negative or insignificant and are biased because the cost of time is excluded from the price variable and is highly correlated with income. Empirical work from fertility studies suggests that the income elasticity for the quality variable is a good deal higher than for the quantity variable.

[3] A serious difficulty with these estimates is the omission of the cost of substitutes. All anglers come from Connecticut, Massachusetts, or Rhode Island, and they tend to have the same kinds of nonfishing substitutes available to them. However, substitution from one species to another is quite likely and very difficult to capture empirically. The ability to substitute among species implies that the estimates of net benefits presented here are biased upward.

Table 1. Preliminary Results

	Variable				
Equation	Constant	Marginal Cost of Trips	Marginal Cost of Catch Rate	Experience	Rods and Reels Owned
Trips	7.68	−.117	−.0087	.015	—
		(2.84)[a]	(.61)	(.57)	
Catch rate	2.39	−.0087	−.025	—	.628
		(.61)	(1.75)		(6.2)

[a] *t*-statistics in parentheses. Results based on fifty-six interviews of fishing for winter flounder in Rhode Island.

cost of trips are positively correlated, omitting the cost of quality will result in a downward bias for consumers' surplus. (This result is the converse of Burt and Brewer's finding that value estimate will be biased downward if relevant substitutes are omitted [p. 819].) If an individual can effectively choose quality as well as trips, then the mythical perfectly discriminating monopolist can extract rent from him in two dimensions of choice.

Results such as presented here can be used for policy by measuring the change in consumers' surplus induced by changes in the density or availability of fish stocks. For the single equation case we need to know the relationship between fish stock densities and catch rates (q). Then the marginal value of a one period change in the stock of fish can be computed by taking the product of the marginal value of the catch rate and the Δcatch rate/Δfish stock. Conceptually, this task is relatively simple. It is even reasonable to imagine that one could measure the relationship between densities and catch rates (see Stevens, for example). However, equation (13) is too weak empirically to justify such computations.

The household production framework can be used for policy analysis if we know the relationship between the cost of catching another fish (c_q) and fish stock density. Then the marginal value of a one period change in fish stock density is the product of Δc_q/Δfish stock and the change in consumer's surplus induced by changes in c_q. It is possible to design an experiment to show how c_q (or other costs) might change as the density of fish stocks change. However, no such effort has been attempted for recreational fisheries because it requires time series data on stock densities in particular areas as well as detailed information on recreational fishing over time.

Evaluation

The previous section has shown that there are substantial benefits from marine recreational fishing. Regardless of our measurement technique, we know that marine anglers receive benefits for the right to fish, and that those benefits increase as they catch more fish. The evidence at this time is by no means solid enough to compete with the commercial price of fish, but it is growing stronger (for example, we have similar evidence from Stevens and Talhelm).

With this evidence we should expect a willingness by marine policy makers to provide some portions of annual yields for recreational purposes. However, there is evidence that recreational fishing is still a second cousin to commercial fishing. A document reflecting the U.S. Department of Commerce's view of fisheries policy states "First priority has been placed on commercial fishing because of its importance" (U.S. Department of Commerce).

Economists have devoted substantial effort to devising methods of reflecting the social value of harvesting fish for recreational use. Yet many economists have found that policy makers see little connection between social benefits, as measured by economists, and resource allocation. Why are economists' measures of social welfare difficult to accept?

Many decision makers are basically mercantilists. They choose projects on the criterion of total expenditures, rather than net benefits. At the regional level, one can make some sense out of such a policy because it implies maximizing the region's balance of trade surplus. However, at the national level there is no legitimate reason for choosing on the basis of expenditures. Nevertheless, policy makers

are much more interested in estimates of expenditures than total value.

Decisions are made on the basis of the "do no direct harm" thesis (see Schultze, pp. 23–24). On that basis, the harm to commercial fishing interests from reducing their catch is obvious. The damage done to recreational fishermen, particularly when they do not support a substantial service sector, is not visible when one measures the damages by the change in the value of market transactions.

Economists have not measured the producers' surplus associated with harvesting fish commercially. Many fishermen are attracted to fishing as a way of life. A substantial, but unmeasured, social loss may occur when fishermen are forced to leave fishing for other occupations. The prospect of this loss by the fishermen generates much political pressure to ensure that commercial fishing effort is not reduced.

It is a difficult task to argue that society may be better off with a greater recreational harvest simply because sports anglers are willing to pay more for the additional fishing than commercial fishermen must be paid to compensate them for not fishing. It is difficult because we have few measures of changes in willingness to pay from changes in fishery policy. It is difficult because decision makers use many types of measures of welfare, and are as interested in the distribution of benefits as in Pareto-optimal changes.

What can economists do to improve resource allocation? The notion of Pareto optimality is central to economists' definition of improvement, but pure Pareto improvements are scarce. Hence we tend to deal with potential Pareto improvements, which may bring changes in the distribution of welfare. Economists can judge changes in resource allocation which induce welfare redistributions only by judging the relative importance of the welfare of different individuals. It is more plausible to suppose that economists can help improve resource allocation by describing as accurately and concisely as possible the implications of various management strategies. By describing the magnitude of recreational fishing in terms of catch and expenditures as well as consumers' surplus, economists can help ensure that marine recreational fishing receives fair treatment among policy makers conditioned to thinking only of commercial fishing.

Measuring Values of Extramarket Goods: Are Indirect Measures Biased?

Richard C. Bishop and Thomas A. Heberlein

The well-known travel cost method (TC) has been widely applied to outdoor recreation. A second approach has been referred to in the past as the Davis method, the questionnaire approach, and contingent valuation. It will here be termed hypothetical valuation (HV), because it involves creating a hypothetical situation designed to elicit willingness to pay for or willingness to accept compensation for a recreational or other extramarket good (or bad). TC and HV are termed "indirect methods," because they do not depend on the direct information about prices and quantities that economists would prefer to use where available to value goods and services.

A number of potential sources of bias in HV and TC have been discussed in the literature and we shall summarize these in the first section of the paper. When summed together, these potential problems are sufficient to justify considerable skepticism about the accuracy of resulting value estimates. Still, the question remains: How large an impact do these supposed sources of bias have in actual practice? In the second section of the paper we report the results of an experiment where TC and HV values were compared to values based on actual cash transactions. Though preliminary, the results of this experiment indicate that substantial biases exist in both TC and HV estimates.

Potential Sources of Bias

In TC, differences in travel and possibly other costs to recreationists at varying distances from the recreation site are used to infer how recreationists would behave if prices higher than the actual admission fee were charged. Thus, potential sources of bias exist if there are substantial differences in the recreationists' tastes and preferences, access to substitutes, and income levels at varying distances from the recreation site. It is fairly straightforward to control statistically for differences in income. Potential problems relating to tastes and substitute availability are much more difficult.

A particularly thorny problem in developing TC value estimates relates to time costs. It is clear that those who live farther from the recreation site in question not only incur larger transportation costs, but also expend more time in travel. What sort of price should be attached to this time? Several factors make this a complicated issue. Clearly the wage rate of adults overestimates what they could earn from second jobs. Furthermore, in opportunity cost terms, if people were not traveling to the recreation site most would probably be engaged in other leisure time activities rather than working. What is leisure time in the next best recreational activity worth? Also, how to value time of children and adolescent participants is not well understood. To make matters even more complex it is not inconceivable that travel to some recreation sites may actually add to the benefits rather than the costs, as when the route is a scenic one. Cesario has suggested that time be valued at between one-fourth and one-half the wage rate. While this is a beginning, it must be considered as a very crude adjustment since it is based on urban transportation studies and offers little guidance as to the exact figure to be used. As we shall see below, whether a factor of one-fourth or one-half is used can make a substantial difference in the value estimates.

TC requires that recreationists treat travel expenditures as equivalent to admission costs, yet this is a questionable assumption which no one has examined empirically. Travel costs represent an aggregation of many smaller costs, some of which (e.g., tire wear) may not be obvious to the recreationist and which are not

Richard C. Bishop and Thomas A. Herberlein are associate professors of agricultural economics and rural sociology, respectively, at the University of Wisconsin-Madison.

The research was supported by the College of Agricultural and Life Sciences, University of Wisconsin, and by Resources for the Future, the Wildlife Management Institute, and the University of Wisconsin Graduate School.

actually imposed on the recreationists at the time when the recreation is demanded. Admission fees are paid immediately, usually in cash. Particularly in a world of satisficing, travel costs may not be perceived as equivalent to admission fees.

Still other potential problems with TC techniques need to be noted. One stems from the fact that increases in density which recreationists label as crowding may affect quality. A travel cost demand curve implicitly assumes that recreational quality remains constant over the range from zero use to full use at the going admission fee. Thus, it may completely neglect changes in quality as quantity declines along the demand curve. Also, no satisfactory method has yet been devised to handle multiple-purpose trips (e.g., recreation plus work) or multiple-site trips (e.g., vacations involving several stops).

Because of these potential biases and because TC techniques are not applicable to recreational activities involving limited travel (e.g., backyard birdwatching) and many nonrecreational extramarket goods (e.g., air quality; public health programs), HV has evolved as a major alternative method of valuing extramarket commodities. Unfortunately, HV also has major potential sources of bias.

Hypothetical Valuation

Perhaps the source of bias that has most dominated the literature is gamesmanship. People who are asked hypothetically what they would be willing to pay for extramarket goods may recognize two different incentives to distort their responses. Perceiving that they will not actually have to pay and that their responses may influence the supply of an extramarket good or bad, people may respond in ways that are more indicative of what they would like to see done than how they would behave in an actual market. On the other hand, if people believe (correctly or incorrectly) that their responses will influence actual fees they may be more concerned about keeping their fees low than revealing their true values to the investigator. Similar thoughts apply if the HV measure is willingness to accept compensation (willingness to sell) rather than willingness to pay.

Furthermore, the hypothetical nature of the transactions may not be at all indicative of how people would behave in an actual market even if gamesmanship is not a major problem. When people buy things in a market, they may go through weeks or months of considering the alternatives. The process will often involve consultations with friends and may also involve professionals such as lawyers or bankers. It may also entail shopping around for the best deal on the product in question. And, for the majority of items in the consumer's budget, there is a whole history of past experience in the market to base the decision on. All this is markedly different than spending an hour or two at most with a mail survey or a personal interviwer attempting to discern how one might behave in a market for a commodity for which one has never actually paid more than a nominal fee.

Numerous other potential problems exist. Like TC, HV measures relate only to the status quo of the good whereas quality may change along the demand curve as the impact of density on recreational quality is felt. All the problems associated with surveys and interviews also may arise including the necessity of obtaining an adequate response rate, interviewer bias, and variations in responses depending on the construction of individual questions and the overall survey instrument.

Furthermore, while economists have been more or less cognizant of the potential pitfalls of HV discussed so far, they have not given much attention to a whole literature in social psychology which is also rather discouraging about HV's prospects for success. In a classic study from that field completed in the early 1930s, La Piere wrote to 251 restaurants, cafes, hotels, autocamps, and tourist homes asking the hypothetical question: "Will you accept members of the Chinese race as guests in your establishment?" Of the 128 that replied, 91% said no, 9% said they were uncertain or that it depended on the circumstances, and only one said yes. However, prior to mailing the letter, all 251 of the establishments had been visited by a Chinese guest and at only one was service refused. La Piere's study was followed by a host of others examining the relationships between attitudes and behavior. In a review published in 1976 of 150 such studies, Schuman and Johnson (p. 168) concluded that the correlations between attitudes and actual behavior are usually so low that they will not ". . . support the *substitution* of measured attitude for behavior . . . ." In other words, it may not be safe to assume, as economists applying HV techniques do, that what people say is what they would actually do.

As a matter of fact, there is some evidence that people do not even report their past behavior very well. For example, out of 131 people surveyed in one study who had been hospitalized during the preceding twelve months, 42% did not report it when interviewed (Cannell, Fisher, and Bakker). Parry and Crossley found that people overreport contributions to the Community Chest by 40% and voter registration by 25%. If people sometimes fail to report accurately what they have done in the recent past, it is a big step to assume, as we do in HV, that they can adequately predict and report how they would behave if a market for an extramarket commodity were created.

Our intention is not to argue that all answers to hypothetical questions will be inaccurate. Success in predicting many election results would be a counter example. Still, research on both attitude-behavior relationships and recall raise very serious questions about the validity of HV results.

But How Serious Are the Biases?

While all these potential sources of bias in both TC and HV exist, by themselves they are not conclusive. Perhaps their impact is negligible or in total they counterbalance each other. What is needed is empirical research to assess the extent of the biases in practice.

Previously published empirical results are for the most part encouraging. Studies by Bohm, Scherr and Babb, and Smith tend to indicate that fears among economists relating to gamesmanship are exaggerated. Furthermore, Bohm's results indicate that HV measures of willingness to pay may not be far from the mark. In the next section we will report the results of our own experiment, results which are not nearly so encouraging.

Results of the Experiment

Space constraints will not permit a thorough description of the experiment and how the results were arrived at. Only a summary will be presented here and the reader interested in a more thorough treatment is referred to an additional paper by Bishop and Heberlein.

The extramarket commodity that served as the subject of our study was 1978 early season goose hunting permits for the Horicon Zone of East Central Wisconsin. Nearly 14,000 such permits were issued and each entitled a hunter to take at most one goose from a well-defined area during the period 1 October through 15 October 1978. The hunters who were issued these permits fell into two groups. One group had applied for the early season as its first choice and automatically received a permit. The other hunters were allocated to the early season as their second choice, having lost in a lottery for middle season permits or applied for a middle season permit after the deadline.

Three entirely separate samples of goose hunters were drawn at random. The first consisted of 237 hunters who received actual cash offers for their permits. The offers were conveyed by mail along with checks ranging between $1 and $200 with instructions that each hunter should return either the check or his or her early season permit. A second sample (containing 353 hunters) received mail questionnaires specifically designed to develop HV measures of the value of its permits. A third (300 hunters) received questionnaires designed to estimate a travel cost demand curve for early season hunting.

The experiment itself was completed with response rates to all three surveys (recipients of the actual cash offers were surveyed after the early season) in the acceptable range of at least 80%. Comparison of the three samples using a one-tailed difference of proportions test on socioeconomic characteristics, commitment to hunting, past goose hunting experience and the like showed no intersample differences sufficient to interfere with comparison of the results across the samples.

Analysis of the results is still in progress, but our preliminary estimates are summarized in table 1. While our final results may vary somewhat in terms of absolute magnitudes, the data are sufficiently clear to justify confidence in our qualitative conclusions.

Responses to our actual cash offers yielded total consumer surplus associated with 1978 early season goose hunting permits of $800,000 for all hunters combined or $63 per permit. This estimate is a bit conservative since it assumes a maximum value per permit of $200 while both the econometric model and the data indicate that 10 to 12% of the hunters would not have sold at $200.

The actual willingness to sell figure is most easily compared with the HV measure of willingness to sell which turns out to be 60% larger at $101 per permit. This estimate is also based on a maximum value of $200 per permit. In

Table 1. Summary of Results

	Total Consumer Surplus	Surplus per Permit
	--------- $ ---------	
Actual cash offers	880,000	63
Hypothetical offers		
Willingness to sell	1,411,000	101
Willingness to pay	293,000	21
Travel cost estimates		
Model 1 (time value = 0)	159,000	11
Model 2 (time value = ¼ median income rate)	387,000	28
Model 3 (time value = ½ median income rate)	636,000	45

this case, the model predicted that 35% of the hunters would require offers of more than $200 before they would agree to sell their permits in hypothetical transactions. Thus, had the models been truncated at a higher figure the difference between willingness to sell measured using actual money and measured using hypothetical dollars would have been even more pronounced.

Comparisons of actual willingness to sell with hypothetical willingness to pay and the travel cost values are clouded by the well-known theoretical arguments relating to various measures of consumer surplus. However, following Willig, we would argue that for the range of values we are discussing here ($1–$200) and given any reasonable value for the income elasticity of demand for goose hunting permits, willingness to pay, and willingness to accept compensation should be quite close together. If so, then we could take $63 as being roughly the average willingness to pay of goose hunters for early season permits.

Referring again to table 1, it turns out that our HV measure of willingness to pay falls far short of $63 at only $21 per permit. The table also gives three TC values of willingness to pay based on three different assumptions about the value of time. Even using what the literature would indicate is a relatively liberal time value of one-half the income rate, the travel cost estimate averages only $45, 29% below the benchmark figure of $63.

Conclusions

We must be careful at this point to avoid sweeping conclusions based on a single experiment. Our results may not be able to be generalized to other situations. Furthermore, although the market we created for goose permits used real money, it was still highly artificial and may include biases of its own. Still, the results summarized here must be interpreted as supporting the hypothesis that the sources of bias listed above do have significant impacts on HV and TC values for recreation and other extramarket goods. Had we attempted to value goose hunting permits using an HV measure of willingness to sell, a substantial overestimate would have been obtained. If we had used HV willingness to pay or a TC measure of demand we would have apparently fallen substantially short of the true value of willingness to pay.

While a full set of conclusions from our study must come after additional analysis, some tentative conclusions are evolving which will have important implications for future recreation economic studies. First, there has been a tendency to view HV willingness to pay as more or less accurate and HV willingness to sell as badly distorted. Our results suggest that both measures are biased, but in opposite directions. It appears that HV willingness to pay should be considered a lower bound and HV willingness to sell, an upper bound. Secondly, our results support those who have voiced concerns about adequately accounting for time costs in TC studies. Differences in tastes and the availability of substitutes may also be a significant source of bias here.

Finally, and on a more general level, we would suggest that recreation economics has a long way to go before it can claim accuracy comparable to analyses of market phenomena. Much more research is needed to further develop and refine both TC and HV measures. To the extent possible, this should involve experiments like the one reported here. Furthermore, we hope that our results will encourage the discovery of new, improved approaches to valuing extramarket goods of all kinds. Such research is essential if economists are to help society recognize the contribution of extramarket goods to the overall level of economic well-being and facilitate sound assessments of the trade-offs between market and extramarket goods and services.

Valuing Nonmarket Goods—Conceptual and Empirical Issues: Discussion

Sandra S. Batie and Leonard Shabman

A decade ago Stevens lamented that there remained the task of proving to economists and to noneconomists "that the measurement of recreational demand is not a naive empirical 'trick' " (p. 192). Freeman, McConnell, and Bishop and Heberlein have given excellent perspectives on the recent advancement of the state of the art for valuing nonmarket services such as recreation. However, it is our concern that despite this progress, economists' ability to provide the information most often requested by public decision makers still is not well developed. Also, we believe that a reason for the indifference of policy makers to economic analysis goes beyond problems of potential biases in survey responses or travel cost methodologies as discussed by Bishop and Heberlein or the reasons detailed by McConnell. Rather, economists have not established relative values for the policies and inputs over which agencies have control (e.g., habitat management and fish stocking), and instead have focused research efforts on establishing values for recreational services. Figure 1 can help illustrate our point with specific reference to recreational fishing. It depicts the relationship between public policies, recreational services, utility, and value.

McConnell's and Bishop and Heberlein's papers provide a good example of economists' tendencies to estimate the value of the recreational services rather that the variables which policy makers control. McConnell concentrated on the contribution of household inputs to the value of recreational services narrowly defined as trips or catch per trip. Incidentally, we note that he ignored (although in most cases consciously) other determinants of the value of fishing recreation such as substitute and complementary recreational opportunities (e.g., fishing for other marine species) and nonconsumptive recreational services as a joint product with fish catch (e.g., enjoyment of the outdoors). Omission of variables to represent these determinants are more likely to account for the unsatisfactory statistical results of McConnell's regression than is the reported caveat that there were only fifty-six observations. In contrast, Bishop and Heberlein's various value measures of the right to hunt geese are based upon a broader concept of the recreational service. Their findings can help us to improve value estimates of the right to goose hunt, but even so, resource managers are frequently more concerned with the value of an additional goose or increments to goose habitat. Bishop and Heberlein do not address the latter value. Our point is not to suggest these authors' work necessarily should encompass all the variables reflected in figure 1, but rather to suggest that collectively economists have paid too little attention to the physical production and transformation linkages between public policies and recreational values.

Unfortunately, many of the linkages which could help establish the value of alternative resource policies are not well understood. For example, one set of linkages that is not well defined are the "production functions" relating public policies to changes in resource based inputs and the transformation function to recreational services. McConnell states that "it is even reasonable to imagine that one could measure the relationship between densities and catch rates," but he does not elaborate. In his book where he expands on the concepts presented in his paper, Freeman states that "data on the relationship between biological productivity and water quality can be used to determine the increase in net physical yield [of fish], associated with the pollution control program" (p. 68), but does not state how this is to be done. Yet understanding, defining, and quantifying these inputs and linkages is important if economists are to provide economic values that assist public agencies' management of habitat and resource stocks. The lack of knowledge about such

Sandra S. Batie and Leonrd Shabman are associate professors in the Department of Agricultural Economics at Virginia Polytechnic Institute and State University.

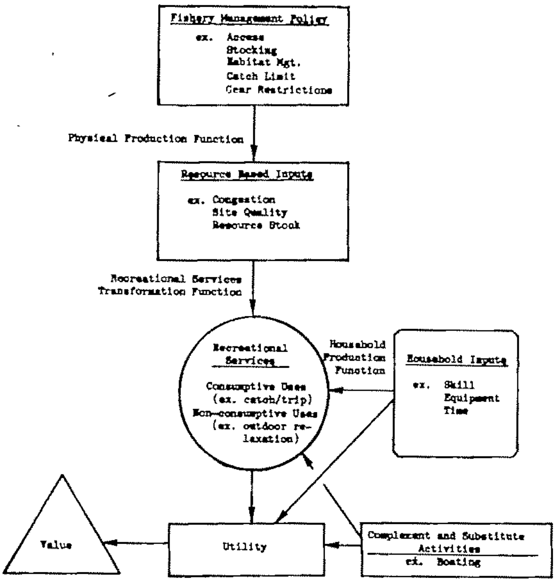

Figure 1. Determinants of recreational value of fishing

production and transformation functions is due, in part, to a lack of physical and biological data. Obviously, economists would be well advised to seek the assistance of biological and physical scientists, but we have done so infrequently.

Until more is known about these inputs and linkages, extreme caution must be used when attempting to impute the value of what is known to the value of that which is not. McConnell, for instance, suggests that "there are substantial benefits from marine recreational fishing" and that "with this evidence we should expect a willingness by marine policy makers at the national level to provide increasing portions of annual yields for recreational purposes." This statement suggests knowledge of the value of fish stocks and by imputation knowledge of the value of public policies which increase such stocks. This reasoning, however, if not used cautiously can be as erroneous as imputing all the value of a corn crop to only one of the inputs, say the corn picker or the corn sheller. Despite these quotes in the paper's conclusions, McConnell does appear to avoid this logical error in the body of the paper by focusing correctly on the role of fishing success as a recreation demand shifter and delineating the need to know the relationship between fish stock densities and catch rates for policy evaluation purposes, but admits that he cannot yet empirically calculate the measure. Given this, it is not surprising that public agencies are not receptive to economic arguments for reallocating fish from commercial to sports harvests when such arguments have not established the role of the fish per se to the value of the service.

These three papers well represent the "state of the art" in the area of value analysis of the recreational experience and of environmental amenities. Yet, there is considerable research remaining if economists are to provide the information necessary for informed public choice. It is our opinion that policy-directed research must focus upon estimating the value and functional relationships of variables that can be influenced by public policy as well as the type of research reported on by these papers.

Small Farm Definition and Public Policy

Thomas A. Carlin and John Crecink

Even the most casual review of literature suggests that there are numerous definitions of small farm. Range in definitions varies from acres of land, units of livestock, value of farm products sold, days worked off-farm, level of farm income, to level of total family income (Lewis). Many authors combine two or more of these classifications to arrive at a more limited definition. Some authors even display wisdom by not attempting to define specifically what they mean by small farms. It becomes clear that the small farm is not precisely defined either within the agricultural research community or for the general public. As Wood recently pointed out, "Small becomes less a descriptive term than it is a philosophical one . . . . Policy objectives and small farm categories are interrelated, and they are identified on the basis of the concerns of interested parties or participants" (Wood).

Public discussion of small farm issues is also confounded by a lingering set of beliefs about farming—some of which may no longer be valid. These beliefs include:

(*a*) The economic performance of the farm establishment is an accurate reflection of the economic well-being of the farm family.

(*b*) Small farms are problems, while family farms have problems. Images of the family farm are inherently positive, while images of the small farm are inherently negative.

(*c*) Small farms are inherently inefficient, thus are poor users of resources.

(*d*) The relative vitality of a rural community is directly dependent on the vitality of the farming sector in and around that community.

Clearly, our individual response to small farm issues depends to some extent on our perceptions about agriculture and rural America.

An imprecise definition of "small farm" may serve the policy process quite well. Groups with somewhat divergent goals can unite in efforts to advance a "small farm" policy with a shared sense of satisfaction. But those who are responsible for implementing small farm policy (particularly if specific assistance programs are involved) must again face the issue of defining a small farm (for eligibility purposes). This problem is particularly acute for statisticians who must provide basic counts of the probable target population, for example. Vague or imprecise definitions are simply not amenable to efficient data collection, particularly in an era alive with concerns about respondent burden and privacy. Thus, we must come to grips with an acceptable small farm definition so that we can get on with the real work at hand—helping those small farm families eligible for assistance.

Attributes of a Good Definition

A desirable small farm definition should have an understood underlying conceptual basis. Frequently used definitions of small farm appear to be derived from two basic concepts. The first concept of small farm is that of a low volume business establishment (area A and B, fig. 1). The most notable definition of this type is farms producing less than $20,000 in gross farm products. Proponents of this type of definition are generally as concerned about issues such as increased concentration in agricultural production and marketing, dependence on capital intensive technology, use of harmful production practices, and land reform, as they are about other issues.

The second concept of a small farm is that of a farm operator or family having a low level of economic well-being (e.g., income) (areas B and C, fig. 1). The recent USDA small farm definition is an example of this type definition. The USDA definition includes all farm families (*a*) whose family net income from all sources (farm and nonfarm) is below the median nonmetropolitan income of the state, (*b*) who depend on farming for a significant though not necessarily a majority of their income, and (*c*) whose family members provide most of the labor and management. Proponents of this type definition generally are more concerned

Thomas A. Carlin and John Crecink are economists with the Economic Development Division, ESCS USDA.

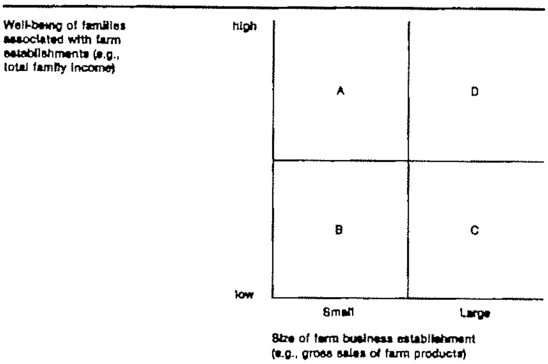

Figure 1. Conceptual bases for a small farm definition

about issues of limited resource farmers and farm poverty than about other types of issues.

Proponents of both types of definition are quick to eliminate certain types of farming activity from their respective focus. For example, they are particularly alienated by "hobby" farmers and others who are able to convert ordinary income into capital gains using special farm tax rules, thus sheltering nonfarm income. Thus, one attribute of "the optimal definition" (if such a definition should exist) would be to exclude the less desirable types. One caution, however: constraining the definition too much may reduce the absolute size of the target population so that political support for small farms (and assistance programs) may be reduced. (e.g., There would be broader support for a target group of 1.5 million than for one of 25,000.)

Debate over a small farm definition also can be minimized if the definition chosen, regardless of its conceptual basis, would include a relatively large common element (area B, fig. 1). This attribute would allow each interest group to identify subcomponents of the small farm population of particular concern and still identify with the coalition supporting the small farm movement.

The chosen definition should have other desirable attributes from a statistical perspective. The definition should be understood easily by all data users. The elements of the definition should be measurable. Most important, the definition should be workable—capable of being implemented using conventional statistical procedures. This, by the way, was one problem with the old definition of a farm—it was becoming impossible to develop a list frame for extremely small establishments. In addition, the definition must allow for feasible data collection and collation, within the constraints of existing budgets.

With the background in mind, this paper will look at three definitions of small farms which are under discussion, at least in Washington, D.C. The first definition will be farm families with a total family income below the median nonmetropolitan income of the region, consistent with the low income concept of small farm. The second and third definitions will be all families operating a farm business selling less than (*a*) $20,000 and (*b*) $40,000 in farm products, consistent with the small business establishment concept. Selected characteristics of families under these definitions will be examined with implications for public policy. Others have examined in detail the characteristics of farms selling less than $20,000 in farm products (Larson, Lewis). But, relatively little is known about the low income farm families, particularly characteristics of their farming operations.

Data

The data presented below are mainly from the 1975 Farm Production Expenditures Survey (FPES) conducted by the Statistical Reporting Service (now Economics, Statistics and Cooperative Services, U.S. Department of Agriculture). This was a national probability sample of approximately 5,700 farmers designed to obtain detailed data on farm production expenses. Information also was obtained on farm and off-farm income, farm assets, and occupation and age of the farm operator. This was the most readily available and most recent source of national data on attributes of farm operators and their farms at the time the paper was prepared.

The unique advantage of the FPES survey data is the ability to sort individual observations (families) by the alternative criteria for defining small farms. Currently, this advantage is not present in other data sources, particularly those which provide information on both the characteristics of the operator and family and attributes of the farming business.

The distribution of farms by value of agricultural products sold is skewed upwards in the FPES survey compared to the Census of Agriculture. For example, the proportion of farms with sales of $40,000 and over is larger in the FPES (36% of all farms) than in the census data (21% of all farms). Thus, distribu-

tion data used below are from the 1974 Census of Agriculture and the Current Population Survey (U.S. Department of Commerce 1974, 1977).

Some characteristics of operators within the lower sales classes derived from the FPES are consistent with census data (e.g., average age, occupation, and days worked off-farm by the farm operator; and median size farm). Median off-farm income appears to be consistent with Census of Agriculture estimates but considerably below USDA estimates. However, estimates of median net cash farm income from the FPES are troublesome, being substantially below those from other sources.[1] Other important attributes of the operator family, such as family size, race, and off-farm occupation, were not included in the FPES survey. No attempt was made to adjust the data presented below. Rather, attention should be concentrated on differences among the alternative small farm groups rather than on the absolute estimates themselves.

Results

Approximately 52% of all farm families have total family incomes below the median nonmetropolitan income for their region in 1975.[2] This low income group is smaller than those families operating a small business establishment; two-thirds (66%) operated farms selling less than $20,000 in farm products; about four-fifths (79%) operated farms selling less than $40,000 in farm products in 1974. Regardless of the definition used, small farmers are located throughout the United States with the major concentrations in the North Central and Southern regions (table 1). Relatively more low income farmers live in the North Central region, particularly the West North Central, than do operators of small businesses. This is due in part to the fact that Southern farm operators are more likely to have an off-farm job which raises total family income.

FPES data suggest that low income farm operators are more likely to have farming as their principal occupation than are operators of small farm businesses (table 2). On the average, low income farmers work fewer days off-farm, resulting in lower off-farm incomes. Total family income for low income operators is almost half that for operators of small farm businesses. Low income operators appear to have larger acreages than operators of small businesses. And low income operators have more invested in their farms than operators of farms producing less than $20,000 in sales.

There appears to be little difference in the operator age-distribution among the three small farm groups (table 2). And there appears to be little difference in the types of farming activities engaged in by low income farmers

[1] Net cash farm income excludes inventory adjustments, value of home-produced and consumed food, and the rental value of the farm dwelling. These items are typically included in other data sources.

[2] This estimate is from the Current Population Survey (U.S. Dep. Commerce 1977a). The estimate from the FPES was approximately 55%.

and those operators of farms selling less than $20,000 and $40,000 in farm products.

About 70% of the low income farmers reported a loss in their farming operation in 1975 (table 3).[3] These farm families had higher average off-farm incomes than those farm families reporting farm profits. But even then, the majority had low off-farm incomes. Operators of small farm businesses were just as likely to have a farm loss in 1975 as low income farm families (table 4). But, small farm business operators reporting losses (75% and 66% of those reporting sales of less than $20,000 and $40,000, respectively) were much more likely to have higher off-farm incomes than their low income counterparts. To the extent that one associates high off-farm income and farm losses with "hobby" farming, it appears that the low income concept of small farm eliminates more "hobby" farmers from a small farm population.

[3] Forty-nine percent of the respondents to the FPES reported a loss on their farms in 1975. The Internal Revenue Service reported that 47% of all sole proprietorship farm businesses operated at a loss in 1975.

A large part of the similarity observed among many characteristics of the alternative small farm groups is due to the size of the common element (area B, fig. 1). The FPES data suggest that about three-fourths (76%) of all operators with farms selling less than $20,000 also had total family incomes below the nonmetro median income. About 71% of operators with farms selling less than $40,000 had total family incomes below the nonmetro median. These two groups constituted, respectively, 72% and 84% of the total low income group. While the FPES undoubtedly overstates the size of this common element because of the reported low farm incomes, the true overlap is most likely sizable. For example, similar tabulations from the 1973 Farm Family Living Expenditure Survey suggests that 62% of all operators with farms selling less than $20,000 in farm products had total family incomes below the nonmetro median for that year.

Relative to the two groups with small farm businesses (table 4), the common population (area B, fig. 1) is more dependent on farming,

working fewer days off-farm and having lower off-farm incomes (table 5). On the other hand, the common population is slightly older than the low income population and has smaller farms (acreages and value) (tables 3 and 5).

The trade-off groups between the two basic concepts of small farm are areas A and C in figure 1. Group A, higher income small farm business operators, appear to be middle-age (almost all between 35 and 64 years old) operators with relatively large off-farm incomes (most reported $10,000 or more), most of whom are not farmers by occupation. Group C, lower income families with larger farms, appear to be middle-age operators whose occupation is farming and who have lower off-farm incomes (most reported less than $5,000).

Implications

There are differences in general policy focus inherent in the two concepts of small farm. The low income definition focuses on individuals and families who have a commonly understood problem—moderate to low income. The implied objective is to undertake actions which improve their income (well-being) level. This objective flows naturally from the concept itself. While the small business concept focuses attention on certain farm establishments, it does not present a commonly understood problem. And the concept itself does not suggest a clear policy objective; rather, the policy objectives emerge from an understanding of population characteristics.

There appears to be some distinction between the populations included in the two concepts of small farm (besides those differences inherent in the concept itself). The above analysis suggests that low income farm operators are tied closer to farming (both by occupation and income) than are operators of small farm businesses. In other respects, there is very little difference in population characteristics between the two concepts. For example, regardless of the definitions considered above, small farmers are concentrated in the North Central and South, a fifth are aged and

perhaps reducing the intensity of their farming operations, and they are engaged in all types of farming. Regardless of the definition used, the small farm population appears to be heterogenous; no single major attribute emerges aside from income level and relative dependency on farming.

While the two concepts of small farms (low income and small business) elicit a different general policy focus, practical approaches to assisting small farmers may not differ. This is due to the fact that a large number of the same farm operators would be included in a small farm population under either concept. Regardless of the definition, programs to assist small farmers must be diverse in order to accommodate the heterogeneity of the population. Some small farmers can benefit most from programs to improve farm operations, others can benefit most from increased off-farm employment opportunities, and still others (e.g., the elderly) may benefit most from improved access to public assistance and social services. The exact combination depends almost entirely on the circumstances faced by the individual small farm family.

Perhaps any final decision on the proper concept of the small farm definition lies in the public's preference for the trade-off groups (groups A and C). This analysis suggests that the trade-off is between (*a*) operators of small farm businesses who are not farmers by occupation having relatively high off-farm incomes versus (*b*) full-time farmers operating larger farms but having problems making a satisfactory income. Given the public's apparent lack of social concern for hobby farmers, the low income concept appears to have a distinct advantage over the small business establishment concept; low income farmers are less likely to view farming as a hobby. Yet, there is enough diversity in the low income farm population to accommodate the concerns of those who are interested in issues typically associated with a small business concept.

A more detailed and accurate description of

the low income farm population must await more extensive surveys. The 1979 Farm Finance Survey, a follow-on survey to the 1978 Census of Agriculture, appears to be particularly promising. ESCS will continue to explore low income farmer attributes using other data files. Those states with good data available can also extend insight into the attributes of low income farm families.

Toward an Agenda for Small Farm Research

J. Patrick Madden and Heather Tischbein

Ever since the days of Thomas Jefferson, the expressed intent of the nation's agricultural policy has been to support family farms, particularly small, land-owning farms. Despite expressions of concern and support by both agriculturalists and statesmen, often the effect (if not the intent) of public policy has been to undermine the economic and political support structures of a system of agriculture and rural communities based on land-owning family farms. Recently a widening array of interested groups of citizens have begun to express alarm over the discrepancy between the avowed intent and the ultimate effect of public policy—that is, the failure of public policy to achieve the goal of supporting family-owned and operated farms.

Increased attention to the changing structure of agriculture has illumined the economic, political, sociological, and ecological ramifications of the trend toward fewer but larger farms (especially highly technical and capital-intensive farms) to policy makers, the private sector, philanthropic organizations, and the public. This increased awareness has created a climate in which the value of small-scale family farms is being reassessed and reaffirmed. Advocates for smaller-scale family farms cite a wide range of adverse social and ecological consequences of current trends in production and marketing and in changes in the structure of agriculture as a rationale for more strenuous political and economic support of smaller-scale family farms. In general, these concerns are characterized by a striving to understand the interrelationships between and among production practices, marketing systems, the structure of agriculture, and their impact on ecological and human well-being. For example:

(*a*) The social, ecological, and economic vitality and viability of rural and urban communities is directly related to patterns of ownership, control, use, and distribution of agricultural resources. As the number of farms in a community decreases and size increases, the resultant migration of displaced residents has aggravated social and economic problems such as unemployment, alienation, inadequate housing and health care, and deterioration of the economic base of both rural and urban communities.

(*b*) The specialization and increased uniformity of farming resulting from the adoption of the techniques of regional monocultural production has increased the vulnerability and reduced the adaptability of agriculture to natural disasters; to large-scale disease and insect attack; to short- and long-term disruptions and shortages of energy supplies for production, processing, transportation, and storage of agricultural products; to soil erosion and depletion of soil organic matter; to pollution and depletion of ground and surface water; and to contamination of the food chain through the misuse and abuse of toxic chemicals used in producing and processing of foodstuffs.

(*c*) The ownership and control of land and other agricultural resources plus marketing and distribution mechanisms is becoming increasingly concentrated in the hands of fewer and fewer individuals and/or corporations, a trend which, if carried to extremes, could have severe implications for the survival of the nation's economic and political institutions.

The questions related to the viability of small-family farms are most realistically framed in the context of (*a*) the overall structure of agriculture, (*b*) the complex set of interconnected causal factors that determine trends in the structure of agriculture, and (*c*) the likely impact of changing structural patterns on the larger society and the environment.

Within the context of the interrelationships

J. Patrick Madden is a professor of agricultural economics at Pennsylvania State University; Heather Tischbein is project manager of the National Rural Center's Small Farms Project.

The Pennsylvania State University Agricultural Experiment Station Journal Series No. 5812. Supported in part by P.S.U. Hatch Project 2327, National Rural Center, National Science Foundation, and five other sources listed herein. The opinions expressed in this paper are those of the authors, not the sponsors.

described above, four areas consistently emerge as priority concerns: (*a*) the declining quality of rural life; (*b*) the impoverishment of limited-resource farm families; (*c*) the human, social, and ecological elements of economic efficiency; and (*d*) the perils of the disappearing middle.

Declining Quality of Rural Life

The quality of life in rural communities deteriorates as the support for various services, schools, churches, and other institutions dries up—a frequent result of the depopulation associated with the demise of small- to moderate-scale family farms.

The sociological studies, such as those by Goldschmidt and Fujimoto (U.S. Congress, p. 1394–96) should be extended to a wide range of locations and types of rural community, to provide a more solid basis for understanding the relationship between changing structure of agriculture and community decline (Rodefeld et al.). This type of research should include systematic collection of longitudinal data at two or more points in time, so that changes in farm structure and quality of rural life can be observed and causal relationships estimated.

Impoverishment of Limited-Resource Farm Families

While the vast majority of small farm families have family incomes above the poverty line (due to off-farm income) (Emerson) many of the small farm families with limited resources could become more self-sufficient and could afford a more adequate level of living if ways were found to increase their incomes—either through improved farming practices, better marketing options, or increased off-farm earnings. The "trapped," or limited-resource, farmers are those who are in poverty because the quantity and/or productivity of their labor, management, land, and other capital is chronically low and often getting less. These families seem unable to enhance their incomes either by moving away or staying. Simply assuming or advocating "perfect resource mobility" is of no comfort to those who have few job skills, few years before retirement or interment, or an unalterable determination to stay put. And while these small farms may be numerically prevalent and durable, their plight is often miserable.

Increasing the income-earning options of these small farms is clearly in the national and local community interest and is a worthy social and humanitarian goal.

The rationale for helping these small farmers to increase their incomes is partly humanitarian and partly pragmatic—it may be less expensive than welfare payments. Research should determine the conditions and situations under which various program strategies may be cost-effective in improving the self-sufficiency of limited-resource small farmers.

The Human, Social, and Ecological Elements of Economic Efficiency

There exists a wide range of phenomena (e.g., use of certain chemical pesticides) which are deemed to be economically efficient according to short-term accounting of firm-level costs and returns. However, if the scope of accounting were broadened to include short- and long-term social and environmental costs and returns, then some of these same phenomena may not be judged to be "efficient." A major research effort is needed to reexamine the concept of economic efficiency in this broader context and to develop measures and theoretical frameworks within which the trade-offs between firm-level efficiency in the conventional sense versus various human, social, and ecological concerns logically and systematically can be entered into the calculations.

The Disappearing Middle

Schumacher, in his book *Small Is Beautiful*, coined the term "disappearing middle," in describing a trend toward bifurcation of technology: very small and primitive technology coexists with mass production technology, while intermediate technology vanishes. Concerned agriculturalists have suggested this phenomenon is occurring in American agriculture. Assuming no major changes in the market structure and the political system, the very large farms are here to stay, probably in increasing numbers, and almost certainly in increasing importance as a source of the Nation's food and fiber, because of their economic efficiency and/or their market power. The very small farms are also here to stay—those part-time and retirement places and little patches of ground on the hilltops and narrow valleys and in the irregular corners of the huge fields, areas that cannot be economically

farmed as a part of a large farming operation. Here the opportunity cost of the land and other resources is often very low, and the farmer or farm resident depends largely on income from an off-farm job or business rather than from the sale of crops and livestock. Other commercial producers of specialty crops and livestock for special and limited markets (roadside stands, local organic markets, etc.) seem to be a permanent part of American agriculture. Still others are the limited-resource farms.

The very large farms are in no danger of disappearing, nor are the small farms whose families are either trapped in impoverished farming or have comfortable incomes from off-farm sources. However, the plight and prospects for the small- to moderate-sized farm that supports a farm family at a level considered "decent" by modern standards, with little or no help from off-farm jobs or other sources of outside income is much less certain. The need for preservation of this middle sector, of small- to moderate-sized family farms seems to be a central value judgment underlying much of the current concern for what is loosely termed the "small farm." Many observers are convinced that society needs to retain the flexibility of keeping options open, options which will disappear permanently if the middle sector of family farms is totally replaced by huge farming operations. Frequently, concern is voiced regarding the need to prevent an irrevocable concentration of farmland in the hands of a few investors—particularly speculators or others who have little concern for the husbandry of the soil or for enhancing the quality of life in rural communities.

Much of the current confusion and dissention related to small farms is the result of an overly simplistic view, implicitly thinking that all "small farms" are alike and that the social and economic or humanitarian rationale is equally compelling for all segments of the small farm sector. Clearly this is not true. More and better research is needed to clarify the issues. A priority in this area is developing a meaningful typology of small farms, indicating distinctly different kinds of small farms in terms of their resource endowments (land, labor, etc.), aspirations, sources of income, and other causal and descriptive factors that interact to determine their long-term survival and their potential for earning a decent level of income (Tweeten et al.).

Widely divergent views abound concerning research related to small farms. Some contend that all research, public and private, is stacked against the small- to moderate-scale family farm, in favor of huge corporate operations. Others contend that all, or virtually all research is "size-neutral," equally benefiting all farms regardless of size. Further, those in government who determine the budgets and the emphasis of research in various public agencies and educational institutions express no interest, or express outright hostility, toward the idea of increasing the level of research activity directly relevant to small farms (U.S. Congress). Other somewhat more sympathetic officials have indicated in personal conversations that if a comprehensive and well-documented research agenda were developed, then, and only then, would adequate research funds be forthcoming. It is primarily in response to statements of the latter kind that a national project on small farms research and policy was initiated by the National Rural Center in 1976.

The NRC Small Farms Project

The National Rural Center (NRC) is a private, nonprofit corporation, established to develop policy alternatives and to provide information which can help rural people improve the quality of life in their communities. A central value judgment underlying NRC's philosophy is that the goal of government ought to be to increase the options people have for a decent life in whatever kind of community they choose to live—rural, urban, or suburban. Because small-scale farming can provide an important option for earning income, and because, despite the predictions of many experts, a large number of people (many of whom, in some sections of the country, are minorities) wish to exercise that option, NRC selected small farm issues as a major policy development effort.

The project is organized into three phases, with the information brought together in each phase providing direction for subsequent phases. The work of each phase is reviewed at a conference whose participants include small farm operators, researchers, policy makers, and representatives from public and special interest groups.

The task in Phase I was to agree on a definition of small farm family and to identify barriers which hinder these families from increas-

ing on-farm income. In Phase II, issue groups reviewed the existing knowledge on each of those barriers, to determine on which issues there is adequate information, and which issues deserve additional research. The output of Phase II is a series of state-of-the-arts review papers, including preliminary discussions leading toward an agenda of research and demonstration projects. The goal of Phase III is to develop a set of federal policy recommendations based on the findings of Phase II. At the conclusion of the third phase, NRC, with the assistance of a wide range of individuals and interest groups, will recommend a federal small-farms program consisting of a research agenda, an agenda of demonstration projects, and policy alternatives.

Phase I was funded by the National Rural Center, Ford Foundation, Farm Foundation, and U.S. Department of Agriculture (USDA). Phase II was funded in part by grants from the Appalachian Regional Commission, the National Science Foundation, the Farm Foundation, the U.S. Department of Agriculture, the Community Services Administration, and the Rockefeller Brothers Fund. Funding for Phase III is in the development stage.

Phase I

The Phase I workshop, was held 16–18 October 1977, at Winrock International Livestock Education and Training Center, Morrilton, Arkansas. Forty individuals from around the nation and with varied backgrounds came together primarily to discuss the questions of small farm definition and barriers which hinder small farm families from increasing on-farm income.

The working definition of small farm family adopted at the conference contains three provisions: (*a*) The family or individual must rely on farm income for a substantial share of their livelihood. Hobby farms of the wealthy are excluded; (*b*) The operating family or individual must manage or control the farm business and must contribute the majority of the farm labor (except in peak seasons); and (*c*) The family or individual income must be moderate or less. The target "moderate" income level (including income from all sources) is the national median, currently about $18,000.[1] In addition, it was agreed that, within the working concept, priority for policy and research should be given to those who have low incomes, desire to become small farm families as defined above, and experience infrastructure barriers to full participation in our economic system.

The lists of barriers to increasing on-farm income developed by separate task groups of the conference were categorized into six general areas. These areas form the basis of Phase II of the NRC Small Farms Research Agenda and Policy Project. The areas identified by participants at Winrock were (*a*) structural change and information needs, (*b*) production efficiency and technology, (*c*) energy conservation, (*d*) marketing, (*e*) government policies, and (*f*) taxation. Two additional areas, (*g*) off-farm income and (*h*) societal values and goals relating to small farms, were added by the project staff and advisory team after the conference.

Phase II

Phase II began in April 1978. Forty individuals, principally researchers from the academic community and government agencies, were selected to review the existing knowledge and propose a research agenda in each of the eight issue areas. Outlines of the papers were developed at a working conference of authors in June 1978, and a completion date of December 1978 was agreed upon.

On 31 January 1979, 106 individuals representing a wide range of perspectives and backgrounds met at the Nebraska Continuing Education Center on the University of Nebraska campus in Lincoln to review and comment on the papers prepared by the issue groups. In addition to those involved in preparing the papers, participants included representatives of government agencies and public interest groups, as well as selected small farmers who had been delegates to the five regional USDA/CSA/ACTION Small Farms Conferences held during the summer of 1978.

The purpose of the Lincoln Conference was threefold: (*a*) to have the papers reviewed by a diverse group of people actively interested in the area of small-scale farming, to generate comments and suggestions to help the paper writers improve their reviews of the literature; (*b*) to strengthen a research agenda for small farms; and (*c*), as a starting point for Phase III of the Small Farms Project, to begin discus-

[1] A new USDA definition includes a slightly lower (on the average) limit on family income: the median nonmetropolitan family income in the state where the farm is located.

sion of possible policy alternatives that would help improve the incomes of families or individuals living on smaller scale farms. The conference was designed to achieve these goals through a series of small group sessions and plenary sessions.

The papers presented at the Lincoln Conference are being published (with a few exceptions) as a series of eight NRC monographs, listed in the references. Some of the major conclusions and the more salient components of the research agendas suggested in these papers, and in the small working groups at the Lincoln Conference, will be discussed here for purposes of illustration.

Deficiencies in Previous Research

Ideally, research contributes three general kinds of knowledge: (*a*) increased understanding of the existing conditions and trends regarding the survival and well-being of various kinds of small farms in different locations and farming situations; (*b*) better knowledge of the underlying causes of these conditions and trends, the underlying forces, constraints, and opportunities; and (*c*) improved capacity to predict what effects possible alternative actions or inactions may have upon the survival and prospering of various kinds of small farms under various conditions.

The state-of-the-arts papers indicate what past research has contributed to knowledge and what gaps remain to be filled. In general, the gaps are substantial—the ideal listed above has seldom if ever been completely realized. There are some areas (such as taxation and governmental price, income, and credit policies) in which present conditions and trends are well documented, and to some limited extent the underlying causes, constraints, and opportunities are known. But the existing state of the arts is rarely if ever completely adequate to provide a solid basis for predicting the outcomes of alternative policy initiatives under the wide range of conditions and resource combinations found on small farms. There are six general types of deficiencies found in the existing literature.

(*a*) Simplistic definitions: Most studies fail to differentiate among various types of small farms (limited resource, part-time, retirement, commercial, etc.). In most studies, small farms are defined naively by a single dimension, usually a gross sales limitation (such as $20,000), or by the level of one resource used by the farm (acres of land, man-years of labor, number of dairy cows milked, etc.).

(*b*) Obsolescence: Much of the research is out of date, not valid for today's technology, prices, or government programs.

(*c*) Chronic gaps: Other information has never been collected and synthesized; essential studies have never been initiated or completed.

(*d*) Qualitative limitations: Much of the information and research findings are either severely limited in scope (a few counties in one state, for example) or flawed by methodological, empirical, or theoretical deficiencies which preclude any valid generalizations regarding existing conditions, trends, underlying causal factors, or predictions of future outcomes.

(*e*) Fragmentation: Another important deficiency of the entire body of small farms research is its fragmentation. It lacks a comprehensive and explicit causal model[2] linking all of the various conditions and factors that interact to determine (*a*) the essential nature (structure) of agriculture at the firm, community, state, national, and international levels, and (*b*) the policy outcomes with respect to specific goals, such as increased income of small farm families, for example. The typical agenda for small farms research reads like a shopping list written with no specific menu or meal plan in mind—just a string of seemingly unrelated items, with no underlying rationale and no apparent plan or framework for pulling it all together. An illustration of this fragmentation is the contention of many persons that the solution to the problem of low income on small farms is simply to provide better technical information—such as fertilization, improved plant varieties, livestock disease control—while ignoring the harsh realities of the marketplace.

(*f*) Lack of predictive validation: Research to date does not provide a reliable basis for predicting the success or failure of small farms or of various programs intended to help them survive and prosper. This is largely because the economic models (Leibenstein) on which this research is based have never been proven

[2] Such a model is presented in the NRC monograph by Madden, Tischbein, and West, to clarify the importance of this approach and to provide a framework for conceptualizing further research and interpreting research findings.

valid for analyzing or predicting the behavior of small farm families. Conventional neoclassical theory of the firm, which leads to the conclusion that only those firms producing at the low point on a long-run average total-cost curve can ultimately survive, fails to explain both the pluralism (the continued existence of a relatively large number of small farms) and the bifurcation (disappearing middle) of American agriculture.

Brief Suggestions for Further Research

In general, our agenda for small farm research covers a wide range of subjects. The following list is illustrative:

(*a*) Research to predict the impacts on various types of small farms of policy alternatives for price, income, taxation, farm credit programs. (See Spitze et al., and Sisson for more discussion of these points.)

(*b*) Research on marketing, including an examination of how conventional and alternative marketing channels can both hinder and enhance the economic and political prospects of small farms (Thompson).

(*c*) Evaluation of various alternative approaches for providing technical and marketing information to small farms including, but not limited to, the use of paraprofessionals.

(*d*) Determination of both the descriptive and causal aspects of the structure of the small farm sector of American agriculture, including new and better data on the resource endowments, opportunities, constraints, and aspirations of small farms, plus the impacts of farm structural change on rural communities (Tweeten and Huffman, and Rodefeld).

(*e*) Interdisciplinary studies on the processes underlying the nature and scope of agricultural research and Extension, including policy decisions at all levels, systems of professional rewards and incentives, and funding levels for research and Extension relevant to various sizes and types of farms; studies to determine the impact of various kinds of research on the economic and political viability of small farms in various locations and types of farming (Thompson, Buttel et al.).

(*f*) New and better research on economies of farm size. New paradigms, to be developed and tested through extensive research, should avoid the conceptual deficiencies of the earlier studies reviewed by Madden in 1967. Specifically, studies should analyze a wide array of actual and potential farm enterprises, rather than the usual assumption of a rather limited range of crop and livestock enterprises modeled after larger commercial farms. Research should take into account the full array of appropriate technology, including both new and used equipment; custom hiring and cooperative arrangements as well as full ownership of machinery; organic as well as conventional farming practices; and other alternative approaches. Research should recognize that many small farms depend heavily upon off-farm income for their livelihood and as a source of operating and growth capital (Jones, et al.). Off-farm jobs or businesses should be included as enterprises, for example, and the income from all sources should be taken into account in calculating efficiency ratios. This kind of change in the approach to the study of economies of size, viewing the farm as a "goods and services firm" rather than as a producer of a rather limited selection of crop or livestock enterprises (Madden, p. 23) undoubtedly would improve the predictive value of those studies in understanding and predicting trends in the structure of agriculture. Here again the need for actual farm data is imperative, to learn what small farms are actually doing.

These and many other research suggestions are discussed at greater length in the first nine of the forthcoming NCR Small Farms Project Reports and will be integrated in the monograph by Madden, Tischbein, and West.

Conclusion

Clearly, a research agenda in and of itself will not solve any of the problems of small farms, nor will it provide the necessary guidance for public policy. The existence of a comprehensive and well-documented agenda for research on small farms would be useful in (*a*) inspiring individual researchers and research administrators to press ahead in meaningful research areas, and (*b*) providing a framework within which the findings of various individual pieces of research may fit together somewhat more meaningfully. It is also possible that the level of funding allocated to small farm research may be related to the persuasiveness of the research agenda. It is in the hope that these outcomes may occur in the long run that this project has been attempted.

Small Farms Definition and Policy Research Agenda: Discussion

William E. Myers

As befits a beleaguered bureaucrat who has tried to confront small farm issues in one state, I will address some problems likely to arise in translating the findings, recommendations, and implications of the presented papers into tangible programs and policies.

A central theme underlying both papers is the problem of enormous heterogeneity in the small farm sector. So far, public policy has not been adept at dealing with such heterogeneity, and one might reasonably argue that small farm problems persist partially because of this failing. How, then, might we better respond to variety, whether in research or in the formulation of policies and programs?

One begins, I think, with disaggregation. Statistics, such as those Carlin and Crecink present, obscure critical differences between subgroups which, when it comes to delivering services, may be more important than many factors they have in common. The Carlin and Crecink approach will prove more valuable when applied to far smaller areas, certainly no larger than states. Such figures could be expected to vary greatly between these smaller areas, which implies that effective policies and programs may themselves have to vary in important respects. This in turn suggests that nationwide policy instruments may be too blunt to serve as the primary vehicles of small farm assistance. Perhaps the federal government, rather than attempting to take on small farm issues alone, might more effectively use its position to mobilize state, local, and private sector activity in support of small farm needs. It must be recognized that the farming sector is a highly complex system in which a wide variety of actors participate in making critical decisions, and at least certain key actors will have to be involved for small farms to become more successful.

To me this implies, and the California experience would seem to substantiate, that both research and services will have to be established to provide comprehensive focus on small farm problems in defined state or substate regions. In this context, I mildly disagree with Madden's suggestion that more small farm research is needed, in part, to help generalize nationally about how different kinds of farms perform in varying situations. I fear there are too many variables and too many comparability problems for that expectation to be realistic. What we can do right now is focus research and program activities on tangible small farm problems in particular areas, trying to solve them in practical and innovative ways.

Previous attempts at comprehensive programming or coordination—such as state rural development committees—seem to have been too weak, *pro forma,* and government centered to accomplish the job of dealing with small farm problems. We need to work together in ways that are more substantive. At the heart of such cooperation must be a far closer working relationship between state and local government and the universities. For this to occur, some important adjustments will have to be made all around. We bureaucrats will have to force ourselves out of our typical top-down, line-authority mode of thinking so as to open up the decision process to wider participation and better ideas and information, providing researchers with more opportunity to educate us. On the other side, university researchers will need to curb their enviable will-of-the-wisp individualism enough to focus on practical problems, and then to stay with them long enough to produce usable results.

Madden is concerned that the excellent and ambitious research agenda to which he refers will not be implemented, or that it will be implemented badly. He fears a vicious cycle of poor research and inadequate funding. I share his concern, but I would note that, to us bureaucrats, much research seems poor sim-

The opinions expressed in this paper are those of the author and do not necessarily represent the position of any department of the State of California.

ply because it is not relevant to real decisions about real issues which real private and public people can act upon. In my view, there is rather more available money that could be turned, at least in part, to small farm research than is commonly recognized in the universities. Much of this money is at sources not conventional to agricultural researchers, and almost always getting hold of it would involve making research pertinent to tangible problems. It may be that the kind of relevant research which could be so funded would not be of interest to academic journals, but then, again, I feel our taxpayer supported universities should exist more to get our problems solved than to promote the fame of individual faculty members.

I would offer a few suggestions for making research outlined by Madden fundable by a variety of agencies having some reason to support assistance to small farms.

(*a*) Researchers should start with a clear view of who is asking what question, in what way, and for what reason. This can be done by searching out and speaking with practitioners faced with the problem. Most of us are aware we have to make too many decisions with too little information, and we would be flattered by your interest. Our problem is that so often researchers do not want to ask a question in the way we are forced by realities to ask it, and hence the findings are of little or no use.

(*b*) Researchers should remember that decision makers probably are working by a decision making paradigm that differs from models most dear to academia. Usually alternatives are weighed by many different kinds of criteria, and researchers who forget this and focus on one set of criteria alone tend to forfeit the context of reality. In many cases, researchers approach a question as though it lies in a single policy domain (e.g., agricultural policy), when in fact it may inhabit several policy domains (e.g., economic development, employment, and social equity).

(*c*) Researchers should make sure they understand legislative and administrative processes pertinent to subjects they research. Many otherwise excellent academics seem to have a poor understanding of government decision-making practices and actors, and consequently miss vast opportunities. Too many researchers have erroneous ideas of the policy process, such as "Legislative branches make policy; executive branches administer it," when, of course, nothing could be further from the truth. Similarly, I have found researchers often too quick to assume that a bureaucracy is a monolith, and that an idea adopted or rejected at the top has no separate life in the ranks. To the contrary, academics could do much to strengthen healthy diversity and debate inside our agencies by seeking out and working with those who are open to their interests.

(*d*) We need much more research about the "next steps" we can take from where we are; optimal solutions are luxuries that policy makers and administrators almost never experience. American democracy moves incrementally. We especially need more studies of successes—of small farmers who succeed and of small farm programs that succeed. We need to be able to estimate the potential that exists for expanding a few successes into many successes. We do not really have to have "predictability," as Madden put it; a significantly better batting average would be help enough for now.

Small Farms Definition and Policy Research Agenda: Discussion

Allen R. Thompson

The paper by Carlin and Crecink lays out quite well the necessity of formulating a definition of a small farm which conforms to the accepted notions as to what constitutes small and which is easily quantifiable for purposes of enumeration and statistical analysis. From the many discussions I have had with various groups, the definition nominally agreed upon by the U.S. Department of Agriculture (USDA) closely resembles that adopted by other groups, such as the National Rural Center, and would appear to meet both criteria—although there could be potential difficulties in identifying what constitutes a significant portion of family income, especially for operations which in a given census year may have experienced a net loss.

Carlin and Crecink also have presented a description of farm families under two alternative definitions: (*a*) small business as defined by gross sales, and (*b*) low income. Their discussion reveals an overlap in the number of farms defined as small under both criteria and a similarity in the characteristics of operators under each of the two definitions.

While I found their paper quite interesting, I did have some problems. In the first place after stating the new USDA definition, they presented no data to indicate the magnitude or characteristics of farm families meeting these criteria. Moreover, while I believe their scheme in figure 1 is helpful in distinguishing the different groups included and excluded by the two definitions, I would have liked to see the characteristics of group A (small by sales, high by income) and group C (small by income, high by sales) shown separately. In this way, the tradeoff between the two alternative definitions would have been more clear. I wonder if that would have revealed the same degree of similarity in characteristics shown in the tables they do present.

Allen R. Thompson is an associate professor of economics, Whittemore School of Business and Economics, University of New Hampshire.

As to the data, I am a bit disturbed by the high potential error associated with the under reporting of farm and perhaps off-farm income. As I understand it, some 12% of the sample failed to report sales of agricultural products which would, I guess, make them small farmers by the gross sales category. In addition, while nearly 80% did report off-farm income, it is impossible in the survey to identify those who failed to report from those with no off-farm income. What this does to the conclusions is unclear.

I would have liked to see the authors stress in stronger language, and perhaps in more detail, the problems inherent in the gross sales concept. They state their difficulty to be the lack of definitive policy objectives inherent in such a definitional concept. More serious to me is the great heterogeneity in what gross sales means in terms of net income for different kinds of farm enterprises. I am glad the USDA definition appears to be moving away from that obsolete and meaningless definition.

A further point not well treated by the paper is the heterogeneity of the group identified as small by any number of definitions. They have given us only a few characteristics, such as age, which show differences within the group. As the authors point out in their paper, the policies for small farmers should be heterogenous because they have different needs and different objectives. So, too, should consideration in a definition be given perhaps to identifying separate and different groups of small farmers. As Madden and Tischbein observe, we need a typology of small farms which distinguishes resource endowments, aspirations, and other characteristics which would enable identification of separate programs and policies to meet the differing needs of this diverse group.

Finally, let me take issue with the characterization of families with income below the median level as limited-resource, or poverty, families. For some of us who propose using a definition of small, such as that proposed by

the USDA, the principal area for farm policy is improved farm income. While no doubt some of those identified as small by this definition lack resources or are poor, others are by most standards moderately successful. While we may wish to target any special small farm programs to a group with less income, I believe many of us wish to separate the concern with poverty, be it rural or farm poverty, from a concern to increase farm incomes of those families seeking that objective.

The paper by Madden and Tischbein presents basically a description and the rationale of the Small Farms Project of the National Rural Center, a project in which I also have been involved. As their paper is almost exclusively about that one project, I wish to comment on what I feel would have made the paper more interesting and insightful although still remaining faithful to their title: "Towards an Agenda for Small Farms Research."

Perhaps one of the major findings in almost every area of the NRC state-of-the-arts review papers was (or in some cases should have been) that small farm research is, for the most part, still to be done. While the authors devoted a paragraph to a listing of the deficiencies, it is perhaps worthwhile to speculate on why the research to date is largely irrelevant or incomplete. In part, it is, as they have stated, a lack of adequate data. Certainly I believe they would agree that the Census of Agriculture is a very poor source of data, especially in the way it is presented. Having to define small exclusively by gross sales as the census requires makes for limited and often meaningless research. Perhaps more important, but unstated by the authors, is the fact that the basic attitudes of USDA and the research community have been such as to preclude the raising of most relevant questions, much less the answering of those questions. Because of the general acceptance of the conclusion that a small farm means inefficiency in production, poverty in terms of income and, for economists, inappropriate allocation of resources, few have worried about the reasons for small farm problems or the contribution of agricultural policy to the declining number of small farms. In the marketing area, for example, the unquestioned acceptance of the efficiency of the current marketing system has led few researchers to explore the relevance or viability of marketing alternatives more suitable to small farms. The latter is, of course, not true for other countries where researchers have helped to develop marketing systems more suitable for small farms.

The assumptions for U.S. researchers have been, and for many remain, that small farms are out of place except for those marginal operators who are stuck because of age, for example, and who are not a farm problem but a welfare problem anyway. If we are to work toward a meaningful small-farms research agenda, we must be willing, as researchers, to take a fresh look at small farm questions and challenge old cliches and old assumptions.

The shortcomings of past research and the necessity for alternative models and alternative assumptions in future research are shortchanged in this paper, although I am sure they are well appreciated by the authors and, I hope, by the research community.

Small Farms Definition and Policy Research Agenda: Discussion

Peter M. Emerson

The paper by Thomas Carlin and John Crecink has two sources of strength: (*a*) their commonsense notion that the definition of a small farm is multidimensional, and (*b*) their use of the 1975 Farm Production Expenditure Survey data. The authors show, for the first time, that low income, small farm families have an important dependence on farming and that they are more closely akin to all low income farm families than to all small farm families.

I believe that the data presented by Carlin and Crecink may stimulate some interesting research projects. For example, why do low income, small farm families that report a negative net farm income appear to be superior off-farm income earners as compared to low income, small farm families reporting a positive net farm income? In short, why are failures on the farm successes off the farm? One possible answer is that families with a negative net farm income need more off-farm income for subsistence. But all of the families under consideration are characterized by low incomes, and it appears reasonable to assume that most of them strive to earn more income. It may be that the success of negative net farm income families in off-farm earnings is more directly related to the fact that they farm fewer acres than the others, or tend to be heavily involved in the production of horticultural crops.

Carlin and Crecink, however, provide very little insight into the importance in absolute terms of the four areas depicted in figure 1. The reader must use a second data source, such as USDA's *Farm Income Statistics*, to estimate farm numbers, share of total farm sales, and other factors that fully describe figure 1. One estimate is that 1.4 million low income, small farm families accounted for about 8% of total farm sales in 1977. The authors also fail to provide information relating specifically to low income, large farm families or to high income, small farm families, although one of their major conclusions is that the current debate about small farms involves important trade-offs between these two groups.

Carlin and Crecink have not directed attention to the fact that some of the most urgent social problems exist among small farmers. How many of the low income, small farm families actually fall below the poverty line? How many are minorities subject to systematic discrimination and often overlooked by existing public programs? It is possible that preoccupation with the structure of agriculture (small farms versus large farms) to the exclusion of other data may direct public attention away from those people most in need of assistance?

In concluding their paper, Carlin and Crecink argue that "the concept [of a small farm] itself does not suggest a clear policy objective." It is my personal opinion that the existing body of research, and the values and goals of most Americans, substantially contradict this argument. I believe that public policies—particularly those relating to price and income support, taxation, credit, research, and extension—ought to be neutral with respect to farm size. Obviously, public policies are not neutral if program benefits are heavily skewed in favor of large farms, if they reduce opportunities to enter farming, or if they tend to discourage the operation of small farm businesses.

My overall assessment of the paper by Madden and Tischbein is that it is rather short on the details of a research agenda and much too long on description of the National Rural Center's Small Farms Project. The reasons for concern about the future of small farms are well presented, though perhaps the authors overstate the potential contribution of small farms to the viability of rural communities. I certainly concur with their recommendation for additional studies of the socioeconomic re-

---

Peter M. Emerson is a principal analyst, Congressional Budget Office, Washington, D.C.

lationships between farming and rural communities. We need to develop research methods that will allow the results of these studies to be generalized and free them from personal bias toward a particular lifestyle.

Madden and Tischbein recognize that the wide diversity of problems and issues makes it difficult, perhaps impossible, to develop a national agenda for small farm research. Given this constraint, I believe it would be useful if the authors simply proposed some guidelines to be followed in developing small-farm research plans. Perhaps the guidelines could take the form of a series of questions to researchers and administrators. For example: Does our research agenda help people fit into the margins of large-scale, industrialized farming? Does our research agenda insure diversity in farming?

I believe that a research agenda explicitly recognizing the option of less specialization will, over a period of time, tend to benefit small farm families without making them dependent on direct government assistance. The range of alternative farming methods and lifestyles to which agricultural research may contribute will be increased greatly if some analysts concentrate on less specialization. One difficulty with this strategy is that the activities of planning and conducting research are controlled by experts who are often willing to consider only the narrow, specialized projects to which their livelihoods are tied.

In addition to the specific research issues suggested by Madden and Tischbein, it seems important to encourage economists and statisticians to get on with the work of establishing linkages between existing data series that describe the characteristics of people and farm businesses. This may enable us to gain much additional information for only a small cost, and with no additional burden on the respondents. Also, I believe that more research based on the direct observation of individual behavior—motives, expectations, and attitudes—would help to improve our understanding of the problems of small-scale farmers and why the farm sector is changing.

Settlement Size, Real Income, and the Rural Turnaround

Irving Hoch

In previous work examining wages and incomes in metropolitan areas (Hoch 1976, 1977), I found that wage rates for the same work increased by about 9% per order of magnitude of population size, and that per capita incomes increased by about 16% with each magnitude of population size. Both the wage and income differentials showed strong persistence over time. I interpreted the wage differential as a compensatory payment, and the income differential as encompassing both the wage differential and differences in factor mix by size of place. The cost-of-living, as measured by a conventional market-basket index, increased by roughly 4.5% per order of magnitude of population, and the remaining wage differential was explained as the net of bads over goods with population size—pollution and congestion costs net of the benefits of increased specialization, such as greater availability of specialized medical services. (Some hedging of these interpretations is necessary. Although considerable effort was devoted to establishing homogeneity in the wage comparisons, some residual heterogeneity of work force may remain. Again, disequilibrium can be a problem in both wage and income comparisons.)

This paper extends the analysis of wage and income differentials to rural occupations and the nonmetropolitan population, thus attempting to bridge the work of some classic studies comparing farm and nonfarm income (e.g., Hathaway) and those relating urban wages and incomes to population size (e.g., Fuchs). In addition, the work is seen as useful in analyzing the rural turnaround, which has received considerable recent attention (e.g., Beale 1975). Results are interpreted as reflecting long-run compensatory payments as modified or distorted by short-run disequilibria.

Irving Hoch is a Fellow with Resources for the Future, Washington, D.C.

The next section analyzes wage rates for two relatively homogenous occupations—hired farm labor and female clerical workers, based on a sample of rural as well as urban counties. The concluding section, recognizing the hazards of income comparisons, considers income and population data for metropolitan areas and nonmetropolitan counties over the period 1969–77. Major conclusions are: (*a*) wage rates increase with population for rural as well as for urban occupations; (*b*) the wage-size relation holds for the small populations of nonmetropolitan counties, as well as for the large populations of metropolitan areas; (*c*) the pattern of nonmetropolitan income differentials then ties neatly into that of metropolitan income differentials; (*d*) the rural turnaround can be interpreted as an equilibrating adjustment, because movement from places of higher to places of lower money wages is consistent with increases in real wages; (*e*) there is little difference in growth in either population or per capita income between nonmetropolitan areas contiguous to and those not contiguous to metropolitan areas, implying that the observed turnaround is not a statistical artifact of urban sprawl extending beyond metropolitan boundaries; and (*f*) the rural turnaround seems best viewed as part of a more general equilibrating process favoring the growth of small relative to large places.

Wage Studies

I asked the basic question: Does the wage-size relation hold for rural occupations and for nonmetropolitan counties? To answer the question, I drew on county data from the 1970 Census of Population and the 1974 Census of Agriculture. Data on median 1969 earnings of female clerical workers and of male hired laborers were obtained from the first source,

while the 1974 value of farm real estate per acre and of estimated annual wages of hired farm workers were obtained from the second source. (The last measure covers farm workers employed 150 days or more.) Although there are some difficulties with these series, they appear to be the best data available at the county level (U.S. Congress).

Four samples were obtained by using all the county observations available for New York, Iowa, Alabama, and California. Those states were selected because of their size, their respective location in one of the four major U.S. regions, and their relatively large number of counties (more than fifty for each). The number of observations varied somewhat between occupations because of incomplete coverage, particularly for farm workers in large metropolitan counties.

The key explanatory variable, area population, was defined as metropolitan area population for counties falling in standard metropolitan statistical areas (SMSAs), and as county population for all other counties, a straightforward extension of the SMSA definition. The spatial unit can be viewed as corresponding to the local labor market or settlement. County and SMSA populations are taken from the 1970 Census of Population and are measured in units of 1,000.

As a first step, real estate value per acre was regressed on spatial-unit population size for each state and for the state data combined in one sample. The log-log form gave the highest explained variance, with positive and statistically significant coefficient in all cases, though some variability occurred between states. Similar results were obtained when the sample was restricted to counties not in SMSAs. Results for the combined state samples were as follows, with log of real estate value the dependent variable:

Sample	Constant	Coefficient of Log Population Size	t-Ratio	$\bar{R}^2$	Number of Observations
All counties	2.223	0.279	12.03	.44	280
Exclude SMSA counties	2.275	0.248	6.31	.51	203

Dummy variables for individual states appeared in the equations as intercept shifters; the constant is the average of individual state intercepts.

Assuming that real estate and land value per acre are well-correlated, a hypothesis explaining the relation of land value and population size is that increases in settlement size cause increases in land values, including farm land values. If more people want to locate in a county, the demand for land and its price, should shift up. Of course, there are alternative hypotheses; a better agricultural base, in terms of better soil, water, topography, climate, or access to markets, can be reflected in farm land values, and in turn, cause greater levels of population. In practice, causation may run in both directions.

Standardized wage rates were related to log of population size, with results in table 1. Standardized wage rates are expressed as a percentage of the average wage rate, and are obtained by dividing each county reading by the average for the specific sample and then multiplying by 100, eliminating differentials between occupations and over time, and facilitating interpretation of results. In the combined samples, dummy variables for state intercept shifters again accounted for state differentials.

The evidence of table 1 supports the hypothesis that wage rates increase with population (a) for rural as well as for urban workers including farm workers, and (b) for nonmetropolitan levels of population (1,000 to 100,000 persons), as well as for metropolitan levels (over 100,000).

The coefficient values in table 1 seem broadly consistent with previous estimates obtained using other data sources for a number of occupations and groups (Hoch 1976, 1977, pp. 38, 39).

Again, when SMSA counties are deleted, the population size effect falls for the hired farm worker, 1969 sample, but it increases for the other two cases, suggesting that the effect is at least as strong in small population locations as in larger places.

Finally, the log of real estate value per acre (RE/A) was brought into each equation as an additional explanatory variable. The general result was that population size dominated land value in the female clerical worker equations, but the reverse relationship held for the farm worker cases. Dominance refers to relative explanatory power of two correlated variables, with the dominant variable having a high t-ratio and relatively large, positive coefficient, and the dominated variable having

Table 1. Regressions of Standardized Wage Rate Estimates on Log of Area Population, by Occupation and Sample

Sample	Constant	Coefficient	t-ratio	$\bar{R}^2$	Constant	Coefficient	t-ratio	$\bar{R}^2$	Constant	Coefficient	t-ratio	$\bar{R}^2$
(1) New York	76.7	9.86	6.87	.45	75.0	10.57	3.27	.15	83.9	6.96	1.44	.02
(2) Iowa	75.2	18.82	4.93	.19	87.6	9.39	2.20	.04	80.1	14.69	1.43	.01
(3) Alabama	87.7	7.38	3.52	.15	86.3	8.29	2.03	.05	62.0	22.90	4.28	.21
(4) California	66.8	16.34	7.60	.51	93.6	3.16	1.16	.01	95.0	2.19	0.67	−.01
(5) Four states combined	71.1[b]	13.83	11.93	.59	88.7[b]	7.27	4.33	.28	92.5[b]	9.12	3.18	.46
(6) Four states combined (excluding SMSA counties)	74.6[b]	20.49	5.93	.37	89.0[b]	8.79	1.94	.24	104.1[b]	2.91	0.33	.37

[a] Number of observations for Hired Farm Workers, 1969, by sample, was (1) 53, (2) 84, (3) 66, (4) 45, (5) 248, and (6) 175. Number of observations for other occupational equations was (1) 58, (2) 99, (3) 67, (4) 56, (5) 280, and (6) 203.

[b] Dummy variables for individual states appeared in the equation as intercept shifters; constant shown is average of state intercepts.

a low t-ratio and a small, sometimes negative coefficient. The pattern held in almost all the individual state equations, and here appears clearly in the equation for the combined samples:

Occupation, Sample: Four States Combined	Coefficients Log Pop.	Coefficients Log (RE/A)	t-Ratios Log Pop.	t-Ratios Log (RE/A)
Female clerical, 1969	13.24	2.13	9.23	0.71
Hired farm workers, 1974	1.00	22.50	0.51	5.41
Hired farm workers, 1969	4.36	18.86	1.29	2.60

This result might be interpreted as follows. By way of multiplier effects, land values are likely to be a central ingredient in a conventionally measured cost-of-living index, which includes only market traded goods. As noted earlier, people living in cities (of any size, including small towns) should also be faced with nonmarket costs, including time spent in the journey to work, various forms of pollution, and other disamenities, together hypothesized to outweigh any amenities of urban life. Female clerical workers usually will work in cities, and will be faced with both the market and nonmarket cost items. Further, urban land values may not be highly correlated with farm land values. Consequently, population size will be a better explanatory variable than farm real estate value in explaining clerical wages. But farm workers, by definition, will not be faced with the nonmarket city costs (save for trips into the city), and so will have their wage rates affected only by the "conventional" cost-of-living, better explained by real estate value than by size of settlement.

My basic question, then, is answered affirmatively: the wage-population size relation appears to hold for rural occupations and for nonmetropolitan settlements, as well as for their urban and metropolitan counterparts. Given the importance of wages in income, these relationships should affect our interpretations of rural income and population shifts, including the "rural turnaround." I illustrate this point in detail in the next section.

Income and Population Comparisons

In this section, I change my focus from wages to income. Table 2 compares nonmetropolitan counties to SMSAs grouped by population size, in terms of deflated per capita incomes in 1969 and 1977, growth in per capita income within that period, and growth in population for the same period. The first two columns of table 2 exhibit the general tendency of per capita income to increase with population size. To some extent, this can be attributed to factor mix, in terms of both labor and nonhuman factors of production, but to considerable extent, it should also reflect increasing wage rates for the same work, as documented in the previous section.

As an initial analysis, using data spanning a number of years on metropolitan areas only, the regression of deflated per capita income on the log of SMSA population and a dummy

Table 2. Per Capita Income and Population Growth by Population Size Class, 1969 and 1977

Population Size Categories; (population in thousands as of 1969)	Per Capita Income Deflated by CPI[a] 1969	Per Capita Income Deflated by CPI[a] 1977	1977/1969	Population in Class 1977/1969

[a] CPI is consumer price index, 1972 = 100.

[b] NYC is New York City metropolitan area.

variable for the South yielded a statistically significant coefficient for the population measure in every year examined. Over the period 1950–72, this coefficient was relatively stable, and it implied that per capita incomes increased by about 16% per order of magnitude of population (Hoch 1977, p. 44). Since 1972 there has been a mild downtrend in the coefficient, so that by 1977, per capita incomes increase by only 13% per order of magnitude of population (from newly run individual regressions 1973–77). An appealing hypothesis explaining the downtrend is a temporary disequilibrium in favor of smaller places, i.e., people in smaller places currently are receiving more than is needed to keep everyone in their place, so there is net migration from larger to smaller places. In table 2, note the inverse relationship between population size (as of 1969) and growth—both growth in per capita income and growth in population.

The average 1969 population of the non-SMSA county was 21,050 (U.S. BEA). An SMSA one population magnitude larger falls in the second SMSA size grouping in table 2 (100,000 to 250,000), and the per capita income for that class exceeded the corresponding non-SMSA value by exactly 16% in 1969 and 13% in 1977. Those specific results are fortuitous embellishments to the interpretation that the non-SMSA income pattern fits the income-population pattern observed for larger places, again paralleling a conclusion of the previous section.

Table 3 presents population and income comparisons over the period 1969–77. The start of the "rural turnaround" might well be dated as 1971, because nonmetropolitan population as a percentage of the U.S. total turns up in that year, and the percentage increases thereafter. In contrast, non-SMSA per capita income increased relative to SMSA levels to 1973, but then fell somewhat through 1976, with no appreciable change in 1977. Net income per farm peaked at a very high level in 1973 (USDA, p. 15), probably a major factor explaining the observed pattern. But despite the turn-down from the 1973 extreme, the 1977 relative income value is well above the 1970 value. If we entertain the hypothesis that the equilibrium percentage is closer to the 1970 than the 1977 figure, given the direction of recent net migration (e.g., U.S. Census 1978, P-20), we can expect a continuation of the rural turnaround for some time to come. Under this interpretation, of course, we can explain the apparent anomaly of people migrating from higher to lower wage localities (Zelinsky), since real incomes obtained in the new locations are higher than in the old.

The rural turnaround is sometimes hypothesized to be a statistical artifact reflecting urban sprawl which has occurred beyond officially designated SMSA boundaries. Several authors (Beale 1977; McCarthy and Morrison) have developed population data which counters this interpretation, showing net growth in rural areas at some remove from SMSAs, as well as growth occurring nearby. Let me extend that discussion by drawing on some additional evidence, which also bears on my interest in the income-population size relation. That evidence was developed using a sample of 711 non-SMSA counties, out of the U.S. total of

Table 3. U.S. Metropolitan versus Nonmetropolitan Population and Income Comparisons, 1969–77

Year	Population in Non-SMSA Counties as Percentage of U.S. Population	Per Capita Income, Non-SMSA Counties as Percentage of SMSA Counties	Per Capita Income as Fraction of Previous Year Per Capita Income: SMSA Counties	Per Capita Income as Fraction of Previous Year Per Capita Income: Non-SMSA Counties
1969	26.04	71.45	1.001	1.014

2,467 such counties; 342 of the sampled counties were contiguous to metropolitan areas, i.e., bordered on an SMSA county, and 369 were noncontiguous. I developed those subsamples using maps appearing in the Census *Current Population Reports* (Series P-26), with each subsample covering most states and selected so that counties were widely and relatively evenly distributed over each state.

Table 4 compares deflated per capita incomes for selected years over the 1969–77 period for the contiguous versus noncontiguous groupings, with each grouping subclassified into population size classes.

Table 4 can support two major conclusions. The first is that the general pattern of increased per capita income with population size occurs for the four largest size classes, but generally the smallest size class (below 10,000 population) exhibits an income level above the next size class and roughly equal to that of the middle grouping (25,000 to 50,000). This suggests a U-shaped pattern of compensatory payments. It is an appealing hypothesis that minimum disamenities occur in the 10,000 to 25,000 range, making that population level "optimal" in terms of preferences; below that point, relative isolation and small size may impose net costs, causing increased wages and incomes as an equilibrating adjustment. But this hypothesis needs some intensive testing.

The second major conclusion suggested by table 4 is the occurrence of basically similar patterns for contiguous and noncontiguous counties. Such occur both for deflated per capita incomes and for changes in per capita incomes and population. Regressions were run relating per capita income for the sampled non-SMSA counties to log of population, regional dummy variables, and a dummy variable expressing SMSA proximity (contiguous counties were assigned a value of one, and noncontiguous counties a value of zero). The coefficient for SMSA proximity was positive and often significant, but its effect was relatively minor, indicating that contiguous counties' per capita income is around 2% above that of noncontiguous counties. This might be either a factor mix or a compensatory payment effect. As indicated above, the U-shaped pattern for deflated wages suggests the need for experimentation with other than logarithmic equation forms, but the SMSA proximity effect can be expected to persist at around the reported magnitude. It is of some consequence for the general argument of this paper that the coefficient for log of population was generally positive and significant, though the 1973 value was negative and significant, no doubt the effect of the temporary increase in agricultural income.

Statistical tests also indicate that only minor differences occur in growth in population and income between the two sets of counties. Segregating the data by region, proximity to SMSA was not significant in explaining change

Table 4. Comparisons of Per Capita Incomes and Growth in Income and Population for a Sample of Nonmetropolitan Counties Classified by Population Size and Location

1969 Population (in thousands)	Number of Observations	Per Capita Income Deflated by CPI, Selected Years						Changes: 1977/1969

75–<100	15	3683.9	3785.0	4161.1	4055.3	4176.4	4276.3	1.161	1.089
All	342	3201.6	3333.0	3991.7	3739.1	3765.2	3875.2	1.210	1.124

in income in either the North or South; it was significant in explaining population change in the South, but not in the North. The Southern result involved 9% growth for noncontiguous counties and 12% growth for contiguous counties. Hence, proximity to a metropolitan area does not seem to be a major factor explaining the rural turnaround.

Speculations on underlying causes of the rural turnaround point to such factors as improvements in transportation and communication; the impact of higher energy prices on both the supply and demand side; and the effects of increased sensitivity to the environment, and of environmental regulation. In addition, inflation in tandem with the progressive income tax tends to increase real taxes because people are moved into higher tax brackets even if real wages are unchanged. The effect appears to be stronger the higher the initial money income level, based on a detailed examination of tax rates and taxes under inflation. Consequently, people will tend to shift to places offering lower money wages but equal real wages, relative to alternative locations, since this will increase real disposable income. (Our income comparisons by location would be improved if we developed data on disposable income per capita.) A specific implication is that people will tend to move from larger to smaller places; given current rates of inflation, such shifts should become even more pronounced over the next several years.

Finally, the shifts involved in the rural turnaround, whatever their causes, seem part of a more general process occurring over the full range of settlement sizes. In turn, this suggests that we may improve our analysis by perceiving rural and urban as part of a continuous, integrated system, rather than as a sharp dichotomy.

Residential Preferences, Quality of Life, and the Population Turnaround

Don A. Dillman

In the early 1970s, before we had statistical evidence of renewed population growth in rural America, several residential preference surveys were taken. The results showed rather dramatically that if people were free to choose they would prefer to live in rural places rather than in cities. Particularly evident was an aversion to living in very large cities (Mazie and Rawlings, Zuiches and Fuguitt 1972, Dillman and Dobash).

Results of these surveys were viewed by some people as a novelty; interesting but not very useful, especially if one's interest were in predicting migration between rural and urban places. Preferences for living in a particular geographic location, other things equal, have never been a very good predictor of rural-urban migration movements. The simple reason is that these other things were not equal. During the first two-thirds of this century millions of rural people found it necessary to choose between an attractive social and natural environment on the one hand and economic well-being on the other. For the most part, they chose the latter and migrated to cities.

Until recently, discussions of whether people's residential preferences affected their geographic mobility were often cut short with such cryptic comments as "rural people have voted with their feet instead of their hearts," leaving the impression that people's residential aspirations were irrelevant to their actual behavior. Even those involved in the early preference surveys tended to justify them as efforts to find out whether the desire to live in more rural environments was sufficiently strong to warrant a deliberate governmental effort to redistribute the population of the United States (cf. Commission on Population Growth and the American Future, 1972 and Dillman and Dobash 1972).

The discovery in the mid-1970s that virtually all rural regions of the country (although certainly not all individual counties or towns) were showing modest growth made arguments for a redistribution policy obsolete almost before they were published. More importantly, it encouraged a reexamination of the possible relevance, if any, of residential preferences in explaining the renewed growth of rural America. My purpose in this paper is to discuss the possible role of preferences, or, to state it in a more general way, the search for a better quality of life, as a determinant of movement from cities to rural places.

The Population Turnaround and Possible Reasons for It

An examination of the role that residential preferences may have played in the population turnaround cannot be done without first considering what is known about the extent of renewed population growth in rural America and various explanations for its occurrence.

First, between 1960 and 1970 the Standard Metropolitan Statistical Areas (hereafter referred to as "metro" areas) of the United States grew at the rate of 1.6% per year compared to .4% for nonmetro counties. But between 1970 and 1975 the relative growth rates reversed with metro areas slowing down to only .8% per year compared to 1.2% per year for nonmetro locations (Beale 1977). Secondly, although some growth in nonmetro counties is the result of "spillover" from metropolitan counties to those that are adjacent, much of it is not, because the nonmetro coun-

Helpful comments from Edwin Carpenter, William Freudenburg, Barbara Hawkins, John Wardwell, and James Zuiches are gratefully acknowledged by the author.

ties that are not adjacent to metro areas have also been growing at a rate faster than the metro centers. Thirdly, the turnaround is spread throughout the United States. By 1975 the nonmetro counties which were not adjacent to metro counties located in only three of the 26 economic subregions of the United States continued to exhibit net outmigration. Based upon these and other findings, McCarthy and Morrison have concluded that "metropolitan expansion is being supplemented by self-contained local urbanization even in remote regions of non-metro America" (p. 18).

We cannot be sure at this time how long lasting the turnaround is likely to be, but it appears to be continuing into the most recent period for which data are available, i.e., 1975–78. Although some of the nonmetropolitan growth coincided with the economic recession of the early 1970s, it is continuing in these better economic times. The migrants to metro counties continue to be outnumbered by those who are migrants moving to nonmetro counties by a ratio of 5 to 4, or a total of 1.1 million people from 1975 to 1978 (U.S. Census 1978).

Many factors may be contributing to the post-1970 growth of nonmetro counties. Among the explanations for which some evidence has been provided are these (DeJong and Sell; Beale, 1975, 1977; Wardwell; McCarthy and Morrison; Morrison; Carpenter, 1977; and Blackwood and Carpenter, 1978); (*a*) continued growth of metropolitan centers and their expansion (spillover) into adjacent nonmetro counties; (*b*) decentralization of manufacturing in pursuit of lower land and wage costs; (*c*) increased employment in service occupations; (*d*) early retirement coupled with higher retirement incomes; (*e*) increased per capita disposable real income; (*f*) increased pursuit of leisure activities and the resultant development of retirement centers outside of Development of retirement centers outside of the sunbelt areas of the United States; (*h*) increased enrollments in nonmetro colleges and universities; (*i*) growth of state governments; (*j*) leveling off of loss of farm population; (*k*) youth revolution with anti-materialistic movement, anti-urbanism and an increase in alternative lifestyle agriculturists; (*l*) narrowing of traditional gaps in urban and rural lifestyles; (*m*) more long distance commuting) (*n*) energy and mineral exploitation; (*o*) completion of interstate highway system; (*p*) lower cost of living in rural areas; (*q*) increased fear of crime and concern with urban disamenities (crime, congestion, and pollution).

The factors mentioned above are diverse. They exhibit varying levels of specificity and lack mutual exclusivity. Many appear to be interrelated. It is beyond the scope of this brief paper to further categorize and attempt to sort out the extent to which each of these factors is contributing to the population turnaround. However, this list suggests that a multitude of factors are contributing; a singular explanation of the turnaround does not seem possible.

We are analyzing a very recent phenomenon. The first systematic evidence of the turnaround was published only four years ago (Beale 1975) and, despite the widespread nature of the phenomenon, insufficient time has elapsed for the normal accumulation of a data base that would allow the detailed analysis necessary for determining the relative importance of these possible contributors to the turnaround.

Several (though certainly not all) of the possible causes of the population turnaround that are listed above suggest a preference for living in more rural settings. For example, early retirement coupled with higher retirement incomes frees people to pursue residential preferences. Such people could perhaps just as easily move to (or remain in) cities if that were their preference. The narrowing of differences in rural/urban lifestyles (from indoor plumbing and electricity to color T.V. reception and senior citizen centers) suggests that it is no longer necessary to give up many of the amenities in a rural residential location, thus increasing the attractiveness of rural living. Growth from recreational development suggests the inherent attractiveness of rural places. More long-distance commuting suggests a willingness of some people to incur the costs of that commuting in order to have a particular residential location. It is even possible that some of the decentralization of manufacturing and expanded employment in service occupations is the result of jobs following people rather than the reverse, as traditionally would have been expected.

My discussion to this point certainly does not prove that preferences for rural living are causing or even contributing to the population turnaround. However, I believe there is sufficient indication of their playing a role in the turnaround to warrant a detailed investiga-

tion of the nature of that role, and the reasons people hold rural residential preferences.

Residential Preferences of the American People

All of the residential preference surveys done since 1970 indicate that in general the American people prefer residential locations more rural than their present ones (Ryan, et al.; Carpenter, 1975; Zuiches and Fuguitt, 1972; Fuguitt and Zuiches; Mazie and Rawlings; Dillman and Dobash; Dillman; DeJong and Sell). For example, a 1974 national survey, one of the most comprehensive surveys that has been done, found that whereas 40% of the population lived in cities of more than 50,000 only 21% preferred to live there (Zuiches and Fuguitt, 1976).

At the same time these surveys have revealed a desire not to escape entirely from urban areas. This same national survey showed that the percentage of people who would opt for living more than 30 miles away from a city of 50,000 or greater is only slightly more than now lives there, 21% actual versus 26% preferred. Taken at face value, preference surveys suggest that if people were to follow their preferences most of the growth would be in the general vicinity of small and medium cities and come at the expense of the very large cities.

The anti-large city attitudes of people also are revealed in other ways. When asked where they would least like to live more than 80% of the respondents in a statewide survey of Washington State residents identified large metro areas containing a city of more than 500,000 whereas only 16% responded that they would least like to live in a rural region with no place as large as 2,500 (Dillman and Dobash).

The greater attractiveness of rural places also is documented by an intriguing question from a 1972 national survey reported by Fuguitt and Zuiches. Respondents were categorized according to whether they most preferred to live in (*a*) metro size cities (50,000 or more people), (*b*) the metro-ring around them (within 30 miles), or (*c*) further away. The percentage choosing each category as first choice was 19%, 55%, and 26%, respectively. But, when those who gave the metro-ring areas as their first choice were forced to choose between the remaining two options, four out of five opted for the more rural choice instead of the larger cities (Fuguitt and Zuiches). However, the preference for rural living is not unconditional. When potential negative consequences of a move to rural areas were presented to people holding rural preferences in the national survey their interest dropped markedly. The authors report that about half would give up the rural preference in the face of a lower income and other potential negative consequences (Zuiches and Fuguitt, 1976). In a survey of Arizona residents it was found that the proportion of respondents interested in nonmetro living dropped from 52% to only 14% under the stringent conditions of a 10% loss of income and a commute of at least an hour to work in a major city (Carpenter, 1977).

Finally, some research evidence suggests that the preference for a more rural environment is intertwined with the desire to live in the countryside. In the previously mentioned Washington State survey 65% indicated they would prefer living outside rather than inside the city limits of the nearest community (Dillman and Dobash). The proportion stating this preference increased steadily as city size preference decreased. Forty-five percent of those who opted for a community size of 500,000 wanted to live outside the city limits as did 83% of those who opted for a community size of less than 2,500 people. To many people a rural preference may imply a home in the country complete with trees, spacious yard, and other idyllic qualities.

Have Preferences Changed?

To the extent that preferences are influencing the population turnaround, it may, on the one hand, be a case of long-standing preferences being realized. On the other hand, it may be the result of a recent increase in rural preferences. There is very little evidence available with which to answer this question, but the data suggest that a change in preferences may have occurred. The 20 cross-sectional surveys that have asked a preference question date only from 1966, except for an isolated 1948 effort (Dillman). The wide variety of question wordings make it impossible to infer a change in preferences with one exception. Five Gallup surveys conducted from 1966 to 1976 show a steady decrease in the percentage opting for the somewhat vague category "city" from 22% in 1966 to only 13% in 1976.

Other evidence of a possible increase in preferences for rural living comes from a longitudinal survey of rural youth from Michigan's Upper Peninsula (Zuiches and Rieger). In this unique study high school seniors were surveyed in 1957, 1968, and 1974. The 1957 graduates were resurveyed in 1968 and again in 1974; the 1968 graduates were also resurveyed in 1974. It is possible from this series of surveys to determine whether residential preferences are different among the classes at the time each graduated and whether preferences changed in later years. The authors report that preferences for rural and open country living were greater for the later graduates at the time of their graduation, being 11% for 1957 females compared to 19% for 1974 females; and 21% for 1957 males compared to 34% for 1974 males. Also, preferences for rural and open country increased with each successive interview of the 1957 seniors so that in 1975 44% of the males (versus 21% in 1957) and 37% of the females (versus 11% in 1957) stated this preference. A similar change occurred among the 1968 graduates. These Michigan data are consistent with results from a series of surveys from 1966 to 1977 of high school students in Texas, Georgia, and South Carolina. In this six-year period there was a definite shift in preferences toward living in rural areas among both blacks and whites (Cosby and Howard).

Are Migrants Following Their Preferences?

The Michigan study also examined the correspondence between original preferences and locations of respondents when they were reinterviewed. The authors report increased congruence. Fifty-nine percent of the 1957 seniors were living in their originally preferred location seven years later. By 1975, 68% were living in accordance with their preferences. Other results in this study show that among those who originally preferred an urban location and achieved it, nearly half changed to holding a rural preference. In sharp contrast, however, fewer than 8% of those who originally preferred a rural location and achieved it changed to holding an urban preference.

The authors conclude that the increase in rural population growth, at least in northern Michigan, is partly attributable to greater rural preferences among rural youth and that part of the increased immigration to rural areas may be the result of changes in preferences of people who previously migrated from rural to urban areas.

The only longitudinal study of a more general population which has measured original preference and subsequent migration is DeJong and Sell's survey of 1,096 Pennsylvania households in 1974 with the follow-up interview a year later. Since only 14% of all movers achieved their residential preference by moving the authors concluded that preferences had little relationship to actual population dispersal behavior. However, their analysis had two major limitations. One was the very short time period between the original survey and the follow-up. The other limitation was the inclusion of local intra-community moves in the analysis. Since the reasons for local mobility (a major factor being housing size and quality) often differ from those leading to inter-community migration, Fredrickson et al., have reanalyzed DeJong and Sell's data, excluding local moves. They found that 79% of the inter-community movers had gone in the direction of their preferences. Neither the Michigan nor Pennsylvania surveys are without limitations, but both suggest that people are acting on their preferences.

Searching for an Improved Quality of Life

Presumably, people who state a rural preference are seeking to improve their quality of life in some way. Several studies have attempted to ascertain the community attributes that are being sought. Data reported by Fuguitt and Zuiches suggest that people who state a rural preference may hold a higher priority for certain community attributes than those who state an urban preference. When asked to indicate whether each of ten community attributes were a reason for their preference, those with rural preferences were substantially more likely to mention these reasons: less crime; quality of air and water; better for children; and lower cost of living. Respondents holding urban preferences were substantially more likely to give these reasons for their choice: better jobs, higher wages, and contacts with a variety of people. The remaining reasons were mentioned only slightly more often by respondents holding rural preferences: recreation or culture, near family or friends, and better schools.

In a 1971 Washington State survey respondents were asked to indicate whether they felt

Table 1. Residential Preferences of Metro (SMSA) Residents versus Percentage that Believe Life is Best in Metro Places for Selected Quality of Life Indicators

	Believe Life is Best in Metro Places	
Quality of Life Items	Prefer to Stay Metro Residence (% of 783)	Prefer Move to Nonmetro Residence (% of 454)
1. Availability of jobs	94.8	79.9
2. Recreation/entertainment opportunities	86.4	53.0
3. Adequacy of medical care	87.1	58.1
4. Lowest costs for food and services	74.0	49.2
5. Equality of opportunity for all residents	69.4	47.4
6. Lowest costs for public services	62.6	38.5
7. Adequacy of public education	71.2	31.3
8. Adequacy of police protection	61.6	27.5
9. Protection of freedom and privacy	51.5	13.6
10. Quality of religious life	34.7	14.1
11. General satisfaction of residents	37.0	7.4
12. Place in which to raise children	40.3	5.3
13. General mental health of residents	29.7	9.7
14. Respect for law and order	20.9	8.4
15. Amount of voice residents have in deciding community affairs	18.0	7.4
16. Community spirit and pride	18.3	4.4
17. Friendliness of people to one another	13.2	3.9
18. Absence of illegal drug use	9.8	5.7

Source: Adapted from Dillman and Dobash, p. 23.

the quality of life for eighteen attributes would be better in metro or nonmetro communities (Dillman and Dobash).

First, those who prefer rural areas were less likely on every item to perceive that life was best in metro communities. Secondly, the availability of good jobs stands out as the one item on which there was very strong consensus that the quality of life was better in metro areas. Further, a majority of those with rural preferences felt that metro areas were best on only three items compared to nine items for those expressing an urban preference. There were eleven items on which a majority of both categories of respondents indicated that life was best in nonmetro areas, but it can be seen that all of these items reflect the more intangible qualities of community life, e.g., respect for law and order and friendliness of people to one another.

Carpenter (1975) has presented further insight into how the desire for certain community attributes may relate to preferences for rural living. He reports that Arizona residents who preferred metro size communities were significantly more likely to deem a wide variety of stores and businesses, cultural opportunities, and opportunities for eating out as "essential" in the community where they choose to live. Those who preferred nonmetro living were significantly more likely to deem low levels of pollution, more privacy, and more outdoor recreational opportunities as essential.

Together, the data from these surveys suggest that those who prefer rural living may be looking for different attributes in their communities. They are also more likely to believe these attributes are in abundant supply in rural communities.

These respondents' views of rural places and their chances of finding satisfaction may be realistic, judging from quality of life surveys of current rural residents. National surveys have shown that residents of smaller communities are less satisfied with many community services than the residents of all but the largest cities. However, on the whole, rural residents are much more satisfied with their communities. Elsewhere I have suggested as a reason for this phenomenon that rural people weight the less tangible community qualities (e.g., items such as 9–18 in table 1) more heavily than the quality of specific services when evaluating their communities (Dillman and Tremblay).

Whether such quality of life motivations outweigh job considerations in migration deci-

sions has been examined by Williams and Sofranko. Their sample survey of 708 people who had migrated sometime since 1970 to one of the 75 high immigration (greater than 10% since 1970) nonmetro counties in ten North Central Region states led them to this conclusion:

> . . . The findings are consistent with the argument that migration from metropolitan to nonmetropolitan areas is, as reported by migrants, substantially a function of the unattractiveness of urban areas and the relative attractiveness of more rural areas, and that it is based more on environmental factors than on employment. (p. 247)

Williams and Sofranko base their conclusion on results of a meticulous coding and analysis of responses to questions about reasons respondents gave for leaving their previous metro residence and selecting their nonmetro location. Employment related reasons were offered by only 24% of the respondents. Other reasons mentioned included ties to area of destination (7%), environmental "push" factors (26%), environmental "pull" factors (14%), retirement (17%), and other reasons (11%). In sharp contrast, 46% of the people who moved from other nonmetro locations to these counties offered employment-related reasons for their move. This figure is much closer to data from a national housing survey that showed 47% of the people who moved throughout the United States between 1974 and 1976 gave job related reasons (Long and Hansen, 1978).

Williams and Sofranko also report that those who move for environmental reasons were no more likely to experience a drop in income than those who moved for employment-related reasons; however, nearly twice as many (42% versus 22%) of those that moved for job reasons were earning more money at the time of the survey. The authors' overall conclusion is that migrants tend to view their behavior in terms of the relative merits of rural versus urban living, and they conclude:

> These migrants, then, are different from those in national surveys not so much as a function of moving for environmental-amenity type reasons to the exclusion of employment considerations, but rather as a function of the fact that quality of life kinds of considerations seem to rank higher in their perceived causal structure. (p. 254)

Conclusion

To conclude, from the available evidence, that residential preferences for a rural location are a cause of the population turnaround would be seen by many as tantamount to declaring "guilt by association." The population turnaround is a very recent phenomenon, and not enough time has passed for the needed longitudinal research to have been conducted. Further, the research designs needed to confirm or deny the importance of preferences are neither simple nor inexpensive to implement. However, the evidence suggesting that residential preferences are influencing migration decisions is such that it is far less tenable to assert that residential preferences have nothing to do with the turnaround. To do so would require us to ignore all past research on preferences.

The available evidence clearly shows that Americans prefer, other things equal, to live in more rural locations than where they presently live. The imposition of severe income and commuting constraints diminishes, but by no means eliminates, interest in rural living. Other research indicates rural preferences have been increasing during the past decade and that some Americans have been able to follow their preferences. Still other research shows that people who want to live in rural places are looking for community features that are likely to be found there; and, recent migrants from metro to nonmetro counties are more likely to state environmental reasons than job-related reasons for having moved to their new location. But the strongest evidence that residential preferences are contributing to the turnaround, is not the results of any one study; instead it is the striking consistency among the results from all studies.

Because I am not an economist I cannot suggest how residential preference concepts can be incorporated into economic models for explaining migration. However, I would urge that ways be found to do that, just as I urge my own colleagues who have produced much of the residential preference literature to find ways of incorporating economic influences into their own migration models. The turnaround seems to be a product of a number of factors which act with and through one another, only one of which is preferences. It would seem that whether we succeed in understanding the causal structure of the re-

surgence of growth in rural America will depend upon how well we are able to influence one another's research.

Modeling Rural Growth

Clark Edwards

Rural economic growth has been in and out of the spotlight as a public issue. Sometimes the concern is how to spur lagging development. Sometimes it is how to limit an unbalanced surge. Other times interest lags and the issue is neglected. When the issue is in the spotlight, there are always ready answers at hand to the question, "What to do?" During the 1960s we often heard: "Stop rural outmigration or reverse it!" Toward this end, we made loans and grants, trained workers, and located firms. The answer by some persons in areas which were growing too fast during the early 1970s was to put up a sign to the effect that "this is a nice place to visit but we don't want you to live here."

Policy makers have identified the issue. And they have many ready answers. What they are frequently missing are the economic reasons which relate the answers to the issues. That is where we, as researchers in agricultural economics, come in: we can help provide the kind of understanding of the issues that comes from research, and which serves as a basis for policy prescription. The point of this paper is that, although we have been performing this function, we are not doing it as well as we might. Our research provides helpful descriptions and useful projections, but our models generally are not reliable for predicting impacts or for calling turns.

This paper addresses three obstacles to modeling rural growth: models, data, and theory. Some of the obstacles are inherent in the way we approach the modeling process; some are attributed to limitations of available data; and others stem from failure to incorporate relevant theory.

Models

The idea of economic modeling brings to many minds visions of mystifying mathematics, dreary data, and cold computers. Of course not all models are mathematical, empirical, and computerized. But let the image stand—let us talk about that kind of model. One important obstacle to building models is that many people simply oppose them. And their grounds for opposition have some validity. They say, for example, that one cannot capture the things that really count in economic progress—the quality of life and a sense of well-being—in a numerical measure or in a computerized system of equations. To many, getting a region to grow is a practical problem unrelated to mathematics. Certainly, negotiations by community leaders to locate a plant employing 500 persons is not a problem in mathematics. And secondary employment induced as a consequence of locating this plant can be calculated with simple counting methods that can hardly be considered mathematical.

"If such problems can be understood in plain English," so the question often goes, "why do we need to treat them mathematically?" The wish to have our models explained in plain language is a reasonable one. It is hard for a researcher to explain that a simple translation of a mathematical model into English is not possible. The mathematical and computerized model is not merely another language, it is also a logical system. The analogy might be that the model translates not into a sequence of simple sentences, but into a syllogism. The model imposes a system of organized reasoning. The reasoning can be understood from ordinary language if one makes a special effort to follow it. But most of us do not think in perfect syllogisms, and the reasoning is likely to be lost when each equation is translated into language.

Maybe if we knew enough about economic growth we would not need to turn to mathematical and computerized models to evaluate alternative policies; we would know by experience what the impacts of each policy would be. But most of us do not know that much. So we make up for it by using models to organize our thoughts and to reason out the

---

Clark Edwards is a senior economist with the Economics, Statistics, and Cooperatives Service, U.S. Department of Agriculture.

likely consequences—either quantitatively or qualitatively—of alternative actions. The gains from organized reasoning need to be compared with costs such as that of reducing to numerical measures certain human values that are properly understood as not numerically measurable.

Let us assume that the trade-off favors modeling and inquire into other obstacles to modeling rural growth that are evident in published research.

Cause or Effect

One common empirical method to identify factors affecting area growth is to sort the data according to the intensity of the problem and then note associated factors. For example, we can rank the 3,000 counties according to rate of growth in population and then notice that slower-growing counties exhibit, say, a lower average level of education than faster growing counties. The beauty of this method is that it always works. There is always a group of slower-growing counties, and such a group can always be found to have certain distinguishing characteristics. This is what makes the method descriptively useful. However, it is not analytically useful to sort on the effect and then notice the cause. If we seek to explain, we should sort on the cause and notice the effect. In this example, we should sort on level of education and test whether counties with lower levels of education are significantly slower-growing.

One reason we persist in doing the thing backwards may be that it requires less thought; in one pass on the computer one may, mindlessly, catch several "explanatory factors" that are statistically significant. To order the data causally, one must think ahead and either do more detailed cross-tabulations or make more computer runs. Another reason may be that it is easier to explain anomalies when we do the thing backwards; it is easier to explain as an exception to the rule a slower growing county with a high education level than a county with a low education level which grew rapidly.

Recent statistical tests of causality, based on an operational definition of the concept, may help us to sort out, at least in a statistical sense, what is cause and what is effect in economic growth, and thereby improve our ability to model causal structures.

Simple or Complex

Many rural growth models are exceedingly detailed and complex. The driving idea behind them appears to be to build a model comprehensive enough to be capable of answering any question which might arise. Of course there are certain economies in building models which are large enough and general enough to warrant repeated use. But there is a tendency to go too far and build models which bog down in their own mathematical complexity and their detailed data requirements. Some detailed models, such as input-output, have large data requirements but follow simple logic; they are therefore easy to understand although expensive to construct. Others, such as simulation, may have simple data requirements but follow complex logical relationships that are exceedingly difficult for a user to understand. One ridiculous equation inadvertently embedded in a large simulation model might never be discovered either by the builder or the user. The high probability of such accidents leaves one concerned about building models more complex than necessary.

At the other extreme, some of our models are entirely too simple to capture the complexities and the many facets of economic growth. Almost all single-equation models are suspect because they cannot allow for simultaneous determination of growth variables or for feedback and reciprocal relationships.

Between the extremes of too big and too small, there must be a size which is just right. One approach to determining model size is this: start with the problem you seek to explain, say rural economic growth, and write down the variables with which you intend to explain it, say population, income, and employment. If it requires three variables to describe the situation, then a minimum of three equations is needed; if the results of a model are to be summarized by these three variables, then fifty or a hundred equations are far too many.

But there is a good argument for using more than three. If you can explain population with one equation, you can usually do it better by explaining a few of its major components with separate equations. For example, two equations, one for working age people and another for dependent oldsters and youngsters, can be expected to give better results than a single population equation. Using this rule, a minimum of six behavioral equations will be

needed for explaining two categories each for population, income, and employment. And three identity equations will be needed to form the totals of each variable. A nine-equation model, then, can adequately explain the stated problem. And a model of ninety equations is not likely to do any better job than one of nine or so in explaining the three variables of concern. Worse, unless a priori totals are incorporated to constrain the ninety equations and keep the results "in the ball park," the larger model is likely to behave less well than the smaller one.

Some obstacles to modeling rural growth would be overcome if we gave more thought to (*a*) the problem the model is intended to solve, (*b*) the variables actually needed to describe the problem, and (*c*) the minimum number of equations needed to adequately explain the essential variables.

Seek Answers or Assume Them

Many models assume answers to questions to which their prospective users are seeking answers. For example, a rural growth model may assume a target population, and perhaps a target level of income, for the year 1990, and then examine the industry mix and resources that would be required to realize the target. There is nothing wrong, of course, in building such models; they are useful. The error arises when the user (and sometimes even the model builder) classifies such a model as a growth model. If a model assumes the level of growth as an input, it is not useful for explaining growth.

Describe or Explain

Many of our mathematical, empirical, computerized models are thought to explain growth when they really only describe it. Descriptions are useful, but they are not explanatory. Stages of growth models describe various stages through which a region is expected to pass without explaining how the region moves from one stage to the next. Shift share models measure the extent to which unique regional factors contributed to growth without identifying what the unique factors were or how they contributed. Projections models describe the likely future based on recent trends. Some of the methods of projection are complex and ingenious but, analytically, they have no more explanatory value than linear extrapolations. Descriptive models can influence decisions by policy makers. But they do not constitute models of growth. They are not capable of forecasting a turnaround. Nor are they capable of being used for evaluating the consequences of policy intervention or for assessing alternative futures.

Data

Major gaps exist in the data base for rural growth models. There are several causes of these gaps. Some data which have been available for a long time, such as for farm employment, are considered obsolete because demands on the data have changed while the supply has not. Some series we would like to use, such as adequate measures of underemployment or hidden unemployment, are not supplied. The reporting units on which data are made available often do not correspond to the analytic units in our models. For example, the data may pertain to establishments (place of work) whereas we want to model families (place of residence). The time detail is often wrong. We have one census for 1970 and will have another in 1980. But families in the 1980 census will not be linked to families in the 1970 census for longitudinal information. And comparable information for intercensal years will not be available to study the turnaround in rural growth exhibited during the late 1960s and early 1970s.

Rurality is a geographic concept and lack of geographic detail in published data is probably the most important source of data gaps with respect to rural growth analysis. Even though many of the geographically specific data needed are collected in various censuses and surveys, this gap continues because such data are generally not released by the data collection agency in sufficient geographic detail.

Data are relatively more or less reliable depending on the number of observations underlying a reported average and on the accuracy with which released data are edited. Several data gaps result from the way the present data system has been conceptualized. For example, much of the industry detail available for rural growth models describes product markets, whereas a growth model may need detail on factor markets instead. Because of increased institutional size, economies of scale, and specialization, the separation of data suppliers from data users has created data

gaps which could be narrowed by means of better communications among institutions.

Some data gaps are formidable—their resolution would not be cost-effective and we must learn to live with them. Others can be narrowed at nominal (virtually zero) cost by making small changes in the way some data are collected and reported. Researchers all too often adapt their models to accommodate existing data series. Sometimes a far better solution would be to become more aggressive about insisting that needed data become available.

Some ingenious procedures are being developed by researchers for getting around data gaps without waiting for perfect data and without sacrificing the logical content of their models. Let me give two examples: one is to use primary data insofar as they are available or considered absolutely essential, and to use inexpensive and readily available secondary data sources as default options when primary data are missing. Another is to merge two files (which together have the required information, but which separately do not) into a synthetic, comprehensive file. The direct benefit of these procedures is to maintain operational models. A fringe benefit is that the results can be used to estimate the benefits that would likely follow from collection of more primary information and more comprehensive data sets.

Theory

Theory allows us to explain economic phenomena. To understand and influence the course of rural economic growth, economists first need a growth theory. Alternative futures can be examined, causes can be understood, and intelligent choices can be made. At one extreme stand those whom William James called the tender-minded; they seem to believe that pure theory alone is all that is required to solve problems of economic growth. At the opposite extreme stand those whom he called the tough-minded; they seem to believe that hard facts alone are required. As for the rest of us, we seek to ground empirical models in appropriate theory. The theories we need are scattered through economic literature. Until these have been merged into a single, comprehensive theory, modelers must chose eclectically. In such an environment, the likelihood that any single model will incorporate all relevant theories must be very low indeed.

The various growth theories can be, and have been, collected and discussed in ordinary language. And the theories have influenced practitioners in community development. But integrating them all into a consistent set of equations which function as a growth model is exceedingly difficult. Obstacles to incorporating some of these disparate bases for growth into a single, comprehensive model are the subject of the remainder of this paper.

Increasing Resource Availabilities and Improving Technology

Neoclassical microeconomic theory incorporates two bases for growth. An increase in output results either from using more resources or else from obtaining more output per unit of resource. These two microeconomic ideas so completely dominate our thoughts that when they are presented in the growth chapters toward the back of our macroeconomics textbooks no one appears to notice a contradiction: models which assume that all savings are invested, that supply creates its own demand, that there is full employment, and that money is simply a veil over the economy are introduced in the back of a book dedicated to contradicting these assumptions. Incorporating resources and technology as bases for growth is relatively easy and is frequently done. So let us assume we have a growth model incorporating these two ideas and inquire into the difficulties encountered in adding other bases for growth.

Expanding Markets

The idea that aggregate demand is a basis for growth has three roots. Classical ideas about the importance of foreign trade embrace the concept. And Keynesian theories center on the importance of demand. Economic base theory is at times interpreted as a simplified, one-sided version of either of the above, but is at other times considered to have an independent origin. As far as construction of economic growth models is concerned, economic base theory and Keynesian macroeconomic theory are very much alike. Each model is driven by demand rather than by the neoclassical bases for growth—resources and technology. And each incorporates multipliers

which measure secondary impacts. Models for rural growth which are driven by demand abound. The obstacle to growth modeling of concern here is encountered when efforts are made to merge the neoclassical and the Keynesian ideas into a single model. The ideas are seen to be, on the face of it, incompatible. Let me illustrate how this is so.

Consider two ways that an input-output matrix can be used. Using Keynesian logic, we can start with a menu of final demands and inquire into the industry mix and resources required to produce it. If there were idle resources, the economy would grow as demand grew. On the other hand, using neoclassical logic, we can start with a menu of resource availabilities, incorporate the input-output matrix into a linear programming format, and inquire into the industry mix that would maximize final product. In this case, the economy would grow as resource availabilities and technology grew. Now ask yourself how to get a model to behave both ways at once. The answer lies in building in some kind of a flip-flop mechanism so that causation flows in one direction through the input-output matrix when resources are slack and in the opposite direction when they are fully employed. If some resources are slack while others are fully employed, it gets even more complicated. So let us simplify the problem further.

Consider a growing economy which can be described by two variables: an input and an output. There are three equations: a demand for output, a supply of input, and a production function. This system is overidentified: three equations for two variables. The neoclassical solution is tantamount to assuming that the demand relation is an inequality—that there is an effective demand for at least as much as will be produced when resources are fully employed. This is accomplished by Say's Law. The Keynesian solution is tantamount to assuming that the supply relation is an inequality—that production capacity is adequate to produce at least as much as will clear the market. That is, only two equalities are needed to determine the system's growth—one pair if demand is the basis for growth, the other if resource availability and technology are the bases. A consistent clue as to which is which is in the production function. If the model is demand driven, the logic flows through this function from output to input. If the model is supply driven, the logic flows in the opposite direction, from input to output.

In a comprehensive model, there must be inequalities describing demand and supply and a flip-flop mechanism describing the direction of flow of logic through the production function. One obstacle to modeling rural growth is to figure out how to make our models consistently incorporate both Keynesian ideas of demand and neoclassical ideas of supply in a comprehensive and consistent system of equations.

Conquering Space

Rurality is a geographical concept, yet many rural growth models fail to incorporate spatial relationships. We should be able to display the results of a rural growth model on a map. The obstacle here is not only redesigning the logic among variables already in the model as was required above, but also to incorporate overlooked variables. There are four categories of flows over space to examine: people (migration and commuting), goods (imports and exports), capital (balance of trade), and ideas (diffusion of information). Other variables already in the model must be identified by location. The logic of the growth models must be redesigned to incorporate opposing forces which induce centralization and decentralization. Centralizing forces are identified by central place theory. They include agglomerative efficiencies and transportation costs. Decentralizing forces include rent gradients and von Thunen rings. Spatial bases for growth are ignored in most of our rural growth models.

Institution Building

Econometric models have tended to capture short-run phenomena by assuming that needed institutional arrangements were in place. Longer-run issues, which were harder to model, were abandoned to the institutional economists who knew that institutional change does matter and knew how to account for it in economic analysis. Now that we have learned to build dynamic models that cover economic change over time, the importance of integrating institutional economics with econometrics is reemphasized. This situation is giving rise to a new breed of institutional economists who are trying to capture the essence of institutional relationships as equations in econometric models.

Two aspects of institutions are fairly easy to capture. First, one function of an institution is

to assess ends or goals. These goals can be written as equations—maximizing gross regional product, minimizing unemployment, and improving the distribution of income, for examples. Institutions help to resolve conflicts among goals; models can be used to exhibit trade-off possibilities among competing goals.

Second, institutions promulgate behavioral rules. These rules can be written as equations. Some examples, such as tax laws and price support levels, are commonly incorporated and recognized as institutional constraints. With imagination, we can capture more institutional rules, for examples, zoning laws, water rights, and licensing requirements.

Other aspects of institution building are harder to capture. Institutions are groups of people acting toward certain ends. How do you capture in an equation a group of area planners acting to promote regional growth? If they change a zoning law or an objective, we can change an equation. But this is ad hoc and likely to miss the essence of a planning organization. Some of it might be captured with a zero-one variable which opens certain synapses among economic variables when the institution is present and closes them in its absence.

Each of the several bases for growth discussed above—resources, technology, markets, space, and institutions—can be, and have been, incorporated in rural growth models. Many models incorporate two or three. A few contain four. I have yet to see one that satisfactorily reflects all five. And I think there is good reason for our failure to do so—it is not easy. But I see it as a challenge which we as a profession need to work on.

Conclusion

A number of models of rural growth have been built and used by agricultural economists. Clients use the results. There is a demand for more and better policy guidance on strategies for rural growth. I have given my reasons for thinking that we are not modeling rural growth as well as we might and that, consequently, we are not providing, as well as we might, the economic reasons which connect policy prescriptions to rural economic issues. I have offered my suggestions about how we, as researchers, can improve our rural growth models. The ideas we need are lying about in the literature—but we have not put them all together yet.

Rural Employment and Rural-Urban Population Shifts: Discussion

Brady J. Deaton

The topic under discussion directs our attention to a major demographic shift unparalleled in modern history. We should note that Western Europe, Canada, and several developing countries are also attempting to deal with urban-to-rural migration and/or declining rates of rural-to-urban movements. So, we are observing a cross-cultural phenomenon of migratory decision making which is constrained by economic realities.

Edward's paper addresses the applicability of economic models to the problems associated with rural employment and population shifts. His assertion that "we should sort on the cause and notice the effect" assumes that we have identified the problem, specified a conceptual model, and can properly measure the relationship between cause and effect. In reality, we often fail in one or more of these efforts. I prefer a problem-oriented focus which forces us to examine alternative dimensions of both cause and effect. From Dillman's paper, I infer that the persistent value placed on rural over urban amenities has finally been recognized by corporate decision makers. Consequently, an increasing number of manufacturing plants are located in rural areas where production costs are lower, workers happier, and profits higher. By way of division of labor, I will be directing the balance of my comments to Hoch's paper.

Hoch's topic was challenging, his concluding hypothesis stimulating, but his approach may be most useful in pointing to some limitations of data and modeling. I was frustrated in trying to come to grips with the theoretical underpinnings of his approach. While his paper reflects intimate familiarity with the broader issues, I fear that sufficient guidelines have not been provided to enable the reader to identify effectively and evaluate the basic information flowing from his analysis.

Hoch recognizes that wage differences among locations may arise from diverse causes, including (*a*) heterogeneity, (*b*) disequilibrium, and (*c*) compensatory payments. His analysis of each cause will be briefly discussed.

Heterogeneity: Hoch defines compensatory payments as wage differences which arise from the disutility associated with larger size communities. That is, compensatory payments are the residual wage after heterogeneity and disequilibrium are accounted for. In order to measure the relationship between compensatory payments and population size, heterogeneity is controlled only by selecting two groups in the work force, female clerical workers and farm laborers. A strong argument could be made that these groups are also quite heterogeneous. A dairy farm worker may not represent the same set of skills and wages as either a tobacco cutter or a pea picker.

Nevertheless, if this selection is accepted, then conclusions should apply only to female clerical workers and/or farm workers. Yet, Hoch reaches rather profound conclusions for all rural workers and rural communities and goes well beyond the strength of his data in the process. For example, he asserts that "the wage-population size relation appears to hold for rural occupations and for nonmetropolitan settlements, as well as for their urban and metropolitan counterparts." At another point he concludes that "minimum disamenities occur in the 10–25 thousand range, making that population level 'optimal' in terms of preferences." While Hoch warns that this hypothesis needs intensive testing, his conclusions are not warranted by the limited data analysis.

Disequilibrium: This topic is addressed indirectly by observing a downtrend (16% to 13% per order of population magnitude) since 1972 in the size of the regression coefficient of population associated with deflated per capita incomes. Hoch concludes that "people in smaller places currently are receiving more

Brady J. Deaton is an associate professor, Department of Agricultural Economics, Virginia Polytechnic Institute and State University.

than is needed to keep everyone in their place, so there is net migration from larger to smaller places." This line of thinking is all based on the implicit notion that observed wage differentials are primarily due to compensatory payments.

On the other hand, the observed changes in regression coefficients could be explained by other more theoretically appealing factors. For example, product prices for most manufactured goods are probably relatively homogenous across rural and urban points of origin. Therefore, the ability of urban manufacturing plants to provide higher compensatory wage payments is quite restricted by competing products produced at lower cost in rural areas. Urban wage flexibility decreases as a larger proportion of manufacturing production originates in rural communities where money wages are lower while product prices are spatially constant. At the same time, an urban-to-rural labor flow places increased wage pressure on urban plants.

The continuing decentralization of manufacturing plants into rural areas strengthens this interpretation. A continuing set of new equilibrium conditions are being established by the changing economic environment. There are no "good old days" of equilibrium around 1972 conditions that we should be yearning for or expect to see again. Wage differentials will probably continue to decline as both capital and labor flows adjust, along with changing technology, preferences, and nonpecuniary diseconomies of scale. The pervasiveness of these dynamic conditions have not been addressed adequately by Hoch. Simply stated, compensatory payments may be part of the reasons for the observed differentials, but are certainly not the full picture. Hoch has not shown us how important they are, nor given any idea of their magnitude.

Compensatory payments: I agree with Hoch that "people will tend to shift to places offering lower money wages but equal real wages, relative to alternative locations, since this will increase real disposable income." Migration streams, particularly urban-to-rural streams, are composed of a complex mix of those who experience income increases as a result of the move; those who are rejected by, or cannot adjust to, the urban work environment; and those who give up higher incomes to enjoy the nonpecuniary benefits of rural life (Deaton and Anschel). Hoch's analysis is primarily concerned with the latter, though he does not draw these distinctions. This issue has profound implications for rural development if it is properly measured and interpreted within a theoretical framework that helps provide direction to our thinking.

For example, I could see the notion of compensatory differentials being linked directly with Kaldor's theory of cumulative causation where the efficiency wage (money wage divided by a productivity index) declines as productivity increases and propels the local economy along an upward growth path. Compensatory wages suggest that the money wage will not be equal as Kaldor assumed, but will be lower for rural areas. The combination of relatively lower money wages and relatively greater productivity provides a "super accelerator" for rural community growth which is consistent with conditions associated with the population turnaround. This approach would provide a foundation for assessing the interrelationship between money and real wages and their linkages with varying productivity levels.

In conclusion, Hoch's work illustrates how far we are from the integrated-modeling approach that concerned Edwards. The lack of a fully integrated model, however, does not keep us from rigorously applying economic concepts and statistical techniques to important rural development problems. The theoretical links between a number of observed effects and reasonable causes may not be amenable to easy measurement even if they are conceptually distinct. However, we can all benefit by reviewing Bonnen's insistence on the rigorous process that transforms mere data into meaningful information. We have seen some of each in this session and should be challenged to apply more rigorous methodological procedures to this issue.

Rural Employment and Rural-Urban Population Shifts: Discussion

Ron E. Shaffer

The three papers in this series focus on why we have had a rural shift in population growth or "rural turnaround." The Hoch paper suggests that the movement of people into rural areas is a rational choice based on economic criteria, even though the rationality may not be readily apparent. The Dillman paper indicates that individuals' nonmonetarily motivated residential location preferences are a very important force in settlement patterns. These preferences may be contradictory to prevailing economic signals. The Edwards paper discusses our conceptual tool-kits to understand and analyze these types of trends, and the obstacles to testing empirically these conceptual ideas.

The papers fail to address what effect the gas shortage and gas prices will have on the marginal rural in-migrant. How strong is the desire to live in a bucolic setting? How many people remaining in metro areas are going to move to adjacent areas or even nearby exurban developments? They did not move before under more favorable conditions. With higher gas prices and unavailability, will they fill the metro out-migration streams? Will jobs follow people to rural areas because the energy cost to society of smaller scattered production units is less than that for concentrated production sites? I believe these critical and still largely unanswered questions will affect the continuation of the rural turnaround. Yet, these papers utilize now questionable historical data to hint at the future trends.

Hoch suggests that comparisons of income differentials require consideration of the following three forces: first, the heterogeneity of the resource base and the economic structure of the areas compared; second, the presence or absence of compensating payments for market- and nonmarket-related cost-of-living adjustments; third, that differentials may signal market disequilibrium and imply a need for resource movement. After reading the paper, I am still convinced that these forces need to be considered, but the author has failed to give me much insight about which has been, and is likely to continue to be, a dominant force in the rural turnaround.

Hoch suggests that people will continue to move to rural areas and accept lower money income because inflation-triggered tax bracket jumping will, in effect, reduce their disposable income. This idea deserves some study, although I believe the effect is minimal. I sense that people are moving to rural areas and accepting lower wages not because of income tax burdens or an implicit income tax windfall, but because of the nonmonetary factors that increase their real income as Dillman's paper suggests.

Dillman shares a compilation of factors that have been suggested as being causal to the population turnaround. Some of these factors are quite likely to continue into the future, but others are not or their influence may even be reversed. Let me mention a few of the specific factors likely to change. Number 7: Increased enrollment in nonmetropolitan colleges and universities is likely to be less of a force as the age structure of our population changes. An additional dampening influence is the budgetary constraints facing higher education. Number 8: The growth of state government is likely to be less of a force as the "Proposition 13" syndrome is felt either explicitly or implicitly in governmental activities. Number 12: More long distance commuting may be completely reversed, depending on how people react to the cost of gas or even its total unavailability. Will we make adjustments through vanpooling and light-density mass transit systems or will there be a movement back into more concentrated settlement patterns? Number 15: The lower cost of living in rural areas may disappear as the cost of energy and housing approach that present in many urban areas. Number 16: Lower crime rates may also be a historical artifact, given the current concern of

---

Ron Shaffer is an associate professor in the Department of Agricultural Economics, University of Wisconsin-Madison.

local officials and citizens in many rural areas about the dramatic increase in crime in those areas.

Probably the most interesting point in the Dillman paper was the different motivations for moving to nonmetro areas and among nonmetro areas. The movement to nonmetro areas is nonemployment-oriented, somewhat in agreement with Hoch's conclusions. However, the movement among nonmetro areas was employment-oriented.

The alarming statistic about the movement of people back to smaller communities is their desire to live outside municipal boundaries. This holds long-run implications for land use, farming-residential use conflicts, and provision of municipal services.

The Edwards paper discusses our inability to incorporate the diversity of factors that affect rural economic growth into precise mathematical models. While I agree that we have been unable to generate precise, comprehensive, and mathematical models of rural economic growth phenomena, I believe we have made some significant advances. Our mathematical modeling abilities have not kept pace with the practitioners. Granted, practitioners have not been able to synthesize their ideas in journal articles, but if you listen closely to what they say, there is a realization of the comprehensive approach required.

The caution about labeling many of our projection and descriptive models as growth models is an issue that deserves attention by many in the profession.

There is much truth in the contention that we must be eclectic in our selection of tools and theories. While we have not been able to achieve a comprehensive community growth model, this does not mean that the rigor of the analysis is anything less for specific community situations. It may be that we need to remind people of the uses and limitations of our theories and caution them about the conditions that make their use appropriate or inappropriate. The synthesis of a comprehensive theory can remain as our long-run goal, and more appropriate use of existing theories and tools remain a legitimate short-run goal.

In summary, a careful reading of the papers reinforces the belief that while our understanding of the rural turnaround has improved, there are still substantial gaps in our knowledge. This is especially evident in the transferability of this knowledge into policy prescriptions.

Nutrition and Food Policy
(Sylvia Lane, University of California, Davis, Chairperson)

The Segments of the World Population at Nutritional Risk

Leonard Joy

I find it useful to distinguish four aspects of "the problem of malnutrition": (*a*) the existence of people currently malnourished, (*b*) the existence of people in situations which are characterized by an unacceptable risk of malnutrition, (*c*) trends and forces which increase the numbers at risk of malnutrition, and (*d*) lack of sensitivity and/or effective response of society to the above realities. The four corresponding tasks include: (*a*) the identification and treatment of the malnourished, (*b*) the reduction of the number of people exposed chronically to the risk of malnutrition, (*c*) reducing or offsetting those forces which make for increase in the numbers at risk of malnutrition, and (*d*) improving the sensitivity and responsiveness of society to nutritional deprivation. While I frequently use this fourfold breakdown, I am constantly reformulating it. The present version is not offered as in any way definitive. This paper discusses aspects (*b*) and (*c*), though its concern is strongly with (*d*), the lack of society's sensitivity and effective response.

Those Currently at Risk of Malnutrition

We conceivably might seek to identify all those individuals currently at risk of malnutrition. Indeed, some programs do just this. They use some criteria for determining who gets food stamps, or a ration card, or food for work. The criteria used typically include socioeconomic, demographic, or locational criteria which define categories of people believed to be in need and which provide tests of whether specific individuals are to be counted in the categories so defined. In practice, the criteria used are varied and situation specific. An answer to the question: "Who are the people at risk of malnutrition?" might therefore be in the form: "People who meet the following criteria. . . ." Or, "People in the following categories: . . . ."

But how do we discover what these categories are? As ever, we can make observations and develop theories using each to prompt, test, and refine the other. An interesting example of such a process and of its product is one that was carried out in Bangladesh (Currey). Here the attempt was made to identify administrative units (*thanas*) with a high famine risk. *Thanas* were assessed in terms of characteristics which can be seen to be either (*a*) risk of trauma (drought, flood, cyclone, and river erosion), or (*b*) characteristics which make for lack of resistance to trauma (population pressure, food supply deficit in normal years, lack of alternative employment, low crop yields, inaccessibility, and unreliable farm input supply system). Some *thanas* are shown to be exposed to more than one class of risk and to have several characteristics which make them nonresistant to shocks or less able to recover from them. The application of this classification shows a varied pattern of constellations of problems calling for equally varied responses. What this classification does not do, however, is to identify which categories of people or households within each of the vulnerable *thanas* are vulnerable. Nor does it, therefore, reveal whether there is a need for a variety of responses to meet specific classes of individual or household situations. Also, it does not reveal that there are some people at risk even in *thanas* which are not, overall, classified as vulnerable.

Leonard Joy is a visiting professor of food and nutrition policy analysis in the Department of Nutritional Sciences at the University of California, Berkeley.

The author would like to express his appreciation to Irma Adelman and Ritva Kaje for the valued comments on this paper.

Clearly, the basis chosen for classification determines whose risks are attended to and whose neglected, which categories of risk are differentiated, and which are lumped together. Clearly, too, the basis for categorization may be operationally congruent with some administrative and organizational patterns and incongruent with others. What this implies is that we need to design classifications which relate to specific administrative structures and to management rules designed for responding to actual or threatened traumas.

In general, however, our response to the existence of at-risk populations will take the form of (*a*) measures to reduce the risk of the trauma to which they are exposed (drought, flood, disease, unemployment, fall in real incomes, etc.), (*b*) measures to make them less vulnerable (improve normal nutrition status, increase wealth and income, stabilize food supplies and prices at desirable levels, strengthen or augment social support mechanisms, crop insurance, etc.), and (*c*) measures to speed recovery (relief and rehabilitation measures). Thus, our tasks are: to determine the nature of the trauma faced by different people; to explore how the threat of trauma might best be reduced; to find ways of increasing people's capacity to withstand trauma; to design a system for responding appropriately and effectively to specific threats and experiences of trauma.

In reality, however, the method of inquiry commonly used in planning for food and nutrition goals does not encourage this. Typically, the focus of investigation and analysis is on nutrition status, the identification of specific nutritional disorders, and the quantification of their incidence and prevalence. This generally is attempted by means of sample surveys of total populations which relate anthropometric and biomedical observations to such demographic and socioeconomic data as family size, income, and environmental sanitation. However, these may not be efficient or even necessary data for understanding the risks to which people are exposed or for the design of appropriate action. Also, prior to the collection of data, we need information in a form which may not be readily processable. Especially, we need stories about people's conditions and how they got that way. We need to know what traumas threaten people and how people react to trauma. From this we might learn what might be done to prevent or mitigate the shocks which result in malnutrition. Different things might need to be done by or for different categories of people. In order to generalize and to design appropriate measures it may be important to know the incidence and prevalence of different categories of people and risks. Thus, surveys may be called for. But the sampling frames and content of surveys used as part of such an approach are likely to be very different from those of the conventional nutrition survey. Generally, too, they will also be designed after we have gained an understanding of what needs to be done rather than in order to gain such an understanding.

Trends in the Numbers at Risk

If we succeeded in identifying all those at risk and took steps to reduce their vulnerability, we might discover that the numbers of those "at risk" continued, nevertheless, to increase. In general there seems to be good reason to expect trend increases in the numbers of those at risk. In order to predict the numbers, and categories, of those who will in future be at risk we need to be able to conceptualize and analyze the system which generates people who are nutritionally at risk. We need to know not only what categories of people are at risk, but also what it is that puts people into these categories. Again, understanding requires both observation and theorizing. My own observations produce some repeated scenarios: families who have inherited, or will inherit, too little land on which to survive; landless families or sharecroppers displaced from reliable dependency on a landlord by a new technology or market opportunities or by the availability of cheap casual labor or by landlord's attempts to avoid land reform legislation; and rural or urban migrants, jobless and no longer able to rely on the support of their families or patrons in distant villages or to follow their families' previous way of life. It is among such people that malnutrition—both chronic and episodic—is especially to be found.

Such observations as these can be refined, tested, and used for theorizing to provide the basis for the design of action. What is needed is an effective conceptualization of the processes which generate economic and social displacement of the sort described above. (I use the word displacement because I am talking about people who cannot find a place in economy or society.) Attempting to build

models of the "displacement" process is a good way to check observation and analysis against each other. It is also, perhaps, essential to providing an understanding of where the behavior of the socioeconomic system might be modified to reduce the unwanted results.

Figure One illustrates a proposal for a system conceptualization of the processes that generate households which are unable to provide reliably the means of their own subsistence in the Machakos District of Kenya. (A comparable formulation conceived with North India in mind can be found in Joy and Payne.) This tentative formulation could be of value, even in its present form, as a presentation with which alternative system conceptualizations might be compared. It provides the basis for a dialectic to improve our understanding of those forces which are most important in generating malnutrition and of how we might intervene to modify their workings. It could also be quantified and used for computer simulation—either of the system as a whole or of some of its subsystems (e.g., land allocation mechanisms, the rates of creation of new households and the factors governing these, local/temporary casual labor migration, technological change, impact mechanisms, etc.). Whatever the level of quantification or complexity used, these simulation models are essentially nondisciplinary. They do not confine themselves to the questions or variables of any one discipline. They attempt to model systems which generate the phenomena that we wish to control. The systems thus modeled are defined by these phenomena and the state variables by which we choose to measure and observe them.

The choice of state variables is critical. (For a discussion of some models which do not use malnutrition as a state variable, and of their usefulness in policy making, see Joy, pp. 114–18.) It will be noticed that in the example shown here nutrition status is modeled directly. However, it might be appropriate instead to use "displacement" as the state variable defining the system to be modeled (or the assumption that "displacement" is a condition in which the risk of malnutrition is high). If this were done the concept of "displacement" would need to be defined by criteria that are observable, and tested for its relationship to malnutrition. The definition used would need to be specified to suit particular contexts and described by characteristics capable of quantification. These specification tasks should promote reflectiveness about the true nature of the concern which gives purpose to our modeling and about the performance criteria appropriate as the signals to which the management of social action should respond.

Apart from their general value in providing a systematic framework for analysis in the design of social action there are many particular applications of such modeling which could sharpen policy analysis. Models could be run to explore alternative possible scenarios, to learn how, and by what processes, possible events—controllable and uncontrollable—might affect these scenarios (for example, with reference to weather patterns, technological innovation, different levels of population growth, specific demographic changes such as delayed marriage, specific development projects, changes in customs and transactions modes, market forces, etc.). The special value of such modeling is in the understanding it provides about the factors important in determining malnutrition as an outcome of the system. This should greatly sharpen understanding of the sorts of action that will be relevant and effective in pursuing social goals. Moreover, publishing the scenarios that such models generate can stimulate debate about issues and help to improve the articulation of goals. If our concern is to improve society's sensitivity and response to malnutrition, as I think it should be, it is important that those whose actions it is intended to influence should be involved in discussions which are part of the process of model building. This is necessary especially to obtain credibility—to ensure that the realities perceived by decision makers are accounted for in modeling (Johnson). This does not mean involving administrators in the technicalities of model building (Swanson), nor does it mean that models should be no more complex than decision makers can comprehend. (Would that we ourselves could fully comprehend our own models.) The value and influence of a modeling project may not be determined by the rigor or polish of any report in which it culminates, nor by the quality of the analysis, or the "correctness" of its recommendations for policy, but rather by its impact as reflected by improvement in: (*a*) decision makers' articulation of purpose; (*b*) their conceptualization of the system which generates malnutrition (and how it might best be managed and stimulated to secure desired change by those with power, or potential power, to initiate action); and (*c*) the resulting

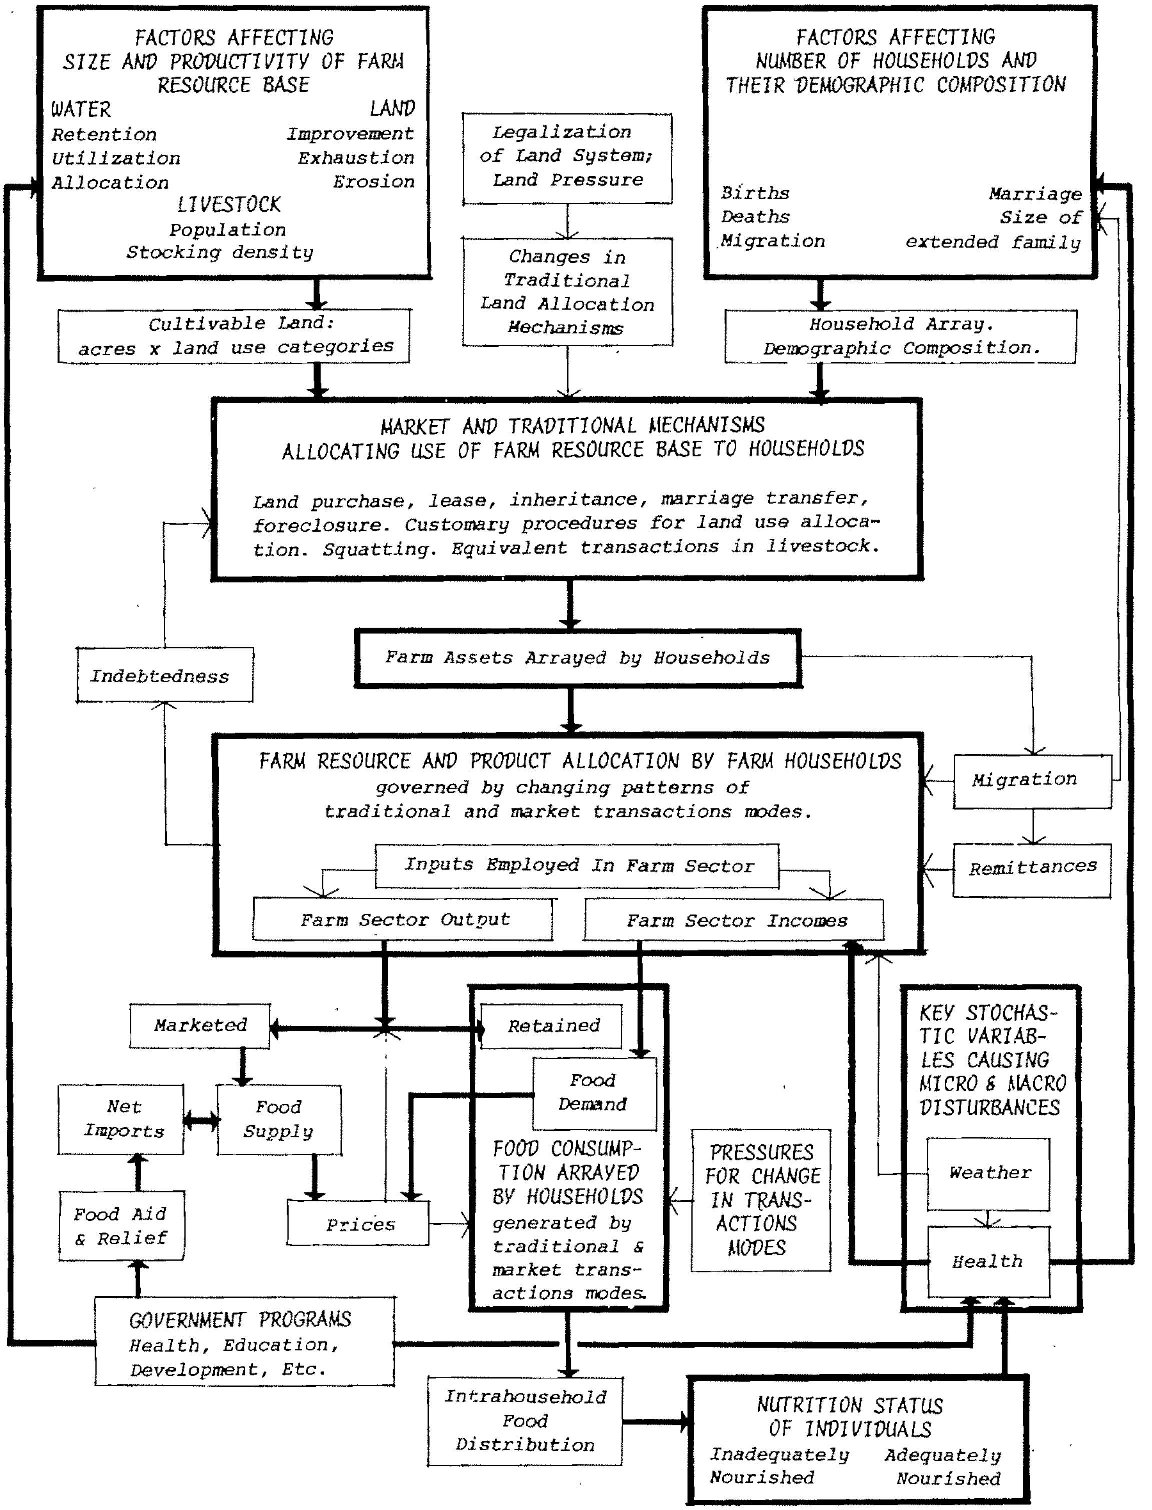

Figure 1. System governing nutrition status in Machakos District, Kenya

action and its effectiveness in securing attainment of desired goals.

Implications

An approach to the design of action to care for those currently at risk would start from an analysis of the capability of specific administrative systems in terms of their sensitivity to signals most relevant to warning of the imminence of trauma (flood, drought, unemployment) and of their ability to respond appropriately. This implies analysis of the risks faced by different groups and of their ability to withstand, and recover from, the shocks to which they are exposed. It implies the design of measures, including routinized administrative or community responses, to prevent, cushion, or in other ways reduce the impact of these shocks and of their threat. This is a significantly different approach from, say, that taken by the FAO, UNICEF, and WHO to "nutritional surveillance" (FAO/UNICEF/WHO). It is also different from that taken in the search for projects which "create employment" or "raise farmers' incomes" without discrimination about the needs of people in different low income situations or insight into the significance of vulnerability and dependency as characteristics of poverty and deprivation—characteristics which vary considerably in their specific manifestations and in what might be done about them.

Longer term planning needs to be focused on the process of "displacement," attempting to slow the process, or avoid accelerating it, where mechanisms for absorbing the displaced are inadequate. Specific concern for absorbing the displaced would also be a prime focus of planning in both the long and the shorter terms. This concern needs to be reflected in a broad view of possible actions embracing innovation in social mechanisms—perhaps at the community level. To see the problem, or solution, simply in terms of optimal resource allocation runs the risk of overlooking a wide range of relevant actions.

National strategy would evolve from a process of attempting to incorporate proposed and actual responses to specific local realities and problem perceptions and to reconcile their general equilibrium and dynamic implications. It would attempt to articulate guidelines for the orchestration of many separate, sometimes localized, actions and responses and the multiplicity of objectives to which they are directed. Nutrition goals would need to be reconciled with many other concerns.

Marxists would argue that the above approach would simply secure bandages for social sores which are an inevitable consequence of the capitalist system; that, at best, it would alleviate the worst deprivations, but allow the system to adapt and survive with other basic ills untreated. I am aware of these arguments and understand that, more generally, I appear to make a presumption that a wider and deeper understanding of how our human ecologies generate malnutrition could lead to steps to correct this.

Estimating Consumption Parameters for Food Policy Analysis

C. Peter Timmer and Harold Alderman

Food policy analysis links nutrition objectives to macroeconomic policies and performance. At the heart of the analysis is a matrix of price and income elasticities that must be income-strata-specific. Obtaining this matrix for aggregated income classes requires a blend of complex theory and sophisticated econometric analysis that is only possible with restrictive assumptions about the separability of the impact of price changes for one commodity class on changes in demand for other commodity groups.

The separability assumptions are not overly restrictive in the context of such highly aggregated commodities as food, housing, or clothing. But when important nutritional effects occur due to substitution of one quality of wheat for another, or the substitution of cassava for rice, then the level of commodity detail needed to reproduce accurately the impact of relative price changes forecloses the "econometric" approach even for combined income classes. Obtaining the full matrix for disaggregated income classes requires a new approach and this paper reports one attempt.

The Consumption Model

Although consumer theory is developed from the decision perspective of an individual consumer or consuming household, it is usually applied empirically in per capita or per household terms to aggregate market data. Thus the opportunity for consumers at different levels to behave differently with respect to economic parameter variation (e.g., changes in prices) which is an integral aspect of the theory, is usually obliterated in the data aggregation process.

Cross-section analysis has been used to understand more about how household decision parameters vary at different income levels. Income-class-specific income elasticities are easy to derive from cross-section consumption surveys, but some care must be used in interpreting such cross-section parameters in a dynamic projection context. The use of cross-section data to derive income-class-specific price elasticities has been extremely limited for fairly obvious reasons. Households are sampled only once at a particular time when the prices they face are given. If the whole sample is taken during a brief period (e.g., one week) then the only price variation observed will be due to spatial differences.

These price differences will by necessity be faced by different households which may have different tastes. In such a situation it is difficult to infer causality to regionally different consumption patterns even when prices are different. The solution to the impass is either to have a cross-sectional panel of consumers whose consumption expenditures are recorded over time or to draw a large sample over enough geographical and temporal diversity to capture significant variance in the relevant variables. Both approaches are quite expensive, but the second does have the advantage of more rapid results if prices show significant seasonal variation. Data from the Indonesian Socio-Economic Survey V (1976)—SUSENAS—used in the empirical analysis reported here capture these effects. With three separate samples of 18,000 households drawn in each trimester of 1976, the sample is large enough so that cell means can be used as observations for analysis. This averages out most individual taste differences, but leaves adequate variations in incomes and prices for statistical analysis. Such analysis can be conducted directly on the raw data when it is accessible by large computers.

C. Peter Timmer is a professor of the economics of food and agriculture at the Harvard University School of Public Health. He also is a faculty fellow of the Harvard Institute for International Development. Harold Alderman is a research assistant in the Department of Nutrition and a graduate student in the Department of Economics at Harvard.

At the level of the individual consumer decision maker, economic theory is quite clear about what economic variables should be included in principle as arguments in the consumption function—own income, all commodity prices, and any factors determining tastes. Given the more than 100 food commodities alone reported by SUSENAS V, inclusion of all prices is clearly not possible. Even with 54,000 observations some aggregation of commodities is necessary to make any sense of the data.

The analysis reported here deals only with rice, fresh cassava, and total calorie intake from rice, fresh cassava, and corn. Attempts to unravel the factors influencing shelled corn consumption alone have not been successful. Because rice, corn, and cassava are the three major foodstuffs for most Indonesian consumers, accounting for more than two-thirds of average calorie intake, whatever functional specification and approach is ultimately chosen must permit accurate estimation of the coefficients determining their use.

Equation (1) presents the standard, general form of a household consumption function.

$$(1) \qquad Q_{ih} = f(Y_h, P_i, P_j \ldots P_z, H_h, T_h),$$

where Q_{ih} is quantity of commodity i consumed by household h (for a given time); Y_h, the income for household h; P_i, the price of commodity i; $P_j \ldots P_z$, prices of other commodities j to z that might influence the consumption of i (significantly); H_h, household size (and perhaps age and sex distribution); and T_h, household tastes (perhaps captured by educational, regional, ethnic, and occupation variables).

The SUSENAS data available for analysis already had converted household observations to per capita terms, and no opportunity existed to investigate the impact of variations in H_h on consumption. Similarly, no educational, ethnic, or occupational variables were available in the provincial level data; only region and urban/rural effects could be specified. The possibility of "taste" changes seasonally was investigated.

Determining a specific functional form from the general specification of (1) is a matter of judgment and empirical fit. Equation (2) shows the general form used throughout this analysis.

$$(2) \qquad Q = A + A_i + a_1 TX + a_2 TX^2 + a_{3_i} P_i + a_{4_i} XP_i + a_{5_j} R_j + a_{6_k} T_k + a_{7_h} D_h + e,$$

where Q is log of per capita commodity consumption in kg. per week for each income class, round, province and urban or rural observation; A, the intercept; A_i, the income class specific intercept; TX, log of total expenditures for respective cell mean observation; TX^2, TX squared; P_i, log of own price of commodity for each observation calculated as commodity value divided by commodity quantity; XP_i, log of cross-price term, calculated as above; R_j, zero-one dummy variable for region j; T_k, zero-one dummy variable for sample rounds January-April, May-August and September-December; D_n, other zero-one dummy or interaction variables, as specified in text; and e, error term assumed normally distributed in logarithms. The Engel function within the overall equation is a double-log quadratic, so that the income (i.e., total expenditure) elasticity of demand for the commodity is specified as $a_1 + 2^{a_2}TX$. Because a_2 is consistently negative for all regression specifications, the income elasticity declines smoothly with higher incomes. A number of alternative Engel specifications were investigated, but (2) gives the best results for the low income observations where our policy interest lies.

Regression Results

The data used in this analysis are cell means reported for twelve income classes for twenty-four provinces (plus Jakarta), separately for urban and rural consumers, for each of three time periods, or approximately 1,800 observations in all. Because the number of households in each cell varied roughly according to its relative frequency in the Indonesian population, all regressions were weighted by the square root of the number of individuals reported in each cell. To avoid the influences of extreme observations due to small cell size, no observation with fewer than ten individuals (approximately two households) was retained. All regressions reported here were run on the entire sample; separate runs by geographic area, by sample round, and by income class are also under investigation.

Table 1 presents the basic statistical results for the rice, fresh cassava, and calories from rice, fresh cassava, and corn regressions. For each of the three categories a general regression is reported (numbers 1, 3, and 5) followed by our best regression with income-class-

Note: All continuous variables are specified in logarithms. *UTX* is the *URBAN* dummy variable multiplied by *TX*, the log of per capita total expenditures. *PTX* is *TX* times *POOR*, a dummy variable equal to one for the lowest of twelve expenditure classes in the sample survey ($TX \leq$ Rp1000/month). *UPCAL* is *URBAN* times the logarithm of calorie prices. *PRICE* always refers to own price for the commodity in question and *XPRICE* refers to cross price (cassava prices in the rice regressions; rice prices in the cassava regressions). All regressions were estimated with *SPSS* regression programs using the *WEIGHT* procedure with the square root of cell size weights for each cell observation.

specific price effects (numbers 2, 4, and 6). Such directly estimated income-class-specific price effects have not been reported in the literature. But the income elasticities are also quite important because of the debate in the nutrition planning literature over the response of calorie-deficit populations to higher incomes. Table 2 shows that for both specific commodities and for calories from the three sources, the income elasticities for the Indonesian poor are quite substantial.

Rice income elasticities are extremely high for the first two income classes, indicating it is almost a luxury good for the bottom 30%–40% of the Indonesian population. Even high income populations increase their rice intake with higher incomes, especially in the rural areas. Regression 2 does not show a

negative income elasticity of demand for rice in urban areas until per capita total expenditures reach Rp12,600 per month, and the figure is Rp16,300 per month in rural areas. Substitution away from rice with higher incomes is occurring for less than 5% of the Indonesian population.

Income elasticities for fresh cassava are also surprisingly high. They are near one for the bottom 10%–15% of the rural population and remain positive for 50%–60% of the population. Although the effective income elasticity of demand for cassava in the past decade has no doubt been negative due to the concentration of income growth among upper income groups, higher incomes among the bottom half of the population, and especially the rural population, would be likely to generate significant increases in demand for fresh cassava. Statistical results for *gaplek,* a form of dried cassava, are not available currently, but graphical analysis shows that virtually all *gaplek* is consumed by the bottom two income classes, and the income elasticity is probably negative even for these groups.

The calorie income elasticities tend to be somewhere between the rice and fresh cassava elasticities. The calorie regression was run on rice, maize, and fresh cassava calories, and it shows income elasticities of about 0.7 for the

bottom 10%–15% of the population, declining to about 0.2 for the upper quarter. Because these income elasticities are likely to be lower bounds to the actual elasticities because fish, meat, eggs, and milk calorie sources are not included, the conclusion must be that directing income to the poor will be a quite efficient way to improve their calorie intake.

Income-class-specific income elasticities of demand for various foods and for calories are standard in the nutrition planning literature if for no other reasons than the good fit of semi-log consumption functions. The same is not true of price elasticities, which are frequently hard to estimate for an entire population where data series are short and none too accurate, as is typical of data from many developing countries. Estimating price elasticities by income class simply has not been done with any confidence.

Consequently, the income-class-specific price elasticities reported in tables 1 and 2 are important just on methodological grounds. More important, however, is the boost they give to the a priori notion that the poor respond much more sensitively to price changes than do the rich. Although the Slutsky relationship argues that this is likely because the budget proportion and income elasticity for basic food staples vary systematically by income class, the more significant price substitution by the poor extends beyond the Engel component of the total Slutsky effect. At least for rice and cassava, the information in table 2 permits the calculation of pure substitution effects which also vary systematically by income class.

Both the income and (average) price elasticities reported in table 2 are substantially larger in absolute magnitude than most of the standard coefficients reported in the literature. It is important to realize, however, that these elasticities are not likely to be representative of short-run change parameters. Since they are estimated from cross-section data, the only appropriate interpretation is that these elasticities refer to long-run responses expected after several years of adjustment to new income or price levels. Although regional and temporal covariance analysis via dummy variables for important provinces and survey rounds mitigates this short-run/long-run dichotomy to a substantial extent (and reduces the own price response as well, some of which depends on regional and temporal price differences that are removed by covariance specification) it would be hazardous to use the parameters in table 2 for predictions of annual changes in commodity or calorie consumption

in the face of income or price changes. However, even if the immediate response is only half of the long-run response (implying an adjustment coefficient of 0.5 in a Nerlovian adjustment model, a figure in keeping with what little empirical evidence exists) the parameters in table 2, and especially the price parameters, remain dramatically large.

Are they surprisingly large? The question can be answered only relative to expectations. But in the multi-staple food economy of Indonesia with prevailing low levels of average caloric intake, such parameters would be quite consistent with an economically calculating population. Relatively wealthy populations can afford both strongly held food preferences and consumption patterns. The income elasticities for rice show that Indonesians do have strongly held food preferences and will exercise them as income permits. But the price elasticities reflect an ability to adjust consumption patterns in economically rational directions despite those preferences. At least among the bottom 30%–40% of the population income and price policies will meet with very sensitive and appropriate response.

Implications for Food Policy Analysis

Raising basic food prices as an incentive to farmers clearly has an adverse effect on food intake by consumers, especially those poor consumers already at substantial risk of consuming inadequate protein and calories. The results reported here argue that for this society "food" should be disaggregated into its important calorie sources. Doing so opens the possibility of providing farmers incentive prices for the preferred food (rice) and charging consumers relatively higher prices as well, while keeping the prices of secondary grains (maize) and root crops (cassava) low, even subsidized, to protect the poor.

A differential price policy targets the nutritional impact without the enforcement costs and leakages of programs using more preferred foods. The policy is self-enforcing because the poor eat staples no longer attractive to the higher income groups.[1] This avoids subsidizing the food consumption of the entire population, which tends to bankrupt a poor country. The strategy calls for high political commitment to increasing the access of the poor to adequate food supplies, but it may also be the only financially feasible way of coping with protein-calorie malnutrition over the next several decades.

As this paper indicates, the data and analytical costs of such a multi-commodity price policy are quite high. But these high analytical costs must be compared with the costs of subsidizing food consumption for much of the population or of attempting to enforce target-oriented food distributions that really reach the poor. The combination of high analytical and high political costs is not very attractive. But neither are the alternatives. Domestic resource constraints and international market realities will force the political costs of higher rice prices to be paid eventually. Paying the analytical costs now may prevent the political costs from being paid without any return in nutritional well-being for the poor.

Government of Indonesia, Central Bureau of Statistics. *SUSENAS*. Indonesian Socioeconomic Survey V. Jakarta, 1976.

[1] We recognize that fresh cassava is eaten in about equal per capita quantities by all income groups, but even this is a much more "equitable" consumption pattern than for rice. Maize seems to be in between rice and fresh cassava in this regard. Hence, subsidizing fresh cassava would involve about equal subsidies to all income groups whereas subsidizing rice subsidizes the rich more than the poor in per capita terms (perhaps not in percentage of income terms). Subsidizing *gaplek* would target the impact almost entirely on the poor unless diversions to livestock feeding became significant.

Target Group-Oriented Food Programs: Cost Effectiveness Comparisons

Marcelo Selowsky

Food programs oriented to specified income or age groups are being implemented at different scales by several developing countries. Others are actively experimenting with them at the level of pilot interventions. International aid institutions have become interested in them for financing. The case for target-oriented programs has become increasingly clear as a result of several factors.

First, there is the recognition that the normal course of development will not close with sufficient speed the caloric deficits observed today in the poorest subgroups of the population of these countries. Young children, overrepresented in the total malnourished population, could suffer further from declines in breast-feeding practices and lower shares of food resulting from increased urbanization. Second, general programs that lower the price of food to all consumers are either too expensive from a fiscal point of view (general production and consumption subsidies) or, if governments want to save in fiscal costs, they entail a disincentive to domestic producers (price controls, procurement policies). Finally, the fact that malnutrition results from an unequal distribution of food consumption—rather than a lack of aggregate supply—calls for programs that redistribute food within the population instead of general subsidies encouraging aggregate consumption.

In an earlier work (Reutlinger and Selowsky) comparisons were made between the effects of target and general programs, the objective being an expansion of food consumption in families with caloric deficit. Target-oriented programs were defined as those that only subsidize or deliver concessionary food to these target families. General programs were those that subsidize all types of consumers. Cost effectiveness was defined in terms of the fiscal cost of achieving this extra consumption in these families, irrespective of how this extra consumption is being distributed between adults and children.

Here we want to evaluate programs in terms of their effectiveness in increasing food and calorie consumption in the children of these families. Children have become a distinctive objective as countries increasingly recognize the adverse effects of children's malnutrition. Where present general food programs must be scaled down or are not feasible due to fiscal constraints, sharply targeted approaches to nutrition interventions must be identified. This paper presents, first, a simple taxonomy of target-oriented food programs that leave unchanged the marginal rate of substitution among foods. Their cost effectiveness is compared relatively to an equivalent income transfer (i.e., equal to having received the subsidy in cash). It then addresses programs that induce substitution among foods and its probable effect on calorie consumption. Finally, it discusses the implications of moving from a (fiscal) cost effectiveness analysis of programs to a benefit-(resource) cost evaluation.

Cost Effectiveness Comparisons

Three programs are compared: a ration shop scheme where preselected families received subsidized rations of food, a subsidized food stamp program for the families, and a free on-site feeding program for children in those households. When these programs are inframarginal to previous levels of consumption, they all become equivalent to an income transfer. This holds when the quantity of food or stamps distributed is smaller than the amount previously consumed by the family, or by the child in the case of the feeding program. This is true even when ration shops or site-feeding programs distribute several foods in different proportions to the ones previously consumed.

Marcelo Selowsky is economic adviser in the Development Economics Department of the World Bank.

The views presented here are those of the author and do not necessarily represent those of the World Bank.

As long as all foods are inframarginal to previous levels of consumption, the marginal rate of substitution will remain unchanged, the condition for a program to operate like an income transfer. We believe inframarginality characterizes most programs being implemented today.

If programs provide subsidized food, on-site feeding or food stamps in excess of initial consumption (noninframarginal programs), households will try to make use of the possibility of resale so as to increase their set of consumption choices.[1] Food eaten on site cannot be resold, so for this program the option is not open. However, part of the concessionary food received in ration shops as well as a fraction of the food stamps can be resold. Consequently, the effectiveness of these programs becomes equal to an income transfer. Assume, however, the food or stamps, due to heavy policing or high transaction costs, are not resold. What is then the cost effectiveness of these programs? Is that effectiveness still equal to an equivalent income transfer? How do these three different programs now compare in terms of the additional food consumed by children?

Cost effectiveness will be defined as the fiscal cost of increasing by one dollar the aggregate food consumption of children (not the per capita consumption by each child). The comparisons do not distinguish or capture the distribution of that additional dollar among children. A second consideration is that the effectiveness of an income transfer relative to the other programs is quite sensitive to the precise definition of "children." The effectiveness of an income transfer is proportional to the marginal propensity to spend in children's food (i.e., the increase in the aggregate value of food consumption of that group of children). If the group is defined rather widely (i.e., those below age 15) the relevant marginal propensity is much larger and income transfers become more effective. The reason is obvious: a smaller fraction of individuals is now considered as a nontarget age group, diminishing the "leakage" of the program. It is always possible to define children narrowly enough (i.e., those below age five) so as to make income transfers extremely inefficient: the additional consumption of older children also becomes a leakage.

In order to capture explicitly this last effect, we will define the marginal propensity to spend on children's food as γm_T, where γ is the fraction of individuals defined as "children," and m_T is the marginal propensity to spend on food consumption for households as a whole. This proportionality assumption is a simplification insofar as it assumes that the individual marginal propensity is the same for children as adults.[2]

Table 1 shows expressions for the cost effectiveness of the three programs. When the programs are inframarginal, all have the same cost effectiveness and are equal to an equivalent income transfer. In this case, the cost is inversely proportional to the marginal propensity to spend on children's food consumption, γm_T.

If the programs are "large enough" and resale is possible, the only program different from an equivalent income transfer is a site-feeding program for children. For the program to operate differently than an equivalent income transfer, the required scale of the program (the food given on site to all the children of the household) must be at least $1/1 - \gamma m_T$ times the food previously received at home. Under this type of program, the net increase in children's consumption—even if families stop feeding children at home—will be equal to the excess of the food given on site over the food previously eaten at home. Therefore, the cost effectiveness formula $\frac{1 + \lambda}{\lambda}$ is relevant for all programs where λ, the fraction by which one wishes children's consumption to increase, is larger than $\gamma m_T/1 - \gamma m_T$. For any objective λ below this value, the effectiveness of the program will be equivalent to an income transfer.[3]

---

[1] In fact, resale will start when the value of the food transfer is $\frac{1}{1 - M}$ times the food initially consumed, where M is the marginal propensity to spend in food.

[2] We can predict the bias of the assumption if adults have a larger individual marginal propensity than children—and we do have some evidence on it—the earlier assumption will overestimate the marginal propensity to spend in children; i.e., our estimates of the effectiveness of income transfer also will be overestimated. This will be important in interpreting the results.

[3] Let us explore the effectiveness of a site-feeding program under $\gamma m_T = 0.15$. In this case, any program whose objective is to increase children's consumption by more than 17.6% $\left(0.176 = \frac{0.15}{0.85}\right)$ can only do so by feeding children the full amount previously eaten at home plus an additional amount of food equal to the objective. If the program wishes to increase consumption by 20%, it has to feed children an amount 1.2 times the amount previously eaten at home. Thus, programs whose objective, λ, is larger than

Table 1. Cost Effectiveness Comparisons: Cost of Increasing by One Dollar the Value of Children's Aggregate Food Consumption

Type of Program	Inframarginal Programs	Programs in Excess of Initial Consumption	
		Under resale	Under No Resale
A subsidized food program for the household	$\frac{1}{\gamma m_T}$	$\frac{1}{\gamma m_T}$	$\frac{1+\lambda}{\gamma m_T + \beta\eta^s}$ [a]
A food stamp program for the household	$\frac{1}{\gamma m_T}$	$\frac{1}{\gamma m_T}$	$\frac{1}{\gamma}\left[1+\left(\frac{1-f}{\lambda}\right)\right]$ [b]
Direct on-site feeding of all children	$\frac{1}{\gamma m_T}$	$\frac{1+\lambda}{\lambda}$ (full feeding)	$\frac{1+\lambda}{\lambda}$ [c] (full feeding)
An income transfer to the household		$\frac{1}{\gamma m_T}$	

Note: γ is children as a fraction of family size; m_T, marginal propensity to spend in household's food consumption; λ, desired increase in children's food consumption as a fraction of the initial consumption; η^s, "pure substitution" price elasticity of children's demand for food; β, share of food consumed by children; f, price charged for the food stamps, expressed as a fraction of the initial amount of food consumed by the family.

[a] Assumes that the total price elasticity of demand is equal for children and adults.

[b] Holds for $f > 1 - \lambda\left(\frac{1-m_T}{m_T}\right)$.

[c] $\lambda > \frac{\gamma m_T}{1-\gamma m_T}$; condition for "full feeding."

It can be shown that an increase in a household's food consumption by a fraction λ can be achieved by providing the family with stamps equal to $(1 + \lambda)$ times their previous consumption and charging a price for the stamps that ranges between $1 - \lambda(1 - m_T)/m_T$ and one times the value of the food initially consumed. The higher the price charged—within the above range—the higher the effectiveness of the program (i.e., the cheaper the program). If either the price charged for this amount of stamps is below $1 - \lambda(1 - m_T)/m_T$ or the implicit subsidy of charging this price is maintained and less stamps are distributed, the program will be equal in its effectiveness to an equivalent income transfer. The expression in table 1 can be broken down into two components: $1 + (1 - f)/\lambda$ is the cost of inducing one extra dollar of food consumption in the household; γ is the fraction of that extra dollar that will be consumed by children.

The subsidized food price program defined here is different from the typical ration shop scheme where the family does not have the freedom of buying as much as it wishes at the subsidized price. In the ration shop scheme, the family receives an inframarginal ration which, as discussed earlier, is equivalent to an income transfer. Here the family has the freedom to purchase at the subsidized price as much as it wishes; however, given that resale is not possible it will only purchase the amount demanded for own consumption, the quantity purchased will be on the demand schedule of the household. The cost effectiveness expression for this program includes two new parameters other than λ and γm_T. One is η^s, the (pure substitution) price elasticity of food demand of children, capturing the substitution in favor of food that takes place when the subsidy changes the relative price between food and nonfood. The program has changed the marginal rate of substitution between food and nonfood, an effect that was not present in programs equivalent to an income transfer. The larger the value of η^s, the more cost effective will be the program. The parameter β corrects for the additional leakage—being financed by

$\gamma m_T/1 - \gamma m_T$, can only be implemented by what might be called a "full feeding" program, i.e., the program must be able to compensate for the possibility of a 100% replacement at home.

the subsidy—that takes place when part of the additional food demanded by the family is consumed by adults.

Table 2 presents the cost of the program in terms of the cost effectiveness of an equivalent income transfer (i.e., the numeraire). Table 3 presents results under alternative values of the parameters.

A value of m_T—the households' marginal propensity to spend in food—equal to 0.5 is used throughout the analysis. We believe this figure to be an upper limit.[4] Thus, the effectiveness of an income transfer is being overestimated. It means the relative cost figures for the other programs shown in table 3 represent maximum values. The two assumed values of γ, equal to 0.2 and 0.33, can be interpreted as two alternative definitions of "children." A value of 0.2 corresponds to children below age five, and a value of 0.33 to children below age ten. Under the broader definition of children, the income transfer clearly becomes more effective due to a smaller leakage. The relative cost of the price subsidy and site-feeding programs increases. The relative cost of the food stamp program remains the same since the food leakage resulting from redefining children affects proportionally the effectiveness of both programs.

[4] Only for the poorest one-third of households in Calcutta we have found values of this magnitude. For most poor income groups in urban Latin America, the value of m_T fluctuates between 0.3 and 0.4. See C. Lluch et al.

As expected, a very narrow definition of children makes all programs more cost effective than an income transfer. The exception is "low" priced food stamp programs; f must be larger than 0.75 for these programs to be better than an income transfer. For objectives equal to $\lambda = 0.3$, stamps programs with a high price, and on-site feeding programs become the best interventions. This is also true under a wider definition of children, which only induces a difference in ranking between "high" priced stamps programs and on-site feeding: stamp programs become now more effective than site feeding.

For policy purposes the above figures must be adjusted by two factors: first, the difference in administrative costs of the different programs. Countries who already have an infrastructure of health centers, rural schools, etc., require less additional (nonfood) resources to carry out on-site feeding programs. Second, the assumption of no resale is perhaps less realistic for some programs than for others (i.e., subsidized food price programs relative to food stamp programs). If resale is always possible the only intervention that can be more cost effective than an income transfer is an on-site "full feeding" program.

Substitution

The programs discussed earlier did not induce a change in the composition of food consumption. Therefore, the percentage change in

Table 2. Cost Effectiveness Comparisons: Relative Cost of Increasing by One Dollar the Value of Children's Aggregate Food Consumption, Cost Relative to an Income Transfer Program (all figures of table 1 are divided by $[1/\gamma m_T]$)

Type of Program	Inframarginal Programs	Programs in Excess of Initial Consumption No Resale
A subsidized food program	1	$\dfrac{1+\lambda}{1+\dfrac{\beta\eta^s}{\gamma m_T}}$
A food stamp program	1	$m_T\left[1+\dfrac{(1-f)}{\lambda}\right]$ [a]
Direct on-site feeding of all children	1	$\gamma m_T\left(\dfrac{1+\lambda}{\lambda}\right)$ [b]

[a] Holds for $f > 1 - \lambda\left(\dfrac{1-m_T}{m_T}\right)$.

[b] Holds for $\lambda > \dfrac{\gamma m_T}{1-\gamma m_T}$; condition for "full feeding."

Table 3. Cost Effectiveness Comparisons in Terms of the Cost of an Income Transfer Program (m_T = 0.5)

Type of Program	Inframarginal Programs	f	Programs in Excess of Initial Consumption; No Resale: $\gamma = 0.2$, $\lambda = 0.15$	$\gamma = 0.2$, $\lambda = 0.30$	$\gamma = 0.33$, $\lambda = 0.15$	$\gamma = 0.33$, $\lambda = 0.30$
A subsidized food program	1		0.76	0.87	0.88	0.99
A food stamp program[a]	1	f = 0.25	1	1	1	1
		f = 0.50	1	1	1	1
		f = 0.75	1	0.92	1	0.92
		f = 0.9	0.83	0.66	0.83	0.66
		f = 1.0	0.50	0.50	0.50	0.50
Direct site feeding of all children[b]	1		0.77 (full feeding)	0.43 (full feeding)	1	0.71 (full feeding)

Note: The other parameter values are: $\eta' = 0.5$; $\beta = 0.1$.
[a] The conditions for the program to operate like an income transfer are: For $\lambda = 0.15$, $f < 0.85$; for $\lambda = 0.30$, $f < 0.70$.
[b] The conditions for the program to operate like an income transfer are: For $\gamma = 0.2$, $\lambda < 0.11$; for $\gamma = 0.33$, $\lambda < 0.197$.

calorie consumption was equal to the one in food consumption. For noninframarginal programs and no resale the earlier analysis assumed that either one food provided most calories (i.e., cereals)—where all programs were designed in terms of that food, or in the case of several foods, that the program left unchanged the marginal rate of substitution among foods. For the price subsidy program, this assumes all foods are subsidized by the same percentage. For the site-feeding program, it assumes the composition of foods given on site to be equal to the composition of foods previously eaten at home.

What happens if programs do change the composition of food consumption? How do we then predict the change in calorie consumption? When substitution takes place, the increment in the consumption of a particular food (that is being subsidized or provided by the program) can induce a decline in the consumption of foods that are substitutes. If that substitution is strong and the foods being substituted account for an important share of the initial calorie consumption, the net effect on calorie intake could be negative. In order to predict these changes, cross-price elasticities of children's food consumption are needed. This information is extremely scanty even at the level of aggregate household consumption.[5] For children it is absent. Thus, we can only speculate about the effectiveness of particular programs when these substitutions are present. It will become clear that many of the present nutrition interventions fall into this category.

Milk price subsidies or free distribution (take home programs) of milk in amounts substantially above the previous consumption of the household are typical cases. If resale is not possible, these policies will induce a substitution among food commodities. Let us assume children consume two basic foods, cereals and milk. The effect of those programs will be to increase children's consumption of milk and to increase or decrease children's consumption of cereals, depending if milk and cereals are complements or substitutes, respectively.[6]

If milk and cereals are substitutes (the decline in milk's implicit price decreases children's cereal consumption), total calorie consumption could decline if, as is usually the case, most of the calories are derived from cereals. It can be shown that, in this case, even a small degree of substitution between the two foods could induce a negative effect on caloric intake.

The percentage change in calorie consumption induced by a one percent decline in the price of milk, K_M, can be written as:

$$K_M = \alpha_M \eta_{MM} + \alpha_C \eta_{CM}, \tag{1}$$

[5] For an interesting use of these elasticities in predicting the caloric effect of changes in the supply of particular foods, see Pinstrup-Andersen et al.

[6] We define substitution including the corresponding income effect, i.e., gross substitution.

where α_M and α_C are the initial shares of calories derived from milk (M) and cereals (C), respectively; η_{MM} is the (own) price elasticity of demand of milk and η_{CM} the (gross) cross elasticity between cereals and milk; η_{CM} is assumed positive, both foods are (gross) substitutes. In order for K_M to be positive, i.e., for the subsidy on milk to have a negative effect on calorie consumption, we need the condition:

$$\frac{\alpha_M}{\alpha_C} < \frac{\eta_{CM}}{\eta_{MM}}. \tag{2}$$

If $\alpha_M/\alpha_C = 1/5$, initially four-fifths of the calorie intake came from cereals, any cross elasticity larger than one-fifth the value of the own price elasticity for milk will induce a negative effect on calories. If the price elasticity of milk is one, any (positive) cross elasticity larger than 0.20 will have this effect. Milk subsidies and free distribution of milk programs are popular programs in the present. Perhaps they were basically conceived with the objective of increasing the consumption of "high quality" proteins. However, if calories are the major nutritional problem, a reevaluation of milk programs along the lines described earlier becomes of prime importance.

The problem of predicting this substitution becomes even more difficult when a program introduces a food previously not being consumed by children. In this case, the notion of an inframarginal or noninframarginal program loses its meaning: any amount of the food being distributed could affect negatively the consumption of calories. When a program distributes an inframarginal amount of a food previously being consumed, the released purchasing power is used to expand the consumption of all food commodities, by both adults and children.[7] If the new food being introduced by the program can only be consumed by children (specific baby foods), or is fed directly to children (milk programs in schools when children were not previously consuming milk), the only mechanism by which the rest of the family can also benefit from the transfer is by withdrawing some other food from the children in question.[8] As long as the rate of substitution between foods, as seen by the household, does not fully internalize the different calorie intensity of foods, the resulting substitution could adversely affect the calorie consumption of children.

From (Fiscal) Cost Effectiveness to (Resource) Cost-Benefit Analysis

The cost effectiveness formulation presented earlier is clearly incomplete from the point of view of a full welfare economics analysis. First, it includes as costs all fiscal outlays, regardless of what fraction of them represent a resource cost or simply a transfer. It becomes more relevant when the fiscal budget is the ultimate constraint to the selection of programs. Second, the benefits are expressed in terms of physical quantities without prices being attached to it. Implicitly each extra unit of consumption has the same value to society. Third, a zero value is given to the extra consumption in the nontarget groups when they also become subsidized.

A more comprehensive welfare analysis could be undertaken if a "social" demand—different from the market demand—is used to value the extra consumption in the target group. As suggested by Harberger this will be the case if the extra consumption of particular commodities (i.e., calories) by particular subgroups of the population is considered as an externality or public good to the rest of society. In these circumstances we can determine the subsidy or scale that maximizes the welfare gain of each program and then choose among programs according to the magnitude of this welfare gain. Let us illustrate this graphically.

Assume additional food consumption by the children of poor families represents this externality, generating a social demand (D^*) that is higher than the market demand (D_p). The pro-

---

[7] We assume all foods are superior at low levels of income.

[8] Assume a utility function of the household equal to: $U = F^{\alpha} R_a^{1-\alpha}$, where R_a is rice (or an index of cereals) consumed by adults and F is an index of the food consumed by children. Suppose F is a CES index of milk (M) and cereal intake (R_d) consumed by children.

$$F = [\delta M^{\rho} + (1 - \delta) R_d^{\rho}]^{\frac{1}{\rho}} \qquad \rho = \frac{\sigma - 1}{\sigma},$$

where σ is the elasticity of substitution. If initially the child did not consume milk, first order conditions yield an allocation of cereals, A_o, equal to $A_o = \frac{R_d}{R_a} = \left(\frac{\alpha}{1-\alpha}\right)$. When the child is fed at school an amount M_o, the first order condition yields a new allocation of rice equal to $A_1 = \dfrac{A_0}{\left(\frac{\delta}{1-\delta}\right)\left(\frac{M_o}{R_d}\right)^{\rho} + 1}$. Clearly $A_1 < A_o$, the relative allocation of rice to children declines. Because expenditure in rice (cereals) is always equal to total income, this decline involves a decline in the absolute amount of rice consumed by children.

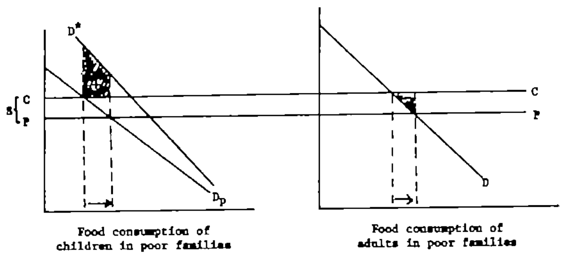

Figure 1. Food consumption in poor families

gram under consideration is a price subsidy (s) to these families (resale is not possible) to bring down its price below its resource cost C

tion there exists an "optimal leakage," the one associated with the subsidy s^*.

From a theoretical point of view, this type of welfare analysis is clearly an improvement over the (fiscal) cost effectiveness approach presented earlier. Several issues must, however, be resolved to make the analysis operational. First, how do we derive the value of ϕ. Second, a penalty must be imposed on that part of the fiscal funds that end up as pure transfers. The (fiscal) cost effectiveness approach treats one dollar of transfers as one dollar of real cost. In the welfare analysis pure

Some Issues in Transportation Policy: Problems in Preference Articulation

James D. Shaffer

In this paper I deal mostly with questions, not answers. The questions have implications for policy analysis. I am concerned with political-economic problems of improving the performance of the U.S. transportation system. Attention is focused on problems of instituting market and political mechanisms for articulating preferences for transportation. Because of public goods characteristics and pervasive externalities of transportation, the blending of market and political processes is especially difficult and important. By preference articulation, I mean the processes by which participants in the political economy get their preferences taken into account. Preference articulation has two aspects: the mechanisms for identifying preferences and the responsiveness of the system to preferences.

I have organized discussion of issues under five general headings—pricing and regulations, jurisidictional boundaries, energy, settlement patterns, ownership, and some observations on difficulties encountered in implementing a public program in rail service continuation. All the issues are interrelated.

The discussion of issues suggests the need for comprehensive long-run planning, while the observations of political practice illustrate the difficulty of political decision making even for a small program.

The Transportation Meta Plan

Consider the attempt to develop transportation meta plans at the national, state, and local levels. By a meta plan I mean a plan for making plans and policy decisions. The objective would be to provide a process for systematic evaluation of our long-run transportation "needs" and alternative approaches to transportation policy given the probable constraints of the future. We cannot know with certainty either the future demands for transportation or the constraints, but current decisions must be made based upon the best estimates available. The process of debating a meta plan should provide a framework for more informed political preference articulation with respect to desired performance and major alternative developments in the transportation system. The meta plan should provide useful guidelines as a framework for making specific planning, funding, and regulatory decisions affecting transportation. The current Rural Transportation Task Force may provide elements of such a plan.

We are spending more than 20% of the gross national product (GNP) for transportation. Performance of transportation affects all aspects of the economy, and disruption threatens the social order. We face critical issues in transportation which should be identified and debated, not only in the Congress but also in the political parties, state legislatures, within and among interest groups, and among economists and other policy analysts.

Pricing and Regulations

The concept of an unregulated market is a meaningless construct. Markets always reflect both preferences for specific products and political preferences reflected in regulations, rights, taxes, and subsidies. Thus, all prices are political and a particular equilibrium price has no unique economic significance as an indication of preferences or value. Broadly conceived, price is an instrument of regulation. It is an inexpensive means of rationing. It is also an effective instrument for reflecting prefer-

ences of large numbers of people once the pattern of political constraints is established.

Decisions in regard to regulation and government participation in transportation must be pragmatic. The market price system, where buyers have strong incentives to weigh alternatives before purchasing and sellers have incentives to identify consumer demand and search the opportunity set for low-cost means of responding to demand, is a marvelous mechanism for preference articulation where the appropriate benefits and costs are taken into consideration. The political process produces regulations, taxes, subsidies, and government provision of services in an effort to achieve performance which is preferred to what would have resulted without the government action. The problem is that the political process is not a very effective mechanism for citizen preference articulation. It is difficult to express efficiently preferences in the political process and there are problems in designing bureaucracies to be responsive to preferences.

The problem of pricing transportation is particularly difficult because of the nature of the economies of density—the marginal cost of a unit of production is usually very low relative to average total costs—and physical characteristics which limit competition. Thus, rate regulation, government provided service, and politically determined user charges are critical issues.

User Charges

User charges reflecting full costs would test users' preferences and could create an incentive to use the least-cost method. But how should costs be allocated among types of users? This is a critical issue for trucks and cars in determining highway user charges. Full cost pricing would not necessarily result in the lowest system cost in supplying transportation.

A current issue is the failure to maintain and modernize rural roads and bridges. It is a serious problem, but I have not seen good benefit/cost analysis dealing with the investment. Baumel suggests part of the problem arises because of the use of much larger farm equipment and trucks. Would it be more efficient to use smaller equipment than to build larger bridges? If users of large equipment had to pay the extra cost of the roads and bridges, they might choose different equipment. Transportation must be analyzed as a factor of production in a complex system.

Cross-Subsidies

If regulation requires a firm to provide some customers service at a price below costs, resulting in higher prices to others, this is the same as a tax and subsidy. Would the political process weigh costs and benefits more accurately if direct subsidies were used and the costs appeared explicitly in a budget?

Transportation pricing involves extensive cross-subsidies with or without rate regulation. Rates vary from commodity to commodity and from place to place and are not closely related to costs. This raises significant questions of equity. A special problem involves the granting of low rates to large shippers because of the potential effect this has on industrial structure. Has the substantial differential in rates on unit train shipments of grain led to concentration in the grain trade? Or, will it do so? What is the appropriate theory of allocation of overhead costs for multiproduct firms to provide effective guidance for establishing rates leading to desired performance?

Captive Shipper

The problem of the captive rail shipper is especially critical. Where there is not effective competition, some control must be placed on rates. But what are the appropriate decision rules for establishing and enforcing rates? There does not appear to me to be any basis for the belief that two-firm competition among railroads would reduce the need for rate regulation.

Rail Car Shortage

Perhaps the most common complaint about rail transportation by shippers is the shortage of rail cars. To an economist it appears to be a problem of peak load pricing. It simply is not profitable to supply cars to meet peak demands given current price practices. Here the market should work to allocate cars to shippers with greatest demand. J.O. Gerald suggests separate pricing of the car and the hauling service to get a more effective articulation of demand for cars. With appropriate pricing mechanisms, investors would have an incentive to supply more cars if needed. The cost of leaving cars idle or using them for storage

would be increased, thus increasing the supply of cars, and leading to more efficient decisions between shipping and storage. At least there would be no car shortage. What would be the consequences and problems I do not anticipate?

These are only a few of the complex problems involved in pricing and regulation of transportation.

Jurisdictional Boundaries

A general issue in transportation policy involves determining appropriate jurisdictional boundaries.

Geographic Boundaries

Every unit of government from the township and village to the federal government is involved with transportation. As a general rule, better resource allocation would be expected where costs and benefits were closely associated within the same unit. The costs and benefits of a decision by one unit which accrue to other units often are not taken into account by the decision-making unit. The problem of devising appropriate boundaries and related funding and regulation decision rules is complicated by the pervasive effects of transportation and the problems of collecting revenue in relationship to benefits. The classification of roadways and related formula funding by the federal and state governments is a response to this problem.

The Railroad Reorganization Acts provided federal subsidies for rail service continuation on light density lines. At least one state tended to make decisions on the basis of the state's share of the cost, not the total costs. A different evaluation would be made if local governments and users were required to contribute to the funds for rail service continuation.

A benefit frequently included in analyses of rail service continuation projects is its effect on employment and income. These estimates are clearly related to the boundary of the area under consideration. Discontinuation of rail service may affect employment and income in the immediate area, but would have little if any effect for the total nation.

The federal government has an advantage as a tax collector. For example, state and local taxes on gasoline result in purchases in lower tax areas. State taxes may affect location decisions, and tax competition among states is common. Economies may exist for both collecting and paying taxes. Thus, federal taxation and funding of transportation is appropriate, but what decision rules for distribution would contribute to desired performance?

The recent truckers' disruption of service was due in part to inconsistent regulations among states. The variations in regulations would be justified if they reflected real differences in circumstances or preferences. In this case, the federal government has a role in establishing regulatory standards. Perhaps federal regulation should prevail on highways built with a specified percentage of federal funds.

Agency Boundaries

The jurisdictional boundaries among agencies is another important issue. The problem is to design agency responsibilities in such a way that benefits and costs are compared among alternative actions. Are multimodal departments of transportation more likely to take into consideration the extensive interdependence among transportation modes than the single mode agencies? Interdependencies of transportation policy with other areas of policy are pervasive. Rural areas and farming interests, for example, are likely to be better served if the U.S. Department of Agriculture (USDA) and state departments of agriculture participate in government transportation decisions. The same is true of most other agencies.

Adjusting to the Energy Situation

Energy and transportation policy are closely linked. Estimates are that more than 40% of the energy marketed in the United States is used for transportation. The current transportation system is designed to use oil-based fuels. Oil reserves are being depleted at a rapid rate. My colleague, Herman Koenig, has calculated that oil production has doubled about every ten years since 1890; and if this rate were to continue, the most optimistic assessments of remaining world recoverable crude oil (169×10^9 barrels) and oil from shale (760×10^9 barrels) would be depleted in only thirty-four years. The real cost of oil will increase substantially and we will run out of oil that is economically available for transportation in a relatively short period of time unless

significant conservation occurs. Other sources adaptable to transportation needs are uncertain and probably will be expensive.

Market Problem

The price system alone is not an adequate means of articulating preferences in this situation. The market does not provide a mechanism to express adequately the demand for the option to buy in the future. Nor does the market adequately reflect preferences for conservation because of the free rider problem? That is, if I conserve and others do not, my conservation because of the free rider problem. That future. The use of oil by one person imposes costs upon others. Dependence on foreign oil has substantial and critical implications for defense, international relations, and monetary stability which cannot be reflected in the market. What is the appropriate policy to deal with the allocation of a critical nonrenewable resource over time?

What policies are appropriate to make transportation more efficient in the use of energy resources and to reflect effectively preferences for conservation? Modes of transportation differ greatly in energy use related to lengths of haul and size of load. Water and rail are much more efficient for long hauls and large loads than trucks. Trucks are more fuel efficient for short trips and small loads. Thus, an energy efficient transport system will be one with efficient intermodal connections. What role should the government take in facilitating development of cost-effective multimodal systems? Individual carriers cannot make effective systems changes.

Railroads

An energy efficient, integrated, multimodal transport system requires efficient railroads. Many diagnoses of the rail system have been made and the conclusions are that many factors have contributed to their poor performance. Because of economies of density, the loss of one shipper reduces the ability of the railroad to serve others, and a process of sequential quality deterioration sets in. Large volumes of commodities are shipped by truck for long distances, commodities which could be shipped by rail at considerable saving of fuel. Shippers chose trucks for long shipments because of differences in quality of service relative to direct transportation costs. Some rail subsidy may be necessary to obtain the benefits to be derived from energy savings. An alternative to the subsidy would be to require certain classes of shipment to go by rail. This would create private costs, equivalent to a tax, but would be largely beyond observation by those ultimately paying.

Conservation Practices

There are many public and private practices in transportation that waste energy. Examples include: the scheduling of aircraft take-off and landings results in large energy losses while planes circle and wait in line; the subsidy or nonpricing of parking by employers and cities which reduces the incentive to car pool and to use public transit; the organization and revenue splits of railroads, which results in longer-than-necessary routing; and extra miles traveled due to competition on delivery and assembly routes which could be served by a common carrier. There must be hundreds of examples. Higher fuel prices will modify some of these practices, but others will not be altered by prices—political action will be required. Responding to the truckers' demands for lower diesel fuel prices would, of course, have a perverse effect on efficient use of energy.

Regulating Use of Oil

A major issue of significance in oil conservation is the type of energy used for different purposes. In the production of electric power, close substitutes to oil exist. Space heating and rail transport could be converted from oil to processed pelletized coal or coal-based electric. Large-scale changes in energy sources would require complex systems changes and huge investments. Also, coal involves major environmental problems. Again, prices have a significant role to play in selecting uses consistent with preferences, but political decisions must also be made. The tradeoff decision between oil savings, current trucking services, personal mobility, and environmental quality are extremely difficult. My judgment is that adjustments to the evolving energy situation involve the most critical and difficult policy issues in transportation.

Settlement Patterns

Settlement patterns, transportation, and energy are intimately linked. Individual decisions in regard to location of activity are not likely to result in aggregate settlement patterns consistent with the preferences of those making the individual decisions because important benefits and costs are external to the individual decisions. For example, efficient public transportation requires a certain density of population. We generally have a dispersed population that makes public transportation uneconomical, and thus, the great bulk of the population is dependent upon the automobile. We have a dispersed population because roadways respond to demand generated by individual location decisions. Can policies be developed to achieve patterns of settlement which would reduce costs of assembly and distribution, costs of heating, and enhance the quality of the environment and life?

Early in our history public investment in railroads, waterways, and roads were made to stimulate economic development of the country. The public investment in rural farm-to-market roads influenced the location of agricultural enterprise. The interstate highway system was a huge investment which has had a great impact on location of economic activity. The reduced cost and improved service available by truck attracted business from rail and, because of density economies on rail lines, made some lines unprofitable. This left some businesses and communities without rail service. Lower cost truck service reduced assembly and distribution costs and made larger-sized food-processing plants more economical, thus eliminating many firms, which in turn reduced the viability of some small communities. Few of these consequences seemed to be taken into account in the planning of the interstate system.

High quality agricultural land is lost every year to alternative uses. Should transportation decisions consider the benefits of preserving this land, not just in terms of the land used for roadways, but for the settlement patterns which result because of the roadways?

Rail and truck regulations include a settlement pattern objective in the public service obligation. Analysts cannot put a value on service to rural areas which preserves small towns, but can provide information about costs and cost effectiveness.

People who are old, handicapped, or poor and who have no access to public transportation are at a serious disadvantage in participating in our automobile-oriented society. Access to many welfare services requires mobility. People in rural areas are generally without public transportation. Should the existing economic incentives be allowed to force this group to live in cities? My observation is that government actions have, on balance, contributed more to the problem than to the solution. For example, where Amtrak provides highly subsidized passenger service in competition with intercity buses, the bus services suffer. Similarly, publicly provided dial-a-ride services may destroy the economic viability of a taxi service. Regulations restricting entry to the passenger transportation business are probably the most important barrier to effective service. Could the market work with "private" vehicles providing the needed service inexpensively, as has been proven in many areas of the world?

My main points are that transportation policy should be in the context of explicit settlement-pattern objectives and that the market is important as a mechanism for articulating some preferences related to settlement patterns and not others.

Ownership

There are many issues of ownership and property rights related to transportation. The most critical issue currently involves the railroads. Much of the rail system is bankrupt or on the verge of bankruptcy. ConRail does not appear to have improved on the performance of the bankrupt railroads it replaced, even with large treasury costs. Prior to establishing ConRail, a proposal was made for government ownership of the railway, with private companies operating on the government-owned and maintained rails. The concept was known as ConFac. What would be the expected performance compared with ConRail-type solutions or long-term subsidies? By separating ownership of functions and reducing entry barriers would competition responsive to shippers' needs be stimulated? Could rate regulation then be eliminated or greatly modified? Restrictions on companies operating both rail and truck services could be eliminated. Would multimodal firms develop improved systems?

If budget decisions for development and maintaining ways, whether road, water, or

rail, were in the same governmental units, would this encourage better consideration of benefits and costs for expenditures in all modes as a system? System interfaces involving signaling and overpasses could be dealt with more rationally than in the current practice where railroads are generally responsible for maintenance of grade crossings and signals. User charges could be established to foster national objectives, including, first of all, effective performance at low cost, but also those relating to settlement patterns, energy conservation, and equity.

There would be many practical problems in changing to a ConFac rail system. Many institutional design decisions would determine the outcome. Traffic control would be a problem. Railroads, however, have operated with joint trackage rights for years; this would be an extension of that concept. The organization of labor would be a difficult problem, also. The political process would probably overinvest in the provision of ways; eliminating lines would be politically difficult.

Pipelines

The proposed construction of coal slurry pipelines is another significant issue involving the role of government and markets in preference articulation. Peterson has provided an interesting discussion of the pros and cons. The immediate issue is, should the government use the power of eminent domain to require the granting of easements for the right of way of coal slurry pipelines? This involves the taking of private property for use by a private firm. The market test for the decision for building such pipelines is expected profitability. There are, however, many benefits and costs external to the firm. Water would have to be obtained in the area of origination and dirty water disposed of at the other end. Both have environmental effects. Elimination of coal revenue to railroads could seriously affect the availability of rail service for shipment of grain and farm inputs or would require rail subsidies. Greatly increased coal shipments by rail creates inconvenience and environmental deterioration in communities through which the trains pass. The pipelines could conserve oil both in shipping coal and in reducing costs of coal, thus facilitating substitution of coal for oil in generating electricity. The issue involves a complex system and a sophisticated benefit-cost analysis.

An Observation of Political Practice

The following are a few cryptic observations on the political process in practice relating to the rail service continuation decisions in Michigan from the vantage point of a member of an advisory council. The observations illustrate issues and problems in preference articulation. The problem of representation of taxpayer interests, a dispersed interest group, in contrast to the concentrated interests, is highlighted.

Michigan has about 900 miles of track under railroad service continuation subsidies. In addition, nearly 1,000 miles of line and 300 miles of car ferry service are either under abandonment petition or believed to be subject to abandonment. Estimated operating subsidies for 1978–79 were $16.7 million, and an additional $6.1 million was spent for rehabilitation projects on the subsidized lines.

My major observation is that a rail service continuation program is needed; that the discontinuation of rail service on all bankrupt and unprofitable lines which solvent lines wish to abandon would disadvantage large numbers of people, would be inequitable, and generally would fail to reflect preferences of Michigan voters. However, the political process as instituted in this case was not very effective in discriminating among projects, in making cost-effective decisions, or in planning the design of a long-run viable rail system.

Settlement Patterns

The settlement pattern issue is best illustrated by the case of a fourteen-county area served by three railroads. Two of these railroads were bankrupt and are currently operated by independent companies under a rail service continuation subsidy. The third is a solvent carrier with all lines in this area under petition for abandonment. Without subsidy or a declaration of public necessity requiring the solvent railroad to continue service, this area presumably would lose all rail service. The subsidized railroad which serves the major portion of the area has 245 miles of track, will receive an estimated subsidy of $3.5 million for 1978–79, and originates or receives 1,752 cars (about $1,997 per car load). The subsidy exceeded revenues by almost $2 million.

Cross-Subsidies

The solvent railroad has about 140 miles of track in this fourteen-county area under abandonment proceedings. Based upon the hearing evidence, costs exceeded revenues by about $1.5 million, and about 2,400 cars originated or terminated on the line. The state's formal position is opposition to the abandonment. If the solvent carrier is forced to continue service, the costs will not show up in the government budgets.

Rationalization

Analysis by Patrick and the technical staff of the Michigan Department of Transportation indicates that approximately 95% of the volume of originations and terminations in the area could be served by combining segments now operated by the three railroads, eliminating half the track mileage and costs.

Major barriers to such a proposal are that 4R Act funds cannot be used to subsidize a solvent carrier. The solvent carrier wants to abandon and does not want to operate under subsidy. A state proposal would weaken the case in opposition to the abandonment. Perhaps most important, transaction costs are high and the availability of federal funds relieves the pressure for effective action.

Ownership

A 104-mile segment of track is operated by a small, solvent carrier at a subsidy cost of about $1.3 million with 388 carloadings ($3,415 per carloading). The area served is not developed but does have a future potential; still, this level of subsidy is difficult to justify. Loss of rail service has been a threat for years, thus discouraging development. The solvent carrier has offered to guarantee service on the line without subsidy if the state would purchase and rehabilitate the line and grant the company a nonexclusive, permanent easement over the right-of-way—that is, for all practical purposes, give the line to the company. The cost would be a one-time investment of about $8 million. Thus, in the long run the government would save money, service would be improved, and uncertainty would be reduced. But such a project would set precedence and transfer property to a private firm. (The situation, as usual, is more complex than I have described.)

Substitute Service

A much less expensive solution to serve those shippers currently using this line and several others would be to subsidize truck-to-rail service. But acceptable decision rules for such a program have not been devised. It is, in fact, difficult to devise decision rules which would provide substitute service without subjecting the treasury to extensive claims by a large group seeking equal treatment.

Benefit-Cost Analysis

Individual line benefit-cost analysis used by the DOT staff estimated the impact of abandonment on local employment, income, and users' costs. The boundary question was not confronted. Energy budgets usually indicated that abandonment and a shift to truck for quantities now shipped would reduce energy consumption. Consequences for road and highway costs were usually negligible. Johnson, in a detailed rail disinvestment study of two Michigan lines, found that rationalization could reduce cost of service with negligible social impact. Benefit-cost analysis on rail segments will, I believe, influence decisions eventually, but are not easily introduced into the political decision process. The uncertainty of potential future shipments and developments is an important factor in political debate.

Public Hearings

Public hearings may produce some useful specific information about the problems of people immediately affected by a transportation project but reveal very little about tradeoff preferences for the majority of citizens. Over several years of hearings I never heard a presentation representing the interests of the general taxpayer. Similarly, legislators argue for economy in government and vote to restrict budgets in general, but almost always support a local group seeking rail service in their districts. The news media present editorials supporting economy in government but dramatize the problems of firms and areas threatened with the loss of rail service.

Implementation

The decisions on rail service continuation which counted the most—the design and

awarding of contracts—were usually done under time pressure. Funding was usually uncertain, making effective planning difficult. Rail planning and rail operations were in separate units. The planning unit complained that the plans and analysis they produced were not used, and operations complained that planning was always too late and inappropriate. Plans were never in the context of total transportation or even the total rail system but concentrated on line by line evaluations. No state group systematically considered the issue of settlement patterns. An annual plan satisfied the federal requirement to have a plan as a condition of funding.

An effort to establish a meta plan failed. It was not possible to adopt a time schedule for making critical decisions in a logical sequence. This was due in part to real uncertainty in regard to budgets and federal policy. Some argued that the 3R and 4R Act concept of limited federal subsidy designed only to facilitate adjustment and which would be phased out over a prescribed period should be taken seriously. Others believed this to be poor strategy.

Conclusion

My assignment was to identify issues and problems in articulation of preferences for transportation, not to provide solutions. The solutions lie in the political process itself, not with any one specialist. There is no unique optimum transportation system. I conclude that neither the market nor the political process is very effective as mechanisms for preference articulation for such complex products as the national transportation system. While good applied political-economic analysis will not produce a perfect system, it can make a useful contribution. To be useful, economic analysis must be tuned into the reality of the political system.

Issues in Freight Transportation Regulation

Wesley R. Kriebel and C. Phillip Baumel

For the past decade some economists, and more recently some politicians, have taken the position that economic regulation of freight transportation should be reduced or eliminated. They suggest that removing regulated motor carriers from economic controls by the Interstate Commerce Commission (ICC) will encourage new entrants into the industry, lower freight rates, and improve service to shippers. The railroad industry and the U.S. Department of Transportation are advocating significant reductions in the economic regulation of railroad freight transportation. They argue that the railroad industry suffers from overcapacity, that it is unable to respond to price initiatives of exempt motor and barge carriers of agricultural commodities, and that ICC regulations interfere with efficient management of rail operations.

Railroad regulation developed in the 1850s–60s, when shipper allegations of unreasonably high rail rates, rebates, rate and service discrimination, and railroad pools led to agitation by farmers and merchants in the Granger territory for state laws to regulate railroads. Passed in ten states, these laws permitted rail rates to be established by state regulatory commissions or by state legislatures and prohibited long haul-short haul discrimination. In 1886, the United States Supreme Court held that a state could not control rates on interstate traffic. A year later, the Interstate Commerce Act (IC Act) established the Interstate Commerce Commission.

In 1917, the Car Service Act authorized the ICC to establish reasonable rail car service rules and to deal with car service emergencies. The Transportation Act of 1920 authorized the ICC to control railroad extensions and abandonments.

In the 1920s and early 1930s the trucking industry became overcrowded with small uneconomic units unable to satisfy the minimum standards of safety, service, or financial responsibility. Concurrently, shippers and communities were finding that motor carriers provided the transport service that accommodated the changing needs of the economy, including door-to-door freight service and reduced inventories. To assure that public demand for essential transportation service would be met, as well as to provide for a financially viable and stable motor carrier industry, Congress amended the IC Act in 1935, bringing most types of interstate, for-hire motor carriers under economic regulation. The philosophy of federal regulation was to create an orderly marketplace, without discrimination because of size or location, and to provide a common carrier system available to all shippers.

A special concession was granted to agriculture in the Motor Carrier Act of 1935. Carriers hauling unmanufactured agricultural commodities were completely exempt from any type of economic regulation. Justification was based largely on the nature of the movement of these commodities. They often are perishable and seasonal, and they require a large number of vehicles during an often short harvest season, thus not lending themselves to the common carriers of general merchandise over regular routes.

Against this historical background, does agriculture or anyone else still need economic regulation of freight transport, and if so, for what purposes and on what scale? This paper discusses the major issues of freight transportation regulation; carrier entry and exit, pricing, quality of service, and regulation of carrier operations.

Entry and Exit

The law requires that applicants for new or additional intercity motor-common-carrier operating authority must prove that the proposed service will be in the public interest. A certificate is granted generally when the ICC finds there is a public need for the service and

Journal Paper No. J-9598 of the Iowa Agricultural and Home Economics Experiment Station, Project No. 2016.

the applicant is fit, willing, and able to perform properly the proposed service. The motor common carrier is legally obligated to accept all shipments of commodities it is authorized to haul and to serve all customers without discrimination in the territory it is authorized to serve.

Supporters of reduced motor carrier regulation claim that the difficulty of obtaining ICC operating authority might have prevented the development of an adequate number of firms, resulting in rates that are higher than they would have been under a deregulated system. According to the 92nd Annual Report of the ICC (U.S. ICC 1978d), more than three-fourths of the 16,800 regulated motor carriers were small, usually family-owned businesses with annual gross revenues of $500,000 or less.

Regulated motor carriers say the ICC is now ignoring the traditional criteria that have formed the basis for disposition of applications for common carrier authority as stated in the Pan American Bus Lines case (U.S. ICC 1936). The present wholesale granting of 95% of the truckload authority applications by the Commission (U.S. ICC, 1979b) is given as evidence that, essentially, entry has already been deregulated. The industry contends that if such action is appropriate, which it does not believe, then the ICC must seek congressional action and not merely toss aside the concept of entry regulation.

The regulated motor carrier industry seeks changes in the present law that would amend the criteria for issuance of operating authorities to include adequacy of service, ability and willingness of existing carriers to meet shipper needs, plus the energy effect on existing carriers of granting new certificates. The industry also advocates consideration of a reasonable broadening of commodity and route restrictions. The motor carrier industry would also redefine private carriage to permit intercorporate hauling for wholly owned subsidiaries and affiliates (Motor Carrier, Regulatory Improvement Act of 1979, H.R. 3549 96th Congress, 1st session, 20 June 1979).

Proposals have been made by some farm groups and the Carter Administration to expand the list of exempt agricultural commodities to include farm inputs and foodstuffs. Proponents argue that regulated carriers are not interested in the short-distance movements of fertilizer, feed, chemicals, and other agricultural supplies. This forces some agribusiness firms into the trucking business. Adding these items to the exempt list would, they claim, enable unregulated truckers to backhaul them. Proposals have also been made to expand the right of agricultural cooperatives to haul nonmember regulated freight.

The regulated carriers dispute these charges and counter further that to expand the exempt agricultural commodities list would allow those whose present business is agricultural hauling to enter the common carrier market in a pick-and-choose manner. Also, this would increase fuel consumption and empty miles. They claim the marketplace would be seriously disrupted, accurate and public market information on freight rates and carrier services would no longer be assured for shippers, the carriers would suffer financially, and the marketplace would become less, not more, competitive.

Empty backhaul mileage is said to result from regulation. But regulated motor carriers point out that empty mileage primarily arises from the inherent regional traffic imbalances and the use of specialized equipment. The ICC has estimated empty mileage for regulated route motor common carriers to be 7% (Glaskowsky, O'Neil, Hudson). It is difficult to fill one empty backhaul without creating another, because eliminating ICC entry regulations would not appreciably increase the amount of traffic.

The railroad industry and the U.S. Department of Transportation (Railroad Deregulation Act of 1979, U.S. Senate Bill No. 796, 23 Mar. 1979) advocate eliminating ICC controls on branch rail line abandonment and on railroad mergers and consolidations. The railroad industry contends that continued operations and maintenance of thousands of miles of light-density branch lines result in large operating losses. Much of this track would require large amounts of capital to be upgraded to handle the 100-ton rail cars. The industry contends that the losses would be magnified if they were forced to maintain and upgrade these tracks. Moreover, they state that because the present ICC abandonment procedures are lengthy and costly, only the most obvious cases for abandonment are brought before the ICC.

Shippers and communities located on branch rail lines argue that the loss of the branch lines would increase substantially costs and probably make it impossible for farmers to market their products and receive

production inputs. They claim that the poor condition of many branch lines is due to railroad neglect and that, with good service and track maintenance, the branch lines could be profitable. They further maintain that rail abandonment would threaten the very existence of their communities and add to the energy problem.

Railroad companies indicate that many branch lines are energy inefficient because of circuity, stop and start operations, and low traffic volume. They claim through trains and unit trains are more energy-efficient than branch line operations. While they concede rail abandonment will increase fuel consumption by trucks hauling the product further to nearby main lines or upgraded branch lines, the fuel savings on the energy-efficient main line operations will more than offset the additional fuel consumption by trucks and will actually reduce total fuel consumption. Moreover, the railroad industry maintains that research has shown that communities located on abandoned branch lines have not declined and many have continued to prosper.

Pricing

As part of their public service obligation, the regulated motor and rail carriers must charge rates that are reasonable and not unjustly discriminatory. They are required to disclose rates publicly. Shippers and receivers contend that knowledge of what transportation rates will be next week, next month, and six months from now is important to a small business owner who must often compete in the same market with a large organization but does not have the staff resources to gather and analyze rate information. With no discounts, all users—large and small—pay the same prices for similar services.

The law provides legal antitrust immunity for collective rate making conducted through tariff bureaus (Reed-Bulwinkle Act, 49 U.S. Code Rev., Sec. 10705, 1948). Both carriers and shippers cooperate in the filing of proposed changes to existing tariffs, subject to approval or disapproval by the ICC. Rate making procedures are designed to insure that unjustified changes cannot be made easily. Proposals for general rate increases are reviewed by the ICC, which can, on its own motion or upon the complaint of any shipper or interested party, decide to suspend the new rate until it determines whether it is reasonable or if it is discriminatory.

Proponents of increased price flexibility claim that open price competition will yield lower rates and improve efficiency. The current rate setting process is said to reduce the incentive for carriers to improve productivity and hold down costs. Rates based on the cost of providing the services, instead of artificial rough-system averages, are viewed as the cornerstone of future transport policy.

The regulated motor carrier industry position is that open entry and freedom to negotiate all rates would create destructive competition in the industry. Entry of new firms undoubtedly would take place in the truckload market. The amount of truck traffic, however, would not expand as rapidly as trucking capacity, leading to severe rate competition on truckload movements, with revenues failing to cover total costs for many carriers. The next phase would be financial difficulty of the local carrier and rate increases or termination of high-cost, less-than-truckload service. It is said there would be chronic over-capacity, a high turnover of trucking firms, reduced financial and operating reliability, and greater difficulty in tracing shipments and in collecting lost or damaged freight. The industry maintains that the process of collective rate making is absolutely essential to the maintenance of a stable, cost-effective, fuel-efficient, freight transportation system. Shipper groups also endorse collective rate making as the only practical way to make sense out of the hundreds of thousands of rates on items to be transported to some 60,000 communities throughout the United States.

The motor carrier industry's legislative proposal for regulatory improvement calls for creation of a zone of reasonableness, including a no-suspend zone of 7% (decrease or increase) annually, for a five-year period.

The railroad industry cites its continued low earnings to support its request for rate flexibility designed to meet competition, to take prompt advantage of innovation, and to market rail service aggressively. The average return on investment in the railroad industry in 1978 was 1.6%, seven railroad companies lost money, and no major railroad had more than a 9% return on investment (Association of American Railroads). The major changes in rail-pricing regulation proposed by the railroad industry include:

(*a*) Ability to establish rates by contract without review by the ICC. The purpose of the contracts would be to provide a more precise definition of the transport needs of the shipper, to base the rate more on costs of the movement, and to define more precisely the shipper and carrier risks and requirements. These contract rates would be filed with the ICC or another government agency.

(*b*) Ability to publish seasonal and peak demand rates without notice. The Railroad Revitalization and Regulatory Reform Act of 1976 (4R Act) provides for seasonal and peak demand rates with a thirty-day notice of publication or cancellation (90 Stat. 31, P.L. 94-210, 5 Feb. 1976).

(*c*) Ability to quickly change the division of rates among railroad companies to reflect changes in costs.

(*d*) Ability to establish general rate increases to provide protection against inflation.

(*e*) Ability to continue joint rate requirements among railroad companies.

Supporters of continued ICC controls over railroad rates point out that the 4R Act provides for establishment of both seasonal and demand-sensitive rates, and that the railroad industry has failed to use this price flexibility. The railroad industry counters that this flexibility is of limited value because of the thirty-day notice requirement for publishing or canceling the rates. Exempt commodity truckers and barges have no such requirement. This enables exempt carriers to charge high rates during peak periods and to quickly reduce rates to hold traffic during periods when the volume of traffic declines. Moreover, the major seasonal rate proposal arising from the 4R Act is in protracted litigation, which likely will be settled by the U.S. Supreme Court (U.S. ICC, 1978c).

Shippers supporting regulation of railroad rates cite the need for stable rail rates as a prerequisite to product pricing. They are fearful that the contract rate provision would favor the large rail user over the small rail user. The railroad industry replies that many agricultural shippers have adjusted successfully to the rate fluctuations of exempt truck and barge carriers and have increased continuously the volume of their products shipped by these modes.

The rail rate structure has influenced agricultural and industrial locations and relocations. The cost, quality, and availability of transportation is critical to the competitive position of agricultural industries in different regions. Rail users in some regions allege that they still face both rate and service discrimination by railroad companies. Whether these rail users are really being "gouged," or whether they are simply paying the full cost (or even less than the full cost) of transporting their agricultural outputs and inputs, given their geographic and light-density location, can only be answered with more refined analyses than are presently available. The important point is that some users think they are being overcharged and other users feel that less regulation of rail prices will recreate the potential for discrimination. Although these users are basically in favor of increasing the efficiency of the railroad industry, they indicate that they will support increased efficiency through less regulation or regulatory reform only if some assurance of protection is provided in terms of rates and/or service that both shippers and railroads can live with. Thus, protection of the so-called captive rail user is a major regulatory issue. While many people are convinced that some users are captive or potentially captive to railroad market power, there is little agreement of precisely what is a captive rail user or what protection should be provided to the captive user under alternative levels of reduced rail regulation.

The railroad industry, while agreeing that some users may be captive to railroads, argue that railroad companies face intra- and inter-modal competition for the products they carry. Moreover, the products they carry face market competition from products produced in other regions. Thus, to raise rates to the point that would drive their producers out of business would, in the long run, lead to the further erosion of traffic from the railroads. They would clearly be better off hauling products at a rate that would generate traffic on their lines. Thus, one potential type of captive-user protection would be to provide a guaranteed rail car supply to captive rail users.

A little noticed issue related to railroad rate flexibility is the commodity clause of the Interstate Commerce Act. This clause prohibits carriers from transporting property it owns except that used in the business of the carrier. Repeal of this clause could enable a shipper the opportunity to sell products at the point of origin to the railroad company and buy them back at the destination at a price that could reflect a discriminatory freight rate.

Quality of Service

The regulated motor carrier industry believes that eliminating economic regulation would introduce uncertainties into the cost and availability of motor carrier service. Small businessmen likely would be faced with the prospect of ordering in larger quantities with less frequent service, thereby incurring increased storage facility and carrying costs and higher total physical distribution costs.

The motor carrier industry believes that price and entry controls have helped to achieve economic and social objectives that free market forces could not always assure. Over time, large and small businesses have been able to locate with the assurance that there already existed, or would soon exist, timely and continuous truck services. Thus, accessibility to markets with certainty may be an implied economic and social benefit of transport regulation.

Although small, rural communities probably would continue to be served by trucks in the absence of regulation, the uncertain issue is whether these towns would be served adequately and/or at higher prices. If cross-subsidization exists under regulation, many small communities may discover that their transport costs have increased sharply after reduced regulation. The regulated interstate carriers believe the most profitable firms would compete only for freight in the high-volume traffic corridors. To the extent that marginal carriers survive, they likely would be left to serve the smaller towns and rural areas. If true, relaxing motor carrier entry requirements and permitting unregulated rates would eliminate the common carrier obligation to serve all who need and want service with reasonable dispatch and with adequate equipment. They further argue that in the absence of regulation, overcapacity and inadequate revenues would lead to deterioration of safety standards, evasion of safety regulations, financial irresponsibility, and generally unsatisfactory service.

Regulation is blamed by critics for protecting the status quo, stifling new technology, and limiting the range of rate and service choices. The implication is that a significant number of shippers have been overcharged for current levels of service. It is alleged that, if the common carrier system were more competitive and were to offer a diversity of services, then overall physical distribution would be improved and consumer prices would be lower.

The motor carrier industry contends that a major test of the variety and quality of services offered by regulated motor carriers is the attitude of users of the service. Numerous shipper surveys show general satisfaction with motor carrier service and support the concept of regulation (Wagner; Constantin, Jerman, Anderson).

Railroad companies cite the need for shortening the time required for ICC decisions on railroad mergers and consolidations. These mergers and consolidations are needed to reduce excess rail plant by providing for joint use of main line track and switch yards. Moreover, they are needed to consolidate rail services. Individual railroad companies say it is difficult to control service quality on interline traffic in the absence of mergers and consolidations. The railroad industry argues that railroad mergers should be handled in the same manner as mergers of other industries. That is, if a merger is found to be anticompetitive, it is prevented. However, rail users and labor leaders contend that additional mergers and consolidations would reduce or eliminate carrier competition and would result in a reduction of jobs and increased rail abandonment.

Control of Carrier Operations

In addition to its control over pricing, entry, and exit, the ICC can influence rail carrier operations. It can control rental rates on freight equipment, charges for accessorial services, the way cars must be routed, the number of cars and locomotives assigned to specific commodities, the number of cars assigned to unit trains, which rail cars will be repaired, and the way cars shall be moved. For example, ICC Service Order 1304 required railroad companies to place a maximum of 20% of its covered hopper fleet in unit grain train service (U.S. ICC, 1978a). The order was issued in 1978 because small grain shippers complained that a large share of the fleet was assigned to unit grain trains. Unit grain train shippers and railroad management argued that each unit grain train car will haul at least twice as much grain as a car in regular train service because of faster turnaround times. Therefore, if the objective is to increase

the amount of grain transported, more—rather than fewer—cars should be assigned to unit grain trains. Service Order 1304, which was cancelled before the car shortage period ended, is a classic example of the issue of efficiency versus equity.

ICC Service Order 1309 requires railroads to place, remove, forward, clean, weigh, and if needed, repair cars within twenty-four hours (U.S. ICC 1978b). Railroad companies complain that it is impossible to comply with this order in all cases because of missed connections, congested ports and terminals, plugged grain elevators, weather, and other uncontrollable events. As a result of the order, some cars are moved in the wrong direction, or moved from the origin point while still empty or from the destination while still loaded.

Car Service Order 1322 required that 70% of all covered hopper cars and 50% of all 40-foot box cars of twelve Midwest railroad companies must be placed in grain service (U.S. ICC, 1978b). The intent was to help solve an acute grain car shortage. The Missouri Pacific Railroad Company generally uses most of its covered hopper fleet to haul fertilizers and other chemicals. Yet, this service order forced most of its hoppers into grain service. The service order was quickly changed after the ICC received vigorous protests from shippers of fertilizer, chemicals, cotton, and sugar that this service order was simply creating a car shortage for nongrain shippers.

Critics of ICC-car service orders contend that the service orders are issued with little analysis or knowledge of the impacts or benefits and costs of the orders. Recently, one ICC commissioner stated: "Over the years, the results of using our emergency car service authority have been extremely mixed. Indeed, sometimes I wonder whether our activities may have done more harm than good!" (Christian).

In the current fuel crisis, the issuance of Special Order No. 9 by the Department of Energy was, in essence, a similar effort to resolve the problem (U.S. Department of Energy). This order established the priority of middle distillate consumption by farmers and haulers of perishable food products. Other high fuel users, specifically the independent truck operators, found the regulation did not provide adequate fuel at an acceptable price level for their perceived needs, resulting in severe operational instability.

The ICC granted a special fuel surcharge to allow for expedited recovery of increased costs (ICC 1979a). This order, however, only applied to the independent operators who contract with regulated motor carriers. The carriers of exempt agricultural commodities do not have an institutional framework for such recourse.

Conclusion

The freight transportation regulatory system is currently under severe criticism. Alternative proposals are being offered and debated by the carriers, the shipping public, the body politic, and economists. The regulated motor carrier industry supports the present regulatory system but is recommending regulatory reforms that it believes will make the system more efficient. The basic industry position is that the country needs a responsive motor-common-carrier freight system, and without regulation such a system is impossible. Some spokesmen of exempt truckers favor further relaxation of entry and price controls. The railroad industry generally favors elimination of much of the railroad regulation. Rail and motor carrier users are found on all sides of the issues. Small community leaders fear the effect of major changes in freight regulation on their towns.

Information on the likely impacts of major changes in the regulatory system is needed to help resolve these disagreements. A significant number of studies have been done on the impact of rail abandonment on shippers and communities. Little research is available on the potential impacts of increased price flexibility of railroads and motor carriers, or relaxation of entry controls for the motor carrier industry, of rail mergers and consolidations, of ICC rail car service rules, and of other regulatory issues on various groups of shippers, carriers, and communities. Little has been done to define the extent to which groups of rail users are captive to the railroad industry. Much of the speculation on the impacts of relaxation of railroad regulation focuses on the impacts of large and small agricultural shippers. These discussions typically fail to define what is large and what is small, and they are often blurred as to who is the shipper. For example, is the grain farmer or the local elevator the shipper? This lack of information presents a unique opportunity to agricultural economists for research to help resolve the conflict on regulatory change.

Issues in Freight Transportation Regulation: Discussion

James Springrose

Shaffer poses many questions which are relevant but perhaps above all, controversial. They have been in debate, in the legislature, studied, studied again, and otherwise under consideration for a long time. And some progress has been made . . . some solutions have been implemented. Those which work best are usually sponsored and supported by the private sector as opposed to the government.

For example, intermodalism has been a fact of life whose adolescence passed in the 1950s. Industry has been quietly but effectively utilizing the concepts of intermodalism for a long time. Its progress has been stimulated by the economics of transportation and distribution. Furthermore, trailers-on-flatcars and containers are but a small component of intermodal activity already in use. I see very little need to change or expand this motivation. Rather, I see intermoldalism expanding on its own momentum.

Above all else, government preference expressed through the political process should be reduced to a minimum, rather than expanded. These preferences often follow special interest desires and become pork barrels which either overstate the benefit-cost ratios (e.g., St. Lawrence Seaway and Arkansas River Project), or overregulate to achieve exaggerated priorities.

We have come to learn and should be willing to admit that there are excesses (emphasis "excesses") in the regulation of commerce within and beyond the transportation sector which fail to contribute to justified national objectives. The excesses of regulation only contribute to inflation.

These excesses are but examples which support Shaffer's position that "the political process is not a very effective mechanism for citizen preference articulation. It is difficult to express efficiently preferences in the political process and there are problems in designing bureaucracies to be responsive to preferences."

With regard to the captive shippers, whoever they might be, I believe their vulnerability rests in the availability of service rather than in the level of rates. I see little value in having low rates if one cannot obtain service to reach market outlets. In most discussions about captive shippers, the impact of freight rates on their competitive posture has been overdramatized.

Likewise, I believe rail car shortages have been overdramatized. To be sure, cars are not able to meet demand but our studies suggest that when the cars now on order are added to the existing fleet, the supply could and should be adequate through 1985. Any more will only clutter up the system. The focus should be on productivity improvement instead of fleet expansion. Self-imposed speed restrictions because of poor trackage, deterioration and inadequacy of classification yards, short circuits of locomotive drive-motors caused by snow, and antiquated work rules contribute far more to car shortages than does the size and number of the rolling stock.

Motor Carrier Deregulation

As to the paper by Kriebel and Baumel, I believe it is unwise on the issue of truck deregulation to reach conclusions which are based on experiences, real or imagined, of the 1920s. Reliance on historical experience precludes the impact of technological advance on the industry in the interim period. Much of the preregulation service deficiencies were caused by mechanical failures long since corrected and by inadequate roadways long since improved.

Second, those who support continuation of the regulatory process should articulate that support in ways which lend credibility to their position. For example, dismissing the empty mileage issue with deadhead mileage estimates

---

James V. Springrose is Vice-President of Transportation for Cargill, Inc., Minneapolis, Minnesota.

for regular route common carriers represents the classic example of the tail wagging the dog. Seven percent is a nice low ratio for that group, but an overall ton mile evaluation suggests the industry as a whole is burdened by much higher percentages (26.3% to 27.9%) of deadheading which just might represent an unjustifiable waste of energy and other costs to the distribution system. Interstate Commerce Commission. *Empty/Loaded Truck Miles on Interstate Highways During 1976,* see table VI.)

With those cautions I will sidestep—neatly, I hope—the issue of motor carrier regulation or deregulation.

Rail Abandonment

In the fifty states which comprise the United States, there are 39,019 communities without railroad service. This is 64% of all communities in America and most of them have never had railroad service. (Motor Vehicle Manufacturers Association, *Motor Vehicle Facts & Figures '77.*) For example, of the 207 communities in Hawaii, not one has railroad service; 90.7% of Alaskan communities do not have railroad service. Before you conclude that these are isolated states and extreme examples: there is Maryland, the birthplace of United States railroads—it is 88.8% non-rail served; and Delaware is 86.5%, Pennsylvania, the home of ConRail, is 76.8% non-rail served.

The average is reduced by lower percentages of non-rail service in the Granger States. However, these comparisons cast serious doubt on the conclusion that abandonment of rail services will "probably make it impossible for farmers to market their products and receive production inputs."

Rail Pricing

The principal thing railroads should learn, in their zeal to obtain freedom for peak demand pricing which they believe barges and exempt trucks enjoy, is that those they envy are usually bound by price and service contracts on large segments of overall capacity. Therefore, the peak demand escalations in these other modes are available for only a relatively small percentage of their business.

From the shipper's point-of-view, demand elasticity of most products is not governed by freight rates. Therefore, there is little hope that lower rates in the "off season" will stimulate new demand. As a result, most shippers view this approach to railroad pricing as simply a gimmick to increase rates during times of shortages.

Issues in Freight Transportation Regulation: Discussion

Ken L. Casavant

The two papers I will discuss today appear to be quite different in approach to the subject matter of transportation policy. Shaffer speaks about the problems of instituting market and political mechanisms for articulating preferences for transportation. Kriebel and Baumel discuss issues in freight transportation regulation from the viewpoint of carriers, shippers, consumers, and policy makers. Shaffer's presentation leads us to a new slant in mostly traditional policy questions, while the Kriebel and Baumel paper summarizes traditional "positions" associated with the deregulation question. But, the papers are not as different from each other as first glance would suggest because both focus on the question of how the conflicting preferences should be resolved in the area of transportation policy, specifically regulation. This commonality is reinforced by the decision of the authors only to raise questions in their presentations rather than provide answers or even a framework for seeking out solutions. I do hope this was the "charge of the paper" received by authors because I do not, as I will indicate below, believe it is the state of affairs in transportation policy.

Shaffer offers us a traditional, nonrigorous treatment of pricing, regulation, and ownership. It is in the areas of jurisdictional boundaries, settlement impact, and energy-market problems where his known innovativeness and perspective became evident. Nowhere is the question of jurisdictional boundaries more evident than the current discussion, at the federal level, of truck weight and length variation in state regulations. Preference articulation in this instance may be achieved by a federal mandate on weight and length to be settled in a court case evaluating "states rights." A point worth repeating is Shaffer's assertion in his discussion on settlement impact, that decisions in regard to location of activity made by individuals will not achieve aggregate settlement patterns consistent with preferences of those individual decision makers. Public transportation's dependence on high-density settlement pattern is a bit of "Catch-22"; we will not necessarily get high density if public transportation and other services are not available, and yet public transportation is often dependent on high-density areas already being in existence before an investment will be made by appropriate decision makers.

In summary, I do concur that the mechanics of the political-economic system is indeed a complex system. The economic signals are often messy, potentially misleading, and yes, even missing. It is necessary to incorporate economic and political externality questions back into the marketing system if preference articulation is to be achieved.

But, it is not appropriate to give up on the process or view it in the rather pessimistic approach contained in the Shaffer paper. The Environmental Protection Agency, agricultural land preservation activities, regulation modernization, etc.; all of these are micro-components of a dynamic system that is working and does offer the mechanics to achieve, albeit marginally at times, preference articulation. Finally, a desirable activity of academic researchers is to develop an investigative framework in this area so that "asking questions" does not continue to be the conceptual methodology this paper seems to suggest it is.

The second paper today can be considered a case study in preference articulation; namely, what are the issues and desires associated with the timely question of freight transportation regulation? The Kriebel and Baumel paper is an excellent discussion of the perceived desires of proponents and opponents of various issues within transportation deregulation. I was disappointed not to find in the paper what Kriebel and Baumel felt about the issues since both have done substantial research in the area.

When the authors review the background,

Ken L. Casavant is an associate professor in the Department of Agricultural Economics, Washington State University.

under the issue of entry and exit, of the agricultural exemption they fail to point out one goal that I feel has been fulfilled—the fact that the exemption allows transportation capacity to be used very efficiently in a geographic and temporal sense. Exempt truckers move throughout the United States following seasonal markets achieving a high-loaded backhaul percentage and providing responsive service to the agricultural producer. Also, the question of deregulation should not necessarily be considered a 0 or 1 dummy variable; we have seen substantial administrative deregulation by the ICC even while legislative deregulation is being considered and undertaken.

The discussion on quality of service was based almost solely on benefits and costs of mergers. Yet studies available in the literature have shown transit time and variability of transit time to be the operational quality of service variables considered by shippers. This relationship could have been developed further.

The overall conclusion of the Kriebel and Baumel paper is that "information on the likely impacts of major changes in the regulatory system is needed to help resolve these disagreements." My contention is that much of the general information already has been produced, and that the questions raised in their discussion seem to ignore this work while projecting the image of a virgin field of policy analysis. The appropriate discussion is no longer "what do the people feel," but what further information on more specific questions is needed to achieve complete articulation. Studies have resolved many of the issues or positions discussed in these papers. It is now time to focus on specific remaining areas of contention, areas where the lack of mechanics of preference articulation are further hampered by the lack of definitive data.

Issues in Freight Transportation Regulation: Discussion

Lynn W. Robbins

In discussing preference articulation, Shaffer points out that "every unit of government . . . is involved in transportation. . . . The cost and benefits of a decision by one unit which accrue to other units are often not taken into account by decision-making units." Shaffer apparently is suggesting a systems solution to the multigovernmental unit problem. However, the transportation policy problem fails to meet two and possibly all three of the preconditions necessary to the systems approach "(*a*) . . . aims and goals of the system are well defined and recognizable if not quantifiable, (*b*) . . . the decision making process in the real system is centralized and fairly authoritarian, and (*c*) . . . a long range planning horizon is possible" (Manetsch and Park, p. 6a). The transportation system's aims and goals may be well-defined in the short run but change and fluctuate according to the varying powers and clout of interest groups in the intermediate and long run. Transportation decision making in any situation, short of nationalization, is neither centralized nor authoritarian. Certainly in a democratic society a long-range planning horizon is very unlikely.

Shaffer gives numerous rail examples of why total systems approach solutions have been inoperable in the face of regulation (e.g., one solvent rail line could not be subsidized as part of an "optimal" three-line solution). He presents examples where first, second, and even third best solutions were not implementable, and yet the need for systems or total network-oriented research remains. At least those efforts intended to direct policy decisions should be multimodal in nature.

Policy-directing systems research should include a prestudy political feasibility test as well as pretests for physical, financial, and economic feasibility. Certainly a good researcher would be unlikely to analyze the impacts of a solution that was not physically implementable. The guidelines for determining political feasibility are not as clear. However, the political feasibility test remains necessary in order to determine, *ex ante,* whether the results will be implemented directly, utilized to educate policy makers, or simply entered into as an academic exercise.

"To be useful," Shaffer concludes, "economic analysis must be tuned into the reality of the political system." He provides us with numerous researchable questions and implied answers that deserve emphasis. A few are liberally paraphrased here in the form of statements.

(*a*) Overhead cost allocation theories may exist that would allow market rate making where, now, regulation is supposedly needed. The implication is that the systems problem can be cured with a proper orientation to decision theory.

(*b*) Government-owned rails and deregulated entry could enhance private rail firms' responsiveness to shippers and eliminate the need for rate regulation.

(*c*) Multimodal transportation firms could be effective.

(*d*) Multimodal regulatory agencies could enhance efficiency.

(*e*) Many other sound researchable questions are presented with respect to coal-slurry pipelines, unit trains, and settlement patterns.

Kriebel and Baumel's "Issues in Freight Transportation Regulation" presents additional researchable questions. They ask the question, " . . . does agriculture or anyone else still need economic regulation of freight transportation, and if so, for what purposes and on what scale?" The authors pose this question and leave it unanswered. They present arguments used by proponents on both sides of the deregulation issue. Even though the authors do not tell us whether economic freight regulation is needed, a review of their remarks cause this respondent to feel the need to further emphasize justifications for deregulation.

When it comes to pricing, the regulated in-

Lynn W. Robbins is an associate professor in the Department of Agricultural Economics, University of Kentucky.

dustry justifies the need for collective rate making to maintain "a stable, cost-effective, fuel-efficient freight transportation system." It seems, however, that the essential ingredient is price information and not rate making. It is not difficult to argue that collective rate making is one "way to make sense out of the hundreds of thousands of rates on items to be transported to some 60,000 communities throughout the United States." It is especially difficult, however, to argue that it is the only practical way. Perhaps the ICC or some other regulator could assist and promote locality or commodity-oriented price information groups if rate boards could not be simply transformed into rate information boards. The unregulated market cannot work without good price and information flows. Information flows are not a natural outgrowth of an unregulated market economy. Consequently, it seems that information discovery should remain as one of the main emphasis areas for regulation.

One of the major problems highlighted by Kriebel and Baumel is that regulated carriers compete against exempt carriers. Regulated carriers cannot, like exempt carriers, charge high rates during peak periods and then reduce them quickly to keep their traffic. Western Kentucky's grain-exporting industry provides a case in point. Preliminary results from a study of that area indicate that an artificial shortage of carriers exists (Richardson). Although these are preliminary results and not yet verified, enough barges and rail cars apparently were available so that together the total shortage should have been no more than 5% or 10% instead of the 50% that was reported. The solution is either more or less regulation. More legislation would be required to keep the barge industry from skimming the market during the grain season or less regulation to allow railroads to implement seasonal rates.

Obviously, there is no current solution as to which is best, regulation or deregulation. Arguments for deregulation have been presented as a balancing tool. Drastic deregulation is just as disruptive as drastic regulation (e.g., nationalization). Anything but marginal changes from the status quo are too difficult to predict and are more likely to reduce rather than improve existing regulations. More unsubstantiated political biases become involved when major changes are initiated by uninformed actors.

An educational rather than empire-oriented policy orientation is needed. Our political problem is not so much that we implement poor policies, but rather that they are left intact. That is, poor policy is not replaced but rather corrections are attempted through countervailing policy.

Finally, this session's title and the titles of its papers make a rather disturbing comment with respect to the state of our profession and the topic of transportation policy. As researchers, educators, and practitioners, we should be defining researchable problems and mapping out paths to their solutions rather than simply enumerating the issues. Thankfully, the authors have done more than enumerate issues. Transportation policy will be made and implemented whether or not we provide the basis for those decisions in the form of sound research.

This is in no way a critique of papers presented in this session. It is improper to criticize authors for doing well what they were assigned to do. Let us not linger on the issues, however, now that we know them; but, rather, begin the search for solutions.

Agricultural Trade Issues among Pacific Ocean Countries (Lyle P. Schertz, ESCS USDA, Chairperson)

Changing Patterns of World Trade

Dale E. Hathaway

Commodity forecasting is a risky but often highly profitable business for private traders. It is equally risky, in a different way, for public officials and never profitable since most people tend to remember the public official's errors and forget the times he was correct. Thus, I shall avoid forecasting and instead examine likely future trends based upon some facts, some extrapolation of the trends of the last three decades, and some personal observations which may be subject to difference of opinion.

For two reasons I will focus my comments on a few widely traded agricultural commodities in which the United States has a major interest. One is that these are products about which I presume to have some knowledge; the second reason is that the nature of production, storage, and consumption of these agricultural commodities differ sufficiently from other primary commodities to warrant separate treatment. Even with these limitations, I would hope to be able to evoke some useful discussion and thought about future problems and policy issues.

The basic points I hope to make are (*a*) trade flows in many of these commodities have changed drastically in the past three or four decades; (*b*) the behavior of countries which play an increasing role in commodity trade results in greater uncertainty and instability in world markets for most of these commodities; (*c*) traditional adjustment mechanisms no longer function satisfactorily and as a result the adjustments fall on relatively small groups; and (*d*) given these circumstances and the unwillingness or inability of certain groups to tolerate the prospective situation, new institutional mechanisms for adjustment must be found as rapidly as possible.

Because I believe the way world commodity markets operate is a function of the policies and actions of participant nations in those markets, I will begin by reviewing the levels and composition of trade in agricultural commodities in which we have an interest. I will discuss trade trends in wheat, coarse grains, sugar, soybeans, cotton, and meat and animal products. These products currently account for 90% of United States agricultural exports, thus they are of major interest. I have classified countries into three categories—developing market economies, developed, and centrally planned, recognizing that the latter category includes both rich and poor countries.

Review of the Level and Composition of Agricultural Trade

Let me start my discussion with grains, namely wheat and coarse grains, commodities in which we have a significant export interest. As one looks at the data on world trade in these grains there are two factors that sharply distinguish them from many other internationally traded commodities and that have significant implications for the future of the grain trade.

The first is the major expansion, indeed one might almost suggest explosion, in the level of trade in both wheat and coarse grains over the last four decades. World trade in wheat, for instance, during the period immediately prior to World War II averaged less than 17 million metric tons per year. In the immediate post-World War II period trade in wheat increased by about one-third, with most of that increase occurring after the 1950s.

Starting with the 1960s, there have been substantial increases in world wheat trade. Using 1960 as the base year, we now find that the average world trade in wheat in the last

---

Dale E. Hathaway is Undersecretary of Agriculture, International Affairs and Commodity Programs.

This paper is adapted from remarks prepared for the Conference on Agricultural Marketing Policies for the 1980s, Perth, Western Australia.

The author is indebted to Gary Williams, U.S. Department of Agriculture, for the statistical work, and to Dr. G. Edward Schuh for comments.

three years is double that of the early 1960s. To briefly summarize, there was an approximate doubling of world wheat trade from the late 1930s until approximately 1960. Since that time, in less than two decades there has been another doubling of wheat trade and, it should be noted, current record levels of wheat trade have been maintained despite concurrent new world records in food grain output. Indications suggest that we can expect continuation of the increase in these trade flows.

The rate of increase in world coarse grain trade has been even more rapid than world wheat trade. Prior to World War II, coarse grain trade was reported somewhat below wheat trade, at about 15 million metric tons per year. Immediately after the war and continuing through the 1950s, there was no appreciable growth in coarse grain trade, unlike the growth in wheat trade. Starting, however, in the 1960s and continuing almost without interruption, there has been a veritable explosion in coarse grain trade which is now approximately six times the pre-World War II level and more than three times the 1960 level.

The second important element relating to world trade in grains is not only its growth, but the change in who exports and who imports. In the case of wheat prior to World War II, the developed market economies accounted for 60% of the exports and for two-thirds of the imports. In other words prior to World War II, more than half of world wheat exports originated in developed market economies, namely North America and Australia. Importers were mostly the developed market economies. After World War II this situation drastically altered. The trend is clear and there is no indication that it is changing. Throughout the post-war period and continuing to the present time, the proportion of exports furnished by developed market economies has grown steadily; they now provide more than 90% of total world wheat exports. Conversely, whereas the proportion of developed market economy imports has dropped from three-quarters to one-quarter of total wheat trade, the developing countries now account for half or more of all wheat imports and the centrally planned economies account for a quarter of all wheat imports.

For coarse grains, the trend in market shares has both some parallels with wheat and some important differences. Prior to World War II developing market economies exported nearly 60% of all coarse grains entering the world markets. The centrally planned economies provided another 20%. Thus, the developed market economies provided less than 20% of world coarse grain exports forty years ago. At that time the major importers, in fact virtually the only importers, were the developed market economies which imported 85% of all coarse grains entering world markets. During the prewar period, the developing market economies accounted for only 2% of the coarse grain imports while the centrally planned economies accounted for about one-eighth of the imports.

Looking at the post-World War II period we see a new trade pattern has evolved steadily and consistently. The developed market economies, namely North America and Australia, increasingly have come to dominate exports of coarse grains to the point where they now account for more than 80% of the exports of coarse grains entering world markets. This has been accompanied, as might be expected, by a steady decline in the proportion of exports coming from both centrally planned and developing countries.

A marked shift in the import pattern for coarse grains has also occurred. During the post-World War II period the advanced or developed market economies show a steady and continuing decline in the proportion of coarse grain imports, and if one removed Japan from these statistics the decline would be even more apparent. Concurrently, the developing market economies and the centrally planned economies have increased their imports of coarse grains.

To summarize the changing trade patterns for these two major grains, we have seen the developed market economies rapidly become the major source of exports while the developing market economies and the centrally planned economies have become the significant grain importers during the post-war period.

Soybeans

Let me discuss briefly another major traded agricultural commodity—soybeans and soybean products. As in the case of wheat and coarse grains, world trade in soybeans has grown tremendously. Prior to World War II, soybean exports were dominated by China, a developing country, and the developed market economies were the major importers. Since World War II there has been a sharp change in

exporters, but the importers have only recently begun to change. Since World War II the advanced market economies, namely the United States, have held a dominant position in world soybean exports, while Brazil and Argentina have replaced China as the only other exporters of consequence. The developed market economies, however, are still largely the importers (in fact, more than 80%). However, the centrally planned economies have been importing significantly more soybeans since about 1960.

Wool and Cotton

Now let me turn to trade in two other commodities, namely wool and cotton. Here we have commodities in which world trade patterns have been different than for grains. The differences, I believe, are significant in several ways. For wool, the data indicate that the level of world trade in wool in the mid-1970s was not markedly higher than prior to World War II or in the immediate postwar period. Indeed, it appears there have been periods during the 1970s in which the average level of world trade was lower than it was during the late 1930s. Not only has world wool trade not expanded, there has not been a sharp change in the patterns of world trade. Prior to World War II the trade was dominated by the developed market economies both on the export and import side. This pattern has continued, the only change has been a decline in developing country exports and their share of world trade; therefore, again the developed market economies now provide an increasing percentage of world exports (about 90%). The wool imports of both the developing market economies and the centrally planned economies appear to be rising in a somewhat irregular pattern while the import share of the developed market economies is trending downward.

World cotton trade shows many similarities with world wool trade and some dissimilarities. As in the case of wool, world cotton trade has not expanded rapidly since World War II as have grains and soybeans. Indeed, the level of trade in the 1970s was not markedly higher than the level achieved in 1960. There have, however, been some significant shifts in the trade patterns for cotton.

Cotton is one agricultural commodity where the advanced market economies have steadily and consistently lost export market shares, mostly to the centrally planned economies. The developing countries, which still provide slightly more than half of the world cotton exports, have maintained their market share at the same levels they enjoyed immediately prior to and after World War II.

There also have been significant shifts in world imports of cotton. Whereas developed market economies constituted more than three-quarters of import markets during the late 1930s through 1950, they now import only half of the world's cotton. At the same time, the developing market economies have increased their cotton imports to nearly a quarter of all the cotton traded at the present time. Centrally planned economies have now increased their import share to more than a quarter of all world trade. Thus, for cotton we find a situation where both the export and import shares of the advanced market economies in world trade have declined mostly because of the export expansion of centrally planned economies and the imports of both the developing countries and centrally planned economies.

Meat and Animal Products

Trade in meat follows the pattern of the other foodstuffs. It has expanded rapidly since just after World War II and especially so since 1960, but the rate is slower than for grains or soybeans. As in other foodstuffs, however, it is the expansion of exports from developed market economies that has been most rapid, while developing countries and centrally planned economy exporters have lost export market shares.

One would expect the meat imports would go in large part to developed market economies, and this is the case. It is worth noting, however, that the growth rate in meat imports is much faster in both developing and centrally planned economies. The two groups now import about one-fifth of meat traded on world markets.

Sugar

Finally, let me summarize the trends in world sugar trade. Here again is a commodity that did not experience a substantial expansion in world trade between the late 1930s and the mid-1950s. Since that time, however, there has been a slow but steady expansion in world trade. By the late 1970s, world trade in sugar

was 50% higher than it was two decades earlier. Again, there has been a substantial shift in both the sources of exports and imports. Here again the advanced market economies have increased their share in world export markets. The developing market economies, which have always dominated sugar exports, have experienced a decline in the world export market share, while the centrally planned economies appear to have maintained an irregular but approximately stable share of world trade over a long period of time.

World sugar imports also have shifted. Between the late 1930s and 1950, the developed market economies imported 80% of the raw sugar traded. This share has now fallen to only slightly more than half of all imports. The share imported by developing market economies has grown moderately but not significantly and still fluctuates around one-fifth of world sugar imports. The major change has been in the centrally planned economies that have rapidly increased their sugar imports over the last two decades.

Can one generalize from this brief review of commodity trade patterns? I believe that some generalization can be made and that certain implications can be drawn.

First, the major growth in agricultural commodity trade has occurred in basic foodstuffs and the growth rates have been highest for products associated with personal income growth, i.e., coarse grains and soybeans. The growth rate for products for which there are close substitutes, namely fibers, has shown modest or no growth in trade.

Second, with the exception of cotton, the export shares of the developing countries have declined and those of the developed market economies have risen.

Third, with the exception of wool, the developing countries and/or the centrally planned economies are becoming increasingly important importers. In the case of wheat, these two groups of countries account for a combined total of three-fourths of the imports and for about half of world imports of cotton and sugar. In coarse grains, these two groups of countries account for 40% of all imports and for a fifth of all world soybean imports.

Future World Patterns of Trade

Are the patterns of trade of the past two decades likely to continue? My view is that they are. Among the reasons I would cite is that the bulk of the world's population increase is and will be in the developing countries and centrally planned economies. Second, in those countries increased income is likely to be translated into increased consumption of grains, soybeans, sugar, and meat and poultry products. Finally, for a variety of reasons including natural resource endowments, structure, and climate, it appears that domestic production of many of these commodities is unlikely to expand sufficiently to meet the internal needs of the developing and centrally planned countries concerned.

Trade Trends and Adjustment Mechanisms

Even though the levels of agricultural commodity exports from the developed market economies have been increasing and, thus, producers of those commodities have benefited substantially from larger markets, certain factors have not changed. What has not changed, even with modern technology, is the fact that the production of these agricultural commodities is a biological process subject to influences outside the control of man (weather) and subject to relatively inflexible lags in production response to price changes.

These adjustment problems have always been there, although they certainly are increased by the high capitalization and large cash flow requirements of large-scale modern agriculture (Hathaway).

Under a more liberal trade regime which once prevailed among the developed market economies it was possible to achieve adjustments in consumption and private stockholding as well as in production. In trade between market economies if supplies were short prices rose, consumption fell, and the adjustment was spread relatively evenly between trading nations. If supplies were large prices fell, consumption increased, and the incentive for private stockholding increased; and producer adjustment, while difficult, was achieved, often with some assistance from governments.

But what are the adjustment mechanisms in the current and future trading world for most economies? By definition, centrally planned economies have a high degree of, if not complete, government control over imports and exports, and thus, import demand is not a reflection of the variables economists nor-

mally use. In general, lower world commodity prices are not reflected in increased consumption levels nor are markedly higher world prices allowed to be reflected in reduced consumption. Thus, almost by definition this portion of the world trading economy does not allow the market mechanism to produce trade adjustment.

It also happens that the government role in imports, exports, and internal pricing of these agricultural commodities is significant in most developing countries. The reasons are somewhat different. When supplies are tight it is neither economically nor politically feasible to reduce consumption levels where large portions of the population already are at or near subsistence levels. Conversely, there are certain political and economic risks involved in expanding consumption markedly during periods of ample world supplies, given the uncertainty over the ability of the economy to sustain the higher levels in periods of shorter supplies and higher import prices. Therefore, developing countries also tend to not allow market adjustment mechanisms to function as our liberal trade adjustment theory would suggest.

In addition, a number of developed market economies have chosen for a variety of reasons to use mechanisms which isolate their consumers from world market prices and, thus, trade patterns based on market adjustment mechanisms no longer function. As a result, the countries which allow some element of market adjustment to occur are the few open market economies, and thus the burden of this adjustment falls heavily upon the producers and consumers in developed exporting countries.

If one reflects on these facts, it is easier to understand the noticeable reluctance to discuss trade liberalization in grains and a similar reluctance for consumption adjustment measures in discussions of price stabilization agreements for grains. This reluctance stems from the fact that market adjustment mechanisms are inconsistent with the economic policies concerning consumption and trade that is being followed by countries that now constitute the majority of the world's import market.

Implications of These Trends for Market Stability

What are the implications for price stability in world trade patterns when the major importing countries reduce or do not allow market adjustment and when exporting countries are primarily market economies?

The expected implication is greater price instability through time. Using a simple measure of price variability in world markets,[1] a rather steady and noticeable increase in that variability is evident. This was masked by U.S. stock accumulation policies of the 1960s, which contributed to significant price stability in world wheat and coarse grain markets as a byproduct of domestic programs.

Many have argued that the great instability in world commodity markets which we experienced in this decade was the result of an unusual run of bad weather followed by an unusual run of good weather in major producing countries. I believe this is not the underlying reason. In fact, if one examines the data, the deviation from world production trends is not markedly different in recent years than in prior periods. What is different is the increased role of trade in determining commodity prices of exporting countries and the increased quantity of that trade done in a world economy which is fully or partially isolated from traditional market adjustment mechanisms.

If my assumption that increasing instability is likely to be a characteristic in future world commodity trading patterns, the question that follows is whether the major exporters or many of the importers can cope with the potential instability. Speaking as an official in a country which is both a major exporter and a major importer, I believe the answer is no. Our producers have experienced great difficulties in this decade, and our consumers and the consumers in many importing nations have also had painful experiences.

Implications for Future Trade Policy

If my reading of past trends is correct; if my assessment that they are likely to continue accepted; and if my belief that the likelihood is low of either centrally planned or developing countries adopting adjustment mechanisms as a part of their trade policy, then we as exporters must reexamine our approach to trade and price stabilization.

The present trading and adjustment system

[1] A simple coefficient of variation was computed by five-year period and by decade for the commodities involved.

puts virtually all of the adjustment on producers in a few exporting countries during periods of large supply. Conversely, in periods of short supply the burden falls upon the consumers in a few countries, namely those that allow consumer prices to reflect world prices either through their market system or because of their inability to isolate themselves from external forces. I doubt that such a system is likely to prove sustainable for either producers or consumers for a prolonged period.

One alternative that could emerge is for current and prospective imports to embark upon a program of expensive self-sufficiency. This alternative finds many supporters in importing countries, especially in those countries which produce a significant portion of their own needs. I do not think I need to point out the implication of that course for producers in countries which are heavily dependent upon these export markets.

A second alternative, which has been pursued by the United States in recent international commodity negotiations, has been international stockpiling to reduce commodity price instability. The U.S. position has been that stockpiling costs should be shared by importing and exporting nations—a position that was viewed more favorably by others for sugar where we are a major importer than for grains where we are a major exporter.

Third, I conclude that the new realities of commodity trade lead to a need for new institutions. I am not prepared to suggest what changes are needed or possible, indeed, I believe that one cannot generalize from commodity to commodity. I believe, however, it is time to recognize that our ability to produce and export has outrun our institutional capacity to deal with the emerging trends in world commodity trade. It is time to turn our attention to building national and international efforts to cope with the new realities.

Finally, let me close by commenting on the role of economists in dealing with these problems. My view is that they have been grossly inadequate in several ways. First, they have failed to recognize the political realities of the world in which commodity trade occurs. Second, there has been little or no work done on the economics of commodity trade in a world where state trading organizations play an increasing role, especially on the buying side.

Australia, Canada, and the United States: Trade Partners or Competitors

Alex F. McCalla, Andrew Schmitz, and Gary G. Storey

Australia, Canada, and the United States are three of the world's largest traders in temperate zone agricultural commodities. More than two-thirds of world exports of wheat, feed grains, and oilseeds originate in the three, with the United States accounting alone for nearly 40% of the wheat, 70% of the corn, and nearly 80% of the soybeans exported. In addition 25% of the world meat trade occurs among the three. Beyond these items, there is significant bilateral trade in fruits, vegetables, and assorted other products. Agricultural trade is important to the countries themselves. Agricultural exports accounted for the following percentages of total exports in 1976—Australia 43.5%, United States 20.6%, and Canada 11%. Agricultural exports are even more important to the agricultural economies of the three countries. It is not surprising, therefore, that there is an interesting set of agricultural trade issues in which all three have vital interests.

The task of this paper is to address some of these trade issues. The title of the paper suggests one approach. We have interpreted trading "partners" to mean those cases where the three countries have significant trade among themselves. In this context four such trade relationships are identified: meat exports from Australia to the United States and Canada; live animal trade; feed stuffs trade and fruit and vegetable trade all between Canada and the United States. We have interpreted "competitors" to mean those cases where the countries compete with each other for third country markets. The obvious and dominant competitive relationship is in grains. Grain exports in 1976 accounted for about 40% of Australian, 56% of Canadian, and 57% of U.S. agricultural exports.

Our justification for concentrating on this subset of issues is that they represent the majority of trade and also they are trading relationships where domestic policy choices are transmitted through the international market to other countries. Conversely, we have excluded from consideration commodities where isolationist policies are pursued, e.g., dairy, tobacco, and sugar or where none, or only one, of the countries is a major producer, e.g., fibers and tropical products.

The next section of the paper presents some data to further describe the trade in the identified products. We also note the trade restrictions that apply. In the following section we discuss the set of bilateral or trilateral trade or "partnership" issues. Section four discusses the competitive issues in the grain markets. Section five identifies some major policy issues that are involved in these relationships. As one might expect, because of the size of the United States, U.S. domestic policy actions have greater impacts on her two smaller neighbors than their policies have on the United States.

The Quantitative Nature of Trade Relationships

Table 1 presents some historical data on the trade in grains and oilseeds originating in the three countries. Third country markets are of much greater importance than intercountry trade. In the period 1975–77, wheat was the largest traded item with the three countries exporting more than two-thirds of total world exports. Trade in wheat between the three countries is small both because each country appears to have similar costs and, therefore, comparative advantage and because of trade barriers erected to protect domestic programs. The United States applies quotas as well as a 21¢ per bushel tariff. Canada requires import licenses managed by the Canadian Wheat

Board and applies a 12¢ per bushel tariff. Australia appears to prohibit grain imports. Trade in feed grains and oilseeds is likewise principally with third countries. One exception is exports of corn and soybeans by the United States to Canada. These volumes, though small relative to total U.S. exports, have significant influences on Canadian prices. Imports of these products are generally regulated by tariffs. Reductions in tariff rates were negotiated in the recent Tokyo Round. These proposed rates are shown in parentheses behind current rates. The United States applies the following rates: barley 7.5(5)¢/bushel (bu.), oats 7(0)¢/bu., corn 25(5)¢/bu., sorghum 40¢/hundredweight (cwt), soybeans $1.00(0)/cwt; Canada applies the following rates: barley 12(5)¢/bu., oats 4(0)¢/bu., corn 8(5)¢/bu., sorghum (5)¢/bu. and oilseeds free. Licenses are required on oats and barley. Australia apparently prohibits grain imports but admits oilseeds free of duty though an import permit is required.

Trade in Meat and Live Animals

Table 2 presents data on trade in beef and veal and live cattle. Trade originating in and/or between the three countries in other products—poultry, pork, and sheep meat as well as processed meat is relatively small with the three representing in all categories less than 10% of world trade. The principal trade flow of interest is the export of fresh and frozen beef from Australia to the United States and Canada. The meat trade is almost as important to Australia as is trade in wheat. Further, more than two-thirds of Australian exports go to North America. However, given relatively low trade barriers between Canada and the United States, there exists something approaching a North American meat market which transmits external impacts to both countries. There is also a significant trade between Canada and the United States in live cattle. Trade barriers in the livestock and meat trade are complicated. Again they were the subject of GATT negotiations. Both current and proposed restrictions are presented with the latter in parentheses. U.S. barriers are: live animals—1-1/2¢/pound (lb.) or 2-1/2¢ depending on weight (1¢/lb.–no quotas), beef and veal–3¢/lb. with a quota if imports exceed 7% of domestic consumption (2¢/lb.–possibly countercyclical quotas). Canada barriers are: live animals 1-1/2¢/lb. (1¢), beef and veal 3¢/

lb.(2¢). However, health and sanitary restrictions may be more important than tariff barriers. Australia requires import licenses and these in conjunction with health restrictions virtually prohibit imports (Hillman).

Trade in Fruits and Vegetables

The United States is the dominant exporter of these products. In the fresh product categories—fruits, nuts, and vegetables—Canada represents a large and important U.S. market with more than one-third of U.S. exports going to that market. Exports of processed products are more diversified. Trade barriers in this trade are minimal except for low seasonal tariffs applied by Canada on competitive crops during the summer production season.

In summary, there exists a complicated trading pattern. The three countries dominate the export side of the grain market and therefore are major competitors for import markets. However, this competitiveness in third country grain markets is related to intercountry trade through U.S. exports of corn and soybeans to Canada. This trade in turn is influenced by Canadian attempts to integrate her feed grain and livestock economy into a North American market. Australia is tied into this market through substantial meat exports to the United States and Canada. In addition, meat production in Australia is partially competitive with wheat production. Thus what appear on the surface to be separate and distinct markets are in fact highly connected through trading relationships.

"Partnership" Trading Relations

In this section of the paper we introduce some of the major issues relating to intercountry trade. Each of the topics would fill an entire paper or monograph. Therefore what we present are vignettes to highlight the issues.

Meat Trade

The establishment of the European Common Market (EC) and the subsequent entry of the United Kingdom fundamentally altered the world beef market. These structural changes coupled with rising U.S. demands for ground beef shifted the axis of Australia's meat trade from Europe to North America. Australia exports about 25% of her beef production into the U.S. market. Given that the cattle cycles in North America and Australia appear now to coincide and that the U.S. market is preferred by Australia, U.S. import policy has a direct bearing on Australian farm income. Current U.S. policy is one of a quota directly tied to domestic utilization which expands and contracts in direct proportion to U.S. production. The United States is currently debating a countercyclical import policy which would expand quotas in low marketing-high price periods and contract it in low price periods. The explicit objective of such a policy would be to reduce the amplitude price changes over the cattle cycle in the U.S. market. However, it would also export instability to Australia. The policy question facing Australia is how to respond. If the Australian cattle cycle remains in phase with the United States, such a policy would increase price instability in the Australian domestic market. On the other hand, if Australia could supply the same quantity of beef over the cattle cycle, export earnings would clearly increase. The optimum policy for Australia would be to shift her cattle cycle out of phase with the U.S. cycle. The interesting conundrum for policy makers would be how to do that.

North American Trade in Livestock and Meat Products

Live cattle, beef, and veal are the most important items in U.S.-Canadian trade. Trade in pig meat and poultry is small, but moving to the advantage of the United States. Little trade in sheep meat or processed meat occurs.

Structurally, the beef cattle cycles in the United States and Canada followed very similar patterns from 1950 to 1979, except for the short period 1965–69 when Canadian commercial slaughter as well as cattle numbers on farms declined whereas there was general expansion in the United States.

The North American regional trade patterns in cattle, beef, and veal are such that Canada exports feeder cattle from Western Canada and slaughter cattle from Eastern dairy and Western beef herds to the United States. The United States in return exports finished slaughter cattle for the meat deficit Eastern Canadian market.

Traditionally, U.S.-Canadian trade in livestock and meat has been relatively free of trade barriers. In recent years, however, na-

tional policy considerations have resulted in the introduction of various intermittent trade barriers. There was an escalation in U.S.-Canadian nontariff barriers starting with the U.S. imposition of a ceiling on retail meat prices in March 1973. The lifting of the ceiling in September 1973 resulted in a flood of cattle onto both the United States and Canadian markets. The effects are different because of the relative size of markets. The United States beef industry dwarfs the Canadian industry by a ratio of approximately 10:1 which at times has resulted in disequilibrium effects and has precipitated trade retaliatory actions by Canada in recent years. For certain weeks in 1973–74, U.S. imports reached approximately 30% of total Canadian slaughter. Canada countered with higher tariffs and import surcharges.

A tendency, particularly by the Canadian government, has been to introduce health regulations on cattle and beef imports. In April 1974, Canada required import certification to prevent the importation of meat of animals that had been fed diethylstibestrol (DES). As the United States has just recently (July 1979) introduced a ban on the use of DES, Canada has lifted this requirement. Canada also requires tests for blue tongue and annaplasmosis. The United States in 1977 applied import restrictions because of brucellosis problems in Canada. In addition, both countries apply quotas on dressed beef imports.

The recently completed GATT negotiations have led to tariff concessions, resulting in cuts of 40–50% and a move to more tariff-free categories. However, in assessing impacts it is clear that tariff levels have had a minor effect on trade in comparison to U.S.-Canadian exchange rate fluctuations and the much more restrictive nontariff health regulations and import quotas. In the future it appears that trade barriers will continue to be episodic based on serious market shocks.

The North American Feed Grain Market

United States-Canadian trade in feed grains is not large in comparison to total international trade and is relatively free from trade restrictions. Traditionally Canada has been an importer of United States corn for the deficit Eastern Canadian feed grain market. U.S. corn exports to Canada average 833,000 metric tons for the 1971–76 period but have declined more recently partly as a result of increased Canadian corn production. Canada is approaching self-sufficiency in corn, as production has doubled in the last ten years (Agriculture Canada 1978b).

Canadian barley exports to the United States ranged from a high of 288,000 metric tons in 1971/72 to a low of 99,000 metric tons in 1977/78. Of this total, U.S. imports of Canadian barley for malting purposes has trended upward, representing 53% of total barley exports in 1977/78 (Canadian Wheat Board). North American trade in oats and sorghum is insignificant.

Of importance to Canada-U.S. trade relations in feed grains is (*a*) the dominant position of the United States in the international feed grains market and (*b*) the Canadian feed grain policy and market structure.

In 1948/49, prairie feed grains, oats, and barley were placed under the control of the Canadian Wheat Board (CWB). This essentially created two feed grain regions in Canada, as the CWB had monopoly control over both export and domestic sales except for feed grains sold outside regular channels on a farm-to-farm basis within each prairie province. This situation created a political backlash against the CWB in the late 1960s as surplus feed grains in the prairies depressed prairie prices, while the CWB continued to price prairie feed grains at corn competitive prices in Eastern Canada. Regional price distortions favored livestock feeding in the prairies. Eastern Canadian livestock and feed grain interests were successful in pursuading the Canadian government to introduce a new feed grains policy which came into effect 1 August 1974.

The new policy essentially provided for a dual market structure, with the CWB retaining responsibility for prairie feed grain exports and domestic nonfeed utilization. Domestic Canadian feed grains were placed back on the open market. Prairie producers now had two main marketing options: (*a*) to deliver feed grain to the CWB where the price is pooled or (*b*) to deliver to the open market where price is set daily. Farm deliveries to the CWB are restricted by quotas which are largely determined by the extent of CWB export sales. Deliveries to the open market have not been restricted by quotas, but are limited by storage capacity regulations, which have not been duly restrictive. However, starting 1 August 1979 domestic marketings will be subject to quotas.

Although the CWB cannot purchase feed grains delivered to the domestic market, it is required to be a residual supplier to the domestic market. Beginning 1 August 1976, the CWB was required by the Canadian government to offer feed grains to the domestic market on a price formula which is based on the price of U.S. corn and soymeal (49%) at Montreal.

The feed grains policy was designed to provide fair and equitable prices. These price performance objectives have not been met. A comparison of the domestic cash price of barley and the CWB formula offer price at Montreal shows wide price differences. For example, the open market corn price in the third quarter of the 1975/76 crop year was 12% above the CWB formula price while in the first quarter of the 1979/80 crop year it was 21% below the formula price. This pricing problem essentially rests with both the structure of the feed grain market as described and the export decisions of the CWB.

As a result of low wheat exports and the wheat acreage reduction program in 1971, which resulted in increased barley production, the CWB developed an aggressive barley export program. Barley exports increased from 462,000 metric tons in 1968/69 to 4,883,000 metric tons in 1971/72. This was accomplished largely by the CWB offering barley below U.S. corn prices, which it was able to do without fear of U.S. retaliation because of the small Canadian market share internationally. However, in the last several years the CWB, in attempting to maximize producer revenue from grain and oilseed sales, has decreased barley exports to allow the export of higher valued wheat, flax, and rapeseed in an industry constrained by transport capacity. This has resulted in low barley delivery quotas, a build up of farm stocks, and increased farm sales to the domestic feed grain market. Increased domestic stocks have been instrumental in forcing down the domestic cash and futures prices, thus creating the price distortions. The move to lower Canadian barley prices *vis-à-vis* corn, resulted in increased Canadian corn exports and reduced U.S. corn imports. The result has also meant an income transfer from feed grain to livestock producers. Lower Canadian feed grain prices relative to corn also would tend to offset the comparative cost advantage the United States has had in livestock feeding.

Trade in Fruits and Vegetables

Canada imports more than half of its agricultural imports from the United States. Fruits and vegetables are major items in this trade. However, the export market is of relatively minor importance to U.S. producers in many commodities. The major exception would be fresh citrus from the West and nuts such as almonds and walnuts. Given that trade barriers in these commodities are minimal, happenings in the U.S. market significantly influence Canadian markets as this market is considered as part of the U.S. fresh market. Much of the U.S. fruit exported to Canada is regulated by market orders. Market orders tend to allocate products between fresh and processed markets. Casual observation of the behavior of market orders suggests that the orders maintain relatively stable shipments to the fresh market and adjust the quantities going to the processing industry with changes in production. For example, if one looks at the utilization of California-Arizona oranges and lemons one finds very stable shipments to domestic and export fresh markets and relatively wide swings in quantities going to the processing market which are directly correlated with changes in production.

"Competitive" Trade Relationships

All three countries are major exporters of grain. In the case of wheat they are most akin to large oligopolists who must take each other's actions into account. A number of authors have attempted to describe relationships among the countries. The most recent piece by Alaouze, Watson, and Sturgess postulates a triopoly price leadership model. On the other hand the overwhelming dominance of the United States in the feed grain market probably allows Canada and Australia to behave as fringe competitors who can export all they want at prices just under those of the United States. Thus the most interesting questions seem to center around the wheat market.

The failure of the Tokyo Round to reach an International Grains Arrangement has reopened the question of price stability in international markets. It is argued by state trading exporters such as Canada and Australia that a market without some form of stabilization agreement operates to the detri-

Table 3. World Wheat Market Shares

Year	Total World Exports (mmt)	Market Shares (%)			
		Australia	Canada	U.S.	Total of Three
1965/66	62.0	9.2	23.9	37.7	70.8
1966/67	55.8	12.5	26.5	35.8	74.8

ment of producers and to the advantage of large exporters and multinational grain firms. To some extent they base their case on their loss of market shares in the turbulent period 1972–75. Table 3 shows the three countries' market shares from 1965 to 1977. Two things stand out clearly. First the share of the export market held by the three countries is rising, now being consistently over 75%. Second, and more interesting, is the fact that the United States share of the market rose dramatically in 1972 and has remained ten percentage points higher in the post-1975 period. This growth in U.S. shares came at the expense of both Canada and Australia. Part of this change can be explained by the dissipation of large U.S. stocks but not all. Clearly the United States emerged from a period of market instability with a larger market share.

However, some in the United States argue that U.S. farmers did not benefit. Thus Americans, such as Congressman Weaver, are supporting Canada and Australia in their call for a grain export cartel. Despite the dismissal of the notion of a cartel as impractical and unworkable by the grain trade among others, it is worthwhile to consider the question. It is well known that for a cartel to work the members must control a significant part of supply, face sloping demand functions, have barriers to entry, and not encounter importer market power. In sum, for a cartel to work it must be a sellers' market and not a buyers' market as hypothesized by Carter and Schmitz. The cartel notion is seductive in that it would allow the exporters to capture monopoly rents which are now going to importers such as the EC and Japan. But developed country importers now account for less than 20% of world wheat imports. Much more important are lesser developed countries (LDC) and centrally planned markets. While it might be argued that the demand for wheat by the USSR and China is price inelastic, it is not so clear that it is for the LDCs. If the LDC demand (now 60% of the market) is price elastic, a price increasing cartel could be counter-productive for exporters and disastrous for the LDCs. On the other hand, a feed grain cartel would seem to have greater potential for success. We are not advocating a cartel. Rather we raise the topic as a policy issue deserving of detailed policy analysis.

Partnership and Competitive Interrelationships

Our discussion has dealt with components of the trading system and therefore domestic interfaces among the three countries. Yet it is obvious that, except for the fresh fruit and vegetable trade, the markets are closely tied together. For example, a significant change in crop conditions or policy in a major grain importer has repercussions on all three countries. Large increases in Soviet grain purchases expand export demand and drive up domestic grain prices in all three countries. Rising feed grain prices reduce the profitability of cattle feeding and reduce feeder steer prices in Canada and the United States reducing the profitability of cow-calf operations. Proportionately more cows and heifers go to market

causing an increase in marketing and decreases in prices. However, as marketings rise, so does the U.S. import quota which further depresses prices. The United States reduces imports of Canadian feeder cattle but expands imports of Australian beef. Thus the USSR purchase has similar direct impacts on all three countries—namely to increase grain prices, but it has different indirect impacts on the livestock industry. U.S. and Canadian industries tend to contract while the Australian industry would tend to expand. Australia experiences a double benefit because of U.S. beef policy. Obviously, if the United States adopted a countercyclical policy, the impacts would be the opposite on Australia.

A second example of interconnectedness occurs in the grain livestock sector of North America. This is a very complicated subject upon which much has been written (*Canadian Journal of Agricultural Economics*). More recently Agriculture Canada (1978a) has developed forecasting models for a number of the components of the North American livestock economy. Thus it would be presumptuous here to delve deeply into this area. It is sufficient to note that Ottawa appears to be moving unilaterally to become more closely related to U.S. markets in feed grains and livestock. As noted earlier it is the clear objective of Canadian feed grain policy to price Canadian barley at corn competitive Chicago prices. Yet another agency of Canadian policy—the Wheat Board—by virtue of its capacity to price discriminate appears on occasion to run counter to that objective. All of this increases uncertainty in Canadian agriculture.

Concluding Comments

Our objective in this paper has been to identify some of the trade and domestic policy issues that arise because of the trade relationships between Australia, Canada and the United States. It is clear that external shocks radiate through trade relationships to all countries. The impact of these external shocks can be exacerbated or dampened by domestic policy initiatives. The importance of international markets to all three countries raises directly the question of whether cooperation in all trading relationships would be preferable to competitive or independent actions. We suggest that this type of consideration underlies Australia's and Canada's interests in cooperative arrangements in the grain-livestock sector. The United States seems less interested because the domestic market is relatively more important and because of a strong commitment to domestic income support. Further the dominant role of the private sector in U.S. agricultural trade makes the contemplation of collusive government to government action less appealing. One thing is clear however from the discussion. What the United States does in terms of domestic and/or international policy changes will have significantly greater impacts on Canada, Australia, and world markets than will changes in the other two. Further decreases in trade barriers will increase this interdependence. Thus the three countries are both partners and competitors in agricultural trade. However, it is an uneasy partnership with the dominant country not always as sensitive to the impacts on others as it might be.

Agricultural Trade Issues among Pacific Ocean Countries: Discussion

Robert L. Thompson

Both papers presented in this session provide useful background information, and I find myself in substantial agreement with them as far as they go. However, neither paper directly addressed the theme of the session. After making several comments on the papers presented, I will comment on several important agricultural trade issues among Pacific Basin countries not treated in either paper.

Hathaway provides a useful review of trends in world agricultural trade flows and shares over the last four decades, but only tangentially discusses Pacific Basin trade issues. I concur with his identification of the developing countries and centrally planned economies as two of the most important determinants of future directions in international agricultural trade. He lists relative growth rates of population and real per capita income as important variables which drive the system. However, there are two related issues which he ignores. First is the ability to pay or balance of payments constraint of both developing countries and centrally planned economies. An important study by Valdes and Huddleston is in progress at the International Food Policy Research Institute on the likelihood of agricultural exports from developing countries being able to generate the foreign exchange to pay for their projected food import needs. We need a great deal more research on understanding the import decision-making process in both types of countries. Second, in developing countries food is a wage good which bulks large in both the consumer's market basket and in aggregate national income. Therefore, any change in food prices causes a significant change in real per capita income, thereby shifting the internal demand for food and, in turn, demand for agricultural imports. Similarly, any shock which shifts the agricultural supply schedule changes real rural incomes, shifts rural demand for food, and alters the marketed surplus beyond that expected from the supply shift alone. Hathaway is not explicit on what he assumes about the future real price of food. This will have an important effect on the future role of the developing countries in world agricultural trade.

Hathaway also emphasizes the effect of nontariff barriers to agricultural trade on the distribution of adjustments to shocks among trading countries. I concur with his statement of the problem, but would add that this is an area where we need much more research in attempting to understand and project changes in such policies and in turn their effect on agricultural trade. To be successful in projecting future agricultural trade, we must endogenize trade policy interventions in our analyses, rather than assuming an unchanging policy set. Lattimore and Zwart have made a very interesting start on this in a study of the world wheat market. Moreover, despite the fact that centrally planned economies have a high degree of government control over imports, I am not convinced that "import demand is not a reflection of the variables economists normally use." I would argue that our lack of understanding reflects inadequate research by analysts with the necessary combination of economic analysis, language skills, and institutional knowledge. We may find that import decision makers in centrally planned economies are much more rational than we presently think. Brainard's economic analysis of agricultural policy cycles in Czechoslovakia suggests that this is not as farfetched as it might sound.

In discussing the rationale for the insulating policies adopted by developing countries, Hathaway cites the political and economic risks associated with permitting consumption to increase markedly during periods of ample food supply. I feel the role of international price risk goes much deeper. Jabara and

---

Robert L. Thompson is an associate professor of agricultural economics at Purdue University, on leave with the International Economics Division; Economics, Statistics and Cooperatives Service; U.S. Department of Agriculture. Views expressed are solely those of the author and should not be interpreted as representative of the U.S. government.

Thompson recently examined the implications of international price risk for price policy in a small open economy. The results suggest that if policy makers are risk-averse and seek to maximize expected welfare of the residents of their country, the optimum policy is not to permit the world terms of trade to be reflected undistorted into the domestic economy as implied by the optimum tariff argument of conventional trade theory under perfect certainty. Rather, a higher expected level of utility is reached by distorting the domestic terms of trade away from the international terms of trade to move domestic production toward a more diversified product mix than under free trade. This provides a rationale for many developing countries' policies which artificially raise the domestic cereals price above the world price to stimulate greater food self-sufficiency, while depressing the domestic price of export crops.

Hathaway argues we should expect greater price instability through time in world markets. Therefore, our results suggest we should expect to see more trade barriers erected which insulate the internal markets from world price instability. If all developing countries do this, their collective efforts will lower the welfare of exporters and at the same time contribute to even greater world price instability. This suggests that it may be in the exporters' interest to support some scheme to achieve greater price stability in world commodity markets. I would second Hathaway's conclusion that we must find new national or international institutions to cope with the new realities of world agricultural trade.

McCalla, Schmitz, and Storey focus their discussion on three Pacific Basin countries: Australia, Canada, and the United States. They analyze whether the three are trade partners or competitors in their main traded products. With respect to competition in grains they suggest the three have "similar costs and therefore comparative advantage." Strictly speaking, comparisons of production costs, even when corrected for distortions (domestic resource costs), can say nothing about comparative advantage, but only absolute advantage. Comparative advantage is concerned with opportunity costs in terms of alternative products which can be produced with the same resources. Moreover, in discussing present and future competitiveness the authors ignore an important issue, the effects of investments in agricultural research and technological change on the locus of comparative advantage. A number of countries are expanding the resources devoted to agricultural research relative to the United States and thereby may be increasing their competitiveness in world markets.

McCalla, Schmitz, and Storey demonstrate that the U.S. market share in world grain trade increased after the period of price instability. It is important to remember that the total volume of world grain trade was growing rapidly as a number of countries' import demand schedules shifted upwards. An important question concerns the difference in the supply response possibilities of Australia, Canada, and the United States. This is related to the comparative advantage issue—both with respect to the total land available for crop production and the profitability of alternative uses for the land in grain production. That is, how do the size and shape of the production possibility surfaces differ among the three countries, and how are they changing through time? The focus of the McCalla, Schmitz, and Storey paper on market structure as a determinant of market shares clouds some of the underlying agronomic, as well as economic, bases for supply response in the respective countries. Differences in the structure of internal demand and substitution possibilities also are important here.

Two other important research issues are raised in the paper. They point out that optimum beef policy depends on whether the cattle cycles of the principal trading countries are in phase or not. A number of recent developments have been made in working out the capital-theoretic basis for livestock supply response (e.g., Jarvis). Some cross-country research applying these principles would seem to be very useful at this point. Second, the authors raise the grain export cartel issue. I would only reemphasize the need to draw upon imperfect competition theory and perhaps game theory in specifying richer models or paradigms for analyzing world grain trade among "large oligopolists who must take each others' actions into account."

There are a number of important agricultural trade issues among Pacific Basin countries which have not been brought out explicitly in either paper. The first is the future role of the People's Republic of China in world agricultural trade. The second concerns the demands by the developing countries of the region for greater food security, whether

through increased self-sufficiency, a reserve stocks scheme, or a food facility at the International Monetary Fund. A third is the issue of agricultural protectionism and adjustment possibilities, particularly in the high income countries of the region.

I will close by seconding Hathaway's call for much more research by agricultural economists to improve our understanding of the world market and its interaction with the domestic market in determining food prices and farm incomes.

Agricultural Trade Issues among Pacific Ocean Countries: Discussion

Leo V. Mayer

Expanded international trade has become a new national priority for the United States. Agricultural trade is the national success story of this decade. And trade in grain and oilseed products is drawing world leaders closer together. These are among the messages that Hathaway; McCalla, Schmitz, and Storey have brought us in their formal papers.

World agricultural trade is a growth story. While our speakers have described it in very low key, almost academic terms, it certainly can be described in far more exciting terms. The growth in both quantity and dollar terms exceeds what analysts have a right to expect, given the inelastic demand for food, the role of food in the national security of nations, and the protectionistic attitude of world leaders toward agricultural markets since World War II.

Against this background, the message in the Hathaway paper showing a doubling of world wheat trade since 1960, a tripling of world coarse grain trade since 1960, "tremendous" growth in soybeans over this same period, and substantial growth in meat and animal products, is far more impressive than it appears at first glance. Nations are placing more emphasis on how their populations eat and this is adding up to more imports of agricultural products. As a major food exporting nation, this trend has redounded to our benefit, and to Canada, and Australia, as McCalla, Schmitz, and Storey indicate.

McCalla and his colleagues also indicate that many restrictions remain between nations, including those imposed by fluctuating exchange rates as well as nontariff health regulations and import quotas, and the authors imply that these restrictions continue to prevent the ideal flow of trade between nations. Unfortunately, this "ideal flow of trade" is largely left out of this discussion. Were it to have been included, it would have been less descriptive, less explanatory of past trends, and more prescriptive and indicative of future trends. In this view, we might ask more nearly, "what should the future hold for agricultural exports rather than what has it held in the past?"

This point is on my mind partly as a result of my participation in the latest round of trade negotiations. Trade negotiations by their very nature focus attention on those commodities which each nation wants to export more of in the future. Obviously, the choices of each nation have to be based on economic feasibility, political acceptability, and international negotiability. But most importantly, trade negotiations force a nation to make choices and it focuses attention on the future.

It was this decision-choice process that I found of interest in the Tokyo negotiations. The U.S. government found it necessary to establish priorities on which agricultural commodities should receive international pressure for market expansion. The resulting assessments were rough in analytical terms but meshed more with trends in food consumption than we perhaps had a right to expect.

I mention trends in food consumption because that was where my attention focused as I examined the priorities on different food commodities in the negotiations. Future trends in food consumption in other nations supposedly will have some influence on the mix of future U.S. agricultural trade. The question was, "could one find any indicators of what that mix of food products was likely to be in future years?" One helpful suggestion came to me from my former colleague Heady who some years ago suggested in writing that "history will prove that the problems of agriculture will follow a definite pattern over time and under economic development . . . (the) . . . quantities needed to prove this proposition are time and economic growth in sufficient magnitude" (Heady, p. 3).

My application of Heady's point was that economic growth is providing many of our

Leo V. Mayer is a senior specialist for agriculture for the Congressional Research Service, Library of Congress.

best overseas customers with the necessary purchasing power to test his hypothesis. Certainly, we can count on the second condition, time, being fulfilled. As these conditions are met, it seems logical that several countries may follow the United States, particularly in terms of a changing mix of food products consumed and, of necessity, of products produced or imported.

That led me to look at the change in food consumption in the United States over the last forty years. Since we are all broadly familiar with it, great detail is unnecessary. Meat and fish consumption is up more than 60%, dairy products are down slightly, flour and cereal consumption is down substantially, and other major categories are much the same after four decades. The broad trends are that protein products increase and carbohydrates decline as development proceeds. Now the question is: does the pattern of U.S. agricultural exports show any such movement?

If one goes back a quarter of a century, the picture does not really support any such trend in U.S. farm exports. Instead, farm exports have moved in the opposite direction. Meat and poultry products have declined as a percentage of farm exports (table 1) and grain and oilseed products have doubled. While the value of all farm exports have doubled several times over, the trends in commodity composition are far different than one might expect, based on any theoretical analysis of changing patterns of economic development and food consumption.

The reasons are not hard to find. Concessional sales of a significant part of our farm exports over the last quarter century are partly the cause. Under public programs, we developed "receiving stations" for U.S. farm products in the low income nations. This practice led to a large increase in shipments to Africa and Asia, for example, relative to Europe and Oceania (table 2). Partly, the different trends are due to restraints of the type McCalla and his coauthors describe which have been imposed by other developed countries. Restraints have been placed on imports of meat by Japan, the European Community, and other developed countries. So while a large part of our exports is going where economic growth has provided expanded purchasing power, proportionately, the expansion has been in other areas of the world.

In my own mind, both the trends in composition of agricultural exports and the destination of those exports raise questions that I think need to be analyzed, and I would liked to have seen our authors discuss them. Perhaps we are doing as well as is possible in terms of our agricultural exports. It is very hard to argue with success like we have experienced since 1972. On the other hand, the need for success is even greater. The U.S. balance of payments is still negative, and will probably remain so for several years. Whether we could improve

on that situation by exporting higher valued farm products is a question that deserves more attention than we are giving it.

Thus, I conclude with several questions: Could we be even more successful if our government maintained a constant diplomatic effort at opening up overseas markets for higher valued farm products instead of the intermittent effort in trade negotiations? Would the higher demand elasticities of these types of products change the stability of agricultural trade, a factor that Hathaway feels is so important? Would expanded trade in higher valued farm goods be the best rural development program we could develop for rural America? Would it also be useful to developing countries by lowering the U.S. competition with them in producing basic farm commodities? Are we drifting into a raw-material-supplier status which has been so unbeneficial to other nations in the last few decades? These are questions that deserve attention.

The Effects of Changes in Population Characteristics on U.S. Consumption of Selected Foods

Larry Salathe

Numerous changes have occurred in the characteristics of the U.S. population since 1960. A steady decline in the birth rate has resulted in a decrease in average household size and the number of preteen children. Also, a sharp increase has occurred in the number of teenagers, young adults, and senior citizens. Other significant demographic shifts since 1960 include a decline in the proportion of the population living in rural areas, the northeast, and north central regions, and an increase in the proportion of the population consisting of nonwhite persons.

Several studies indicate that demographic factors affect food-purchasing decisions, but few studies have examined the impact of changing population characteristics on aggregate food consumption. The purpose of this paper is to explore past effects and implications of probable future changes in U.S. population characteristics on aggregate consumption of sixteen food categories. While past studies (LeBovit, Price, Schrimper, Serow) focus primarily on the changing age-sex composition of the population this paper examines, in addition, the impact of changes in racial mix, household size, and location of residence on aggregate food consumption.

Undoubtedly, statistical problems and data inadequacies have contributed to the general lack of research on the relationship between population characteristics and aggregate food consumption. Population characteristics for the most part change slowly over time, making it difficult, if not impossible, to estimate their effect on aggregate food consumption using time-series data.

Cross-section data have been widely used to estimate the impact of particular demographic factors on household food purchases. Analyses of these data suggest that household size and composition, location of residence, and race affect household food-purchasing behavior (Peterson and Buse). Detailed time-series data on household characteristics are required if results from these studies are to be useful in examining the effects of changes in demographic factors on aggregate food consumption. But population characteristics data pertain almost exclusively to individuals rather than households.

Larry Salathe is an agricultural economist with the National Economics Division, Economics, Statistics and Cooperatives Service, U.S. Department of Agriculture.

The Data

In this study, individual food intake data were used to examine the effects of changes in population characteristics on aggregate food consumption. These data were collected as part of the 1965–66 U.S. Department of Agriculture Food Consumption Survey (USDA 1969). In the spring of 1965, food intake data were obtained for members of 6,200 households. These households constituted the basic cross-section selected for obtaining data on household food consumption. After the household and individual socioeconomic and demographic information was obtained, respondents were requested to provide information on the amounts of various foods eaten by each household member for the day preceding the interview. Food intake included food eaten both at home and away from home. The sample consisted of approximately 14,500 individual records of which 13,771 contained food intake data.

Methodology

To isolate the effect of age and sex on food intake, individual records were segmented

into twenty different age-sex groups. The average intakes of sixteen foods for these groups are presented in table 1. These averages indicate that young children consume more milk and cereal products than young adults. Teenagers consume about the same amount of fats and oils, and larger amounts of milk, soft drinks, sugar and sweets, and bakery products than adults. Except for cereal products and fruits, consumption generally declines after adults reach the age of fifty. Males consume larger amounts of all foods, with the possible exception of fruits, than females of the same age.

Age and sex may not be the only factors that affect an individual's food consumption. Race, location of residence, and other socioeconomic and demographic factors probably also influence the quantity of food consumed. Regression analysis was used to isolate the impact of these factors on food consumption. The regression model expressed the quantity of the ith food consumed by the jth person in the kth household as a linear function of the kth household's income, size, a set of dummy variables defining the region (Northeast, North Central, South, West), a set of dummy variables defining urban, rural nonfarm, or rural farm location, and a set of dummy variables defining race (white, black, other). Household size and income squared were also included as explanatory variables. Separate regression equations were estimated for each of the twenty age-sex categories resulting in 320 equations.

These equations were used to estimate the impact of changes in population characteristics on per capita consumption of the sixteen food groups since 1950. The process of estimating the effect of changes in particular demographic factors since 1950 involved a series of steps. First, Census data were used to obtain estimates of the racial, regional, and urbanization mix for each age-sex group in 1950. Also, household size and income of each age-sex group in 1965 were adjusted to reflect changes occurring between 1950 and 1965. Using these values for the independent variables and Census data on age-sex composition, per capita consumption was estimated for the sixteen food groups in 1950. After these estimates were generated, per capita consumption in subsequent years was estimated by holding all but one demographic factor constant. In these calculations, the demographic factor took on values (for each age-sex category) that reflected its actual or projected change following 1950. Finally, per capita consumption indices were computed with 1950 equal to 100. These index numbers provide an indication of the percentage change in per capita consumption resulting from changes in a particular demographic factor.[1]

In the presentation of the results, 1950 is at times not used as the base year. The impact of demographic changes for such time periods was determined by first estimating the (percentage point) change in per capita consumption during the period resulting from demographic changes. This value was then divided by the actual percentage change in per capita consumption occurring between 1950 and the new base year. For the time period 1980–90, estimated changes in per capita consumption resulting from changes in population characteristics were divided by the percentage change in actual per capita consumption between 1950 and 1978. These calculations were not performed for soft drinks and bakery products in certain time periods because of a lack of information on per capita consumption of these products.

Results

Results of the analysis reflect both positive and depressive effects of demographic change on the five areas explored.

Age-Sex Composition

The U.S. population increased about 18% between 1950–60 (table 2). During this period, the proportion of children increased considerably, reflecting the post-World War II baby boom. The number of senior citizens also increased faster than total population growth. Changes in the age-sex composition between 1950–60 were estimated to have a depressing effect on per capita consumption of all foods except milk, cereal products, fruits, and sugar and sweets (table 3).

During the 60s and 70s the birthrate slowed, resulting in a decline in the number of preteen children. But the maturing of post-World

[1] It can be shown that the effects are not independent. In other words, the change in per capita consumption resulting from changes in all demographic factors may not be equal to the sum of each individual factor's effect. To avoid this potential problem, all demographic factors were allowed to change simultaneously when calculating the total effects of demographic changes on per capita food consumption.

[a] U.S. Bureau of the Census, Series II.

War II babies caused increases in the number of teenagers and young adults. The number of senior citizens also continued to increase faster than total population growth. Holding all other factors constant, changes in the age-sex composition would have produced about a 3.7% decline in per capita milk consumption between 1960 and 1975. Per capita cereal product consumption declined slightly in response to changes in age-sex composition from 1960–75, but for the remaining foods changes in the age-sex composition had a positive impact on per capita consumption. Changes in the age-sex composition during this period were estimated to result in an increase in per capita consumption of cheese, beef, pork, vegetables, and coffee and tea between 3% to 4% while per capita soft drink consumption was increased about 7%.

The Bureau of the Census projects population characteristics under alternative birthrate assumptions. Series II projections, which assume a level of fertility that closely corresponds to recent survey data on birth expectations indicates the total population will increase about 0.9% per year during the decade of the 80s. A large increase in the number of women of child-bearing age is projected to cause a substantial increase in the number of children even though the birth rate is expected to fall below current levels. The number of persons 65 years and over is projected to increase at a rate considerably above that of total population growth during the next decade. These changes in age-sex composition were estimated to have a small negative impact on per capita consumption of all food groups except milk, cheese, poultry, eggs, coffee and tea, and soft drinks. A large increase in the adult population is estimated to contribute to a rather large reduction in per capita milk consumption (2.5%) and per capita soft drink consumption (2.2%). Changes in age-sex composition between 1980 and 1990 were estimated to have a small positive impact on per capita consumption of cheese, poultry, and eggs while per capita consumption of coffee and tea was projected to increase 7.1%.

Household Size

Household size remained relatively unchanged between 1950 and 1960, declining from 3.37 to 3.33 persons. However, household size declined dramatically after 1960, reflecting the decline in the birth rate and an increase in the number of single-person households. Average household size declined to 2.89 persons in 1976. Based upon recent trends and Bureau of the Census projections, average household size will probably decline to about 2.8 persons in 1980 and to 2.6 persons in 1990.

As household size declines, per capita income increases. Thus, a decrease in household size likely will increase individual food intake. Results presented in table 3 indicate that the decline in household size during the 60s and 70s had a positive impact on per capita consumption of all food groups except cereal and bakery products, fats and oils, and coffee and tea.[2] The food group most negatively affected by the decline in household size was fats and oils (2.4% reduction in per capita consumption). Per capita consumption of cheese, beef, fish, fruits, and soft drinks were estimated to have increased 6.2%, 3.7%, 8.1%, 4.2%, and 2.4%, respectively, between 1950–80 as a result of the decline in household size. For the remaining food groups, the decline in household size had little impact on per capita consumption.

[2] The impact of changes in household size on per capita consumption were calculated by adjusting household size of each age-sex group by the percentage change in average household size occurring between 1950 and subsequent years.

Table 3. Estimated Change in Per Capita Consumption Due to Changes in Age-Sex Composition and Household Size

Demographic Factor	Milk	Cheese	Beef	Pork	Poultry	Fish	Eggs	Fats, Oils	Bakery Products	Cereal Products	Fruits	Vegetables	Sugar, Sweets	Coffee, Tea	Soft Drinks	Total Food

1970	100.4	102.3	101.5	100.2	100.6	103.0	100.2	99.1	99.6	99.1	101.7	100.2	100.1	99.3	101.0	100.2
1980	101.1	106.2	103.7	100.5	101.5	108.1	100.5	97.6	99.1	97.8	104.2	100.5	100.3	98.1	102.4	100.6
1990	101.5	108.6	105.1	100.7	102.0	111.5	100.7	96.6	98.8	97.1	105.7	100.7	100.4	97.4	103.3	100.8

If household size declines from 2.8 to 2.6 persons between 1980 and 1990, it is estimated that the decline will result in less than a 1% change in per capita consumption of most foods. However, the decline could increase per capita consumption of cheese, and fruits about 2%, and fish about 4%.

Racial Mix

In 1950, whites comprised 89.5% of the population, blacks 10.0%, and other races 0.5%. Today, whites make up about 86%, blacks 12%, and other races 2%. These trends are expected to continue into the next decade. The Bureau of the Census projects that whites will comprise 85.1%, blacks 12.2%, and other races 2.7% of the population in 1990.

A recent study comparing the food purchase patterns of black and white households concludes that black households spend less on dairy products than their white counterparts (Salathe, Gallo, Boehm). However, black households were found to spend more on pork, poultry, fish, and eggs than similar white households. The study results were derived from data collected in the 1972–74 Bureau of Labor Statistics Consumer Expenditure Survey.

The individual intake data upon which this study is based indicate black individuals consume less milk, cheese, fats and oils, bakery products, vegetables, and coffee and tea than similar white individuals. In contrast, blacks were found to consume more pork, poultry, fish, cereal products, and soft drinks than whites.

Individuals in the "other" racial category were found to consume less cheese, bakery products, and vegetables, and larger amounts of poultry, eggs, and cereal products than similar white individuals. Only limited confidence can be placed in these differences because of the small number of individuals in this racial group (319) in the 1965–66 Food Consumption Survey.

Changes in the racial mix between 1950–80 were estimated to have a negative impact on per capita consumption of milk, cheese, beef, fats and oils, bakery products, vegetables, sugar and sweets, coffee and tea, and total food consumption (table 4).[3] The largest negative impact was estimated for cheese, a 1.6% decline. For the remaining foods negatively affected, changes in the racial mix were estimated to result in less than a 1% decline in per capita consumption since 1950.

Changes in the racial mix had a positive impact on per capita consumption of pork, poultry, fish, eggs, cereal products, fruits, and soft drinks. Per capita consumption of poultry and cereal products were estimated to have increased 2.5% and 3.5%, respectively, between 1950–80 because of changes in the racial mix.

Between 1980 and 1990, changes in the racial mix were estimated to change per capita consumption of most foods by less than 0.4%. The food groups for which greater impacts were estimated included coffee and tea (0.7% decline), poultry (0.5% increase), and cereal products (1.2% increase).

Regional Population Shifts

The proportion of the population residing in the northeastern and north central regions declined 13.5% and 10.2%, respectively, since 1950. The percentage of the population residing in the South remained relatively unchanged between 1950 and 1970. However, the Bureau of the Census estimates the proportion of the population living in the South will increase about 6.5% between 1970 and 1980. Since 1950, a major increase has occurred in the proportion of the population living in the West, rising from 13.4% of the total population in 1950 to an estimated 18.2% in 1980.

The results of the regression analyses suggest that individuals in the northeastern and north central regions consume less cheese, poultry, and eggs than their counterparts located in the western region. But individuals in the north central and northeastern regions generally consumed more beef, pork, fish, and soft drinks than similar individuals in the western region. Individuals located in the South generally had consumption patterns that more closely paralleled their counterparts in the north central and northeastern regions than those of individuals in the western region. Individuals located in the South were found to be the largest consumers of poultry, soft drinks, and bakery products, and the lowest consumers of milk.

Assuming that when individuals move from one region to another they develop the food

[3] The number of individuals by race in each age-sex group was obtained from Census data, and Bureau of the Census, Series II projections.

Table 4. Estimated Change in Per Capita Consumption Due to Changes in Racial Mix, Region, and Urbanization Population Shifts

Demographic Factor	Milk	Cheese	Beef	Pork	Poultry	Fish	Eggs	Fats, Oils	Bakery Products	Cereal Products	Fruits	Vegetables	Sugar, Sweets	Coffee, Tea	Soft Drinks	Total Food

preferences and tastes of persons within the region, these results can be used to estimate the effect of regional population shifts on food consumption. Regional population shifts were estimated to have only a minor impact on per capita consumption of most foods between 1950 and 1980.[4] Regional population shifts were estimated to result in less than a 1.0% change in per capita consumption of all foods except cheese, poultry, pork, fish, eggs, and fats and oils since 1950. Regional shifts occurring between 1950–80 were estimated to cause a 1.5% increase in per capita consumption of cheese and poultry, a 1.1% increase in per capita egg consumption, and a 1.4% increase in per capita consumption of fats and oils. Per capita consumption of pork and fish were estimated to decline by 2.4% and 1.5%, respectively, because of regional population shifts occurring since 1950.

Bureau of the Census projections suggest that the proportion of the population living in the southern and western regions will increase 4.6% and 3.8%, respectively, between 1980 and 1990. The proportion of the population living in both the northeastern and north central regions is expected to continue to decline. These regional shifts were estimated to have little impact on per capita consumption of most foods. The largest positive impact was estimated for eggs, a 0.7% increase in per capita consumption, while per capita pork consumption was estimated to drop 0.6% as a result of regional population shifts in the next decade.

Urbanization Shifts

In 1950, 64% of the population resided in urban areas, 21% in rural nonfarm areas, and 15% were living on farms. During the decades of the 50s and 60s there was a general migration of the population from rural to urban. Nearly all of this migration seems to be accounted for by a movement of persons living on farms to urban areas. In 1970, the proportion of the population living in urban locations increased to 73.5%, while the proportion of persons living on farms declined to 5.2%. But the proportion living in rural nonfarm locations remained almost constant during this period.

The shift in the proportion of the population living in urban and rural farm locations between 1950 and 1970 had a negative impact on per capita consumption of most foods.[5] Per capita consumption of cheese was estimated to decline 1.7%, fish 3.3%, fats and oils 2.2%, bakery products 1.7%, cereal products 3.0%, vegetables 1.8%, and sugar and sweets 2.9%. Per capita consumption of milk, pork, and fruits were estimated to decline about 1.0% between 1950 and 1970 because of the movement of persons from rural to urban locations. In contrast, these movements had a positive impact on per capita consumption of beef, poultry, eggs, coffee and tea, and soft drinks.

The Bureau of the Census estimates that since 1970 the proportion of the population living in urban locations has declined slightly. Also, the proportion of the population living on farms continued to fall but at a much slower rate than in the decade of the 60s. Based upon these trends, the proportion of the population living in urban locations was assumed to decline to 72.5% in 1980 and to 71.0% in 1990. The rural farm population was assumed to decline to 3.7% of the population in 1980 and to 2.5% in 1990. Thus, the proportion of the population living in rural nonfarm locations was projected to increase to 23.8% in 1980 and to 26.5% in 1990. To estimate the impact of these projected changes on food consumption, the urban-rural distribution of each age-sex group was adjusted by the projected percentage change in the urban-rural distribution of the total population.

For the decade of the 1980s urban-rural shifts would seem to have only a very small impact on per capita food consumption. Such shifts were estimated to cause at most a 0.5% change in per capita consumption.

Conclusions

Per capita consumption of milk, pork, eggs, and coffee and tea declined between 1965 and 1975 (table 5). Demographic changes during this period appear to explain a large portion of the decline in per capita milk consumption. But demographic factors were estimated to have a positive impact on per capita consumption of pork, eggs, and coffee and tea. Per

[4] Regional age-sex composition data were obtained from the Bureau of the Census for 1950, 1960, and 1970. The Bureau of the Census also projects total population by region for subsequent years. The impact of changes in regional population shifts on per capita consumption for these years was estimated by adjusting the regional distribution of each age-sex group by the projected change in the regional distribution of the total population.

[5] For this period, the number of individuals by urbanization in each age-sex group was obtained from Census data.

Table 5. Actual Change in Per Capita Consumption, 1965–75, and the Estimated Effects Due to Demographic Changes, 1950–75, 1965–75, and 1980–90

	Actual[a]		Effects of Demographic Changes		
Item	1950–75	1965–75	1950–75	1965–75	1980–90
			(%)		
Milk	−15	−6	−1	−4	−3
Cheese	78	36	5	4	1
Beef	77	21	4	3	—
Pork	−20	−6	−2	2	−1
Poultry	96	4	6	2	1
Fish	3	12	3	6	3
Eggs	−27	−11	2	3	3
Fats and oils	15	11	−2	—	−2
Vegetables[b]	5	5	−1	2	−1
Fruits[c]	−5	6	4	2	1
Bakery products	NA	NA	−1	1	−2
Cereal products	26	−1	−1	−1	—
Sugar, sweeteners	7	8	−2	−1	−1
Coffee, tea	−30	−16	−3	3	5
Soft drinks	NA	44	8	4	−2
Total food	−7	—	—	1	−1

Note: NA, not available; —, less than a 0.5% change.

[c] Includes tomatoes.

capita consumption of sugar and sweeteners increased 8% between 1965 and 1975, but demographic factors were estimated to have a small negative influence on per capita consumption during this period.

Demographic changes appear to explain a large portion of the increase in per capita consumption of poultry and fish between 1965–75. However, changes in population characteristics do not appear to explain the large increases in per capita consumption of cheese, beef, fats and oils, or soft drinks.

During the period from 1950–75, demographic changes appear to explain even less of the changes that occurred in per capita consumption. Per capita consumption of milk and pork declined 15% and 20%, respectively, while per capita consumption of cheese, beef, and poultry increased 78%, 77%, and 96%, respectively. Generally, demographic changes appear to explain less than 10% of the total change in per capita consumption of these foods occurring from 1950–75.

Changes in population characteristics are projected to have a negative impact on per capita consumption of milk, pork, fats and oils, bakery products, vegetables, sugar and sweeteners, and soft drinks between 1980–90. Despite an expected increase in the number of children during the next decade, demographic changes are estimated to cause a 3% decline in per capita consumption of milk and a 2% decline in per capita soft drink consumption. Demographically related changes in the next decade were estimated to result in a 1% to 3% increase in per capita consumption of cheese, poultry, fish, eggs, and fruits and a 5% increase in per capita consumption of coffee and tea.

The Effect of Demographic Shifts and Changes in the Income Distribution on Food-Away-from-Home Expenditure

Benjamin Sexauer

The sociodemographic structure of the American population has been changing rapidly in recent years. In addition, although the income distribution based on income groupings has remained fairly constant, the distribution of income among sociodemographic subgroups of the population has almost certainly changed considerably. Little attention has been given to the possible impact of demographic shifts, and even less to that of income distribution changes, on long-run movements in consumer demand. Most research has implicitly assumed that the income distribution and sociodemographic profile of the population remain stable. Although this assumption may be acceptable for short-run analysis, their impact cannot be overlooked in a long-run context. Ignoring the possible impact of income redistribution and demographic shifts can lead to biased aggregate income and price elasticity estimates. The accuracy of long-run projections also may be affected adversely.

Expenditure on food away from home has grown rapidly and is becoming an ever larger portion of total food expenditure. Some predict that within a decade 50% of food expenditures will be on meals eaten away from home (Langway and Nicholson). Underlying this prediction is the assumption that household characteristics have a strong influence on dining out. Factors such as age, sex, education, and work status of household members are judged to have a major impact on food-away-from-home (FAFH) expenditure. For this reason, FAFH expenditure is especially relevant for analyzing the effect of demographic shifts and changes in the income distribution.

This paper proposes a novel approach to estimating the effect of disaggregate compositional changes on aggregate consumer behavior over time. Earlier contributions have been made in this area by Burk (pp. 56–60), George and King (pp. 82–86), and Kelley. Specifically, this study will attempt to quantify the degree to which aggregate expenditure on FAFH depends on the distribution of income and of households among population subgroups. The effects of population and income shifts between 1960–61 and 1973–74 among forty population subgroups on FAFH expenditure are analyzed. These subgroups were created by cross-classifying by six key sociodemographic factors. In this analysis 1973–74 is treated as the base period and the projections are made back to 1960–61.

Conceptual Approach

The conceptual approach can be presented most clearly by simplifying to a case with just two population subgroups. An Engel relationship can be specified for all households and separately for each subgroup:

$$E_T = a_T + b_T Y_T, \tag{1}$$

$$E_1 = a_1 + b_1 Y_1, \tag{2}$$

$$E_2 = a_2 + b_2 Y_2, \tag{3}$$

where E is average household expenditures on FAFH; a, the constant term; b, the marginal propensity to consume or spend; and Y, average household income. Equation (1) represents the relationship between average household income and average household expenditure for the total population, hence the subscript T, and equations (2) and (3) for two subgroups. These equations apply to a point in time. The proportion of each subgroup in the

Benjamin Sexauer is an associate professor in the Department of Agricultural and Applied Economics, University of Minnesota.

The author is indebted to Jitendar Mann, Terry Roe, Larry Salathe, Ronald Schrimper, and Bill Tomek for helpful comments made on earlier drafts of this paper. However, he retains sole responsibility for remaining shortcomings. Don Groover provided computational assistance for much of the early work on this project. Rueben Buse generously supplied much of the 1960–61 data needed from the tapes available at the University of Wisconsin.

population is W_1 and W_2, respectively, $W_1 + W_2 = 1$. Then, it is true that average household expenditure for the total population is equal to the weighted average of both subgroups:

$$(4) \quad E_T = W_1(a_1 + b_1Y_1) + W_2(a_2 + b_2Y_2).$$

If shifts in the subgroup proportions and incomes, the W's and Y's, occur over time, the change in E_T can be decomposed into two effects. The total differential of equation (4) is

$$(5) \quad dE_T = E_1dW_1 + E_2dW_2 + b_1W_1dY_1 + b_2W_2dY_2.$$

The first and second terms on the right hand side of the equation represent the demographic change effect due to shifts in the subgroup population proportions and the third and fourth terms, the disaggregate income change effect due to changes in subgroup incomes.

This approach will explain only a portion of the actual change in average aggregate expenditure (E_T) over time, since the effects of relative price changes are excluded. In addition, equation (5) allows for changes in the variables, but assumes the parameters remain constant. Demographic shifts are treated as a transference of the average tastes and income of one subgroup of the population for those of another subgroup. The impact of demographic shifts is an amalgam of both a taste-related and an income-related response. Differences in tastes between subgroups influence the income response parameter as well as the constant expenditure factor.

To isolate the income redistribution effect, the impact of income growth with a constant distribution must be removed from the income effect specified in equation (5). The relative distribution of income would remain unchanged if income changed by an equal percentage for each subgroup. Therefore, for the two subgroup case,

$$(6) \quad dE^*_T = W_1b_1\left(Y_1\frac{dY_T}{Y_T}\right) + W_2b_2\left(Y_2\frac{dY_T}{Y_T}\right)$$

is the effect on expenditure of an income change with the distribution held constant, where (dY_T/Y_T) is the percentage of change in income for all households. Thus $\left(Y_1\frac{dY_T}{Y_T}\right)$ and $\left(Y_2\frac{dY_T}{Y_T}\right)$ represent an equal percent change in income for the two subgroups.

The effect of income redistribution can then be isolated by subtracting (dE^*_T) from the disaggregate income change effect in equation (5). Hence,

$$(7) \quad dE^{**}_T = b_1W_1dY_1 + b_2W_2dY_2 - dE^*_T,$$

or, rearranging terms,

$$(8) \quad dE^{**}_T = W_1b_1\left(dY_1 - Y_1\frac{dY_T}{Y_T}\right) + W_2b_2\left(dY_2 - Y_2\frac{dY_T}{Y_T}\right).$$

The terms within parentheses in equation (8) represent the difference between the actual change and the equal percentage change in income for each subgroup, or the income redistribution.

For empirical application, the model for two subgroups must be converted to one involving discrete units of time and J subgroups. The change in average overall expenditure between two periods of time is,

$$(9) \quad \Delta E_T = \sum_{j=1}^{J} E_j\Delta W_j + \sum_{j=1}^{J} b_jW_j\Delta Y_j + \sum_{j=1}^{J} b_j\Delta Y_j\Delta W_j, \quad \text{and}$$

$$(10) \quad \Delta E^*_T = \sum_{j=1}^{J} b_jW_j\left(Y_j\frac{\Delta Y_T}{Y_T}\right).$$

Equation (9) is the discrete, general case analogue of equation (5) and equation (10), of equation (6). Equation (9) contains a third term which does not appear when dealing with the infinitesimally small changes implicit in equation (5).

In equation (9), the change in the population proportion for each subgroup between the two periods (ΔW_j) is multiplied by expenditure by that subgroup in the first period (E_j), then summed across all subgroups. Next, the change in income (ΔY_j) for each subgroup is multiplied by the marginal propensity to consume (b_j), weighted by the population proportion for that subgroup (W_j), and then summed across the subgroups. The third term represents a combination of demographic and income changes and probably is not very large.

To illustrate the above derivations for the discrete case, we present the following calculation for a specific subgroup where the change between two periods of time is a function of W and Y:

$$(11)\quad \Delta(W_1, Y_1) = (W_1 + \Delta W_1)(a_1 + b_1 Y_1 + b_1 \Delta Y_1) - W_1(a_1 + b_1 Y_1).$$

The term to the right of the minus sign represents the effect of subgroup (1) on aggregate expenditure (E_T) in period 1, and the term to the left of the sign the effect in period 2. The change in the population proportion between the two periods is (ΔW_1) and in income (ΔY_1). After rearranging terms,

$$(12)\quad \Delta(W_1, Y_1) = \Delta W_1(a_1 + b_1 Y_1) + b_1 W_1 \Delta Y_1 + b_1 \Delta Y_1 \Delta W_1.$$

Equation (12) specifies for a single subgroup the relationship represented in equation (9).

Data and Subgroup Specification

The data base for this study consists of the 1960–61 Bureau of Labor Statistics and U.S. Department of Agriculture (USDA) *Survey of Consumer Expenditure and Incomes* and the 1972–73 Bureau of Labor Statistics *Consumer Expenditure Survey*. The data actually used from the second survey are from the second year of the diary portion, which covered July 1973 to June 1974. The 1960–61 survey covered some 13,725 households. The 1973–74 data covered some 10,093 households after eliminating those that did not report income or for which two weeks of expenditure data were not available.[1]

Average household expenditure on FAFH in home city was \$490.83 in 1973–74. The comparable figure in 1960–61 was \$197.18, or \$360.34 in 1973–74 prices. Therefore, the change in average expenditure was \$130.49 in 1973–74 dollars (U.S. Dep. Labor). Hereafter, all 1960–61 dollar figures have been converted to their 1973–74 equivalents using the consumer price index (CPI) for FAFH or the Index for all goods in the case of income.

The different definition of away-from-home-food expenditure used in the two data sets eliminates the possibility of comparing FAFH expenditure for the population subgroups between 1960–61 and 1973–74. The diary data tape for 1973–74 confined FAFH to expenditures in the home city, including board, snacks, and nonalcoholic beverages away from home, but excluding meals accepted as part of pay. On the data tape for 1960–61 available for use in this analysis, FAFH covered home city and out of home city expenditures, plus meals as pay.

The six sociodemographic factors used to specify population subgroups were selected on the basis of cross-sectional indications of their importance and because they exhibited large relative changes in the last twenty-five years. This rationale was suggested by Agarwala and Drinkwater.

The six variables ultimately selected were household size, age, sex, and education level of the household head, urbanity, and presence of a working spouse. Each variable was placed on a binary basis: single person versus multiperson households, household head 65 years and over versus under 65, urban versus rural, head college-educated versus not, household head male versus female, wife works outside household versus not. Although more than two age and household size categories would be desirable, there was a need to limit the number of classification factors to a reasonable level. Regression analysis showed that the age and household size categorization used captured the more important effect of each, though.

Table 1 presents the regression results used to establish the importance of the sociodemographic classification factors used. A linear functional form with ordinary least squares (OLS) was used to estimate the relationship between FAFH and the sociodemographic variables. The dependent variable was annual household dollar expenditure on FAFH. Each sociodemographic variable was allowed to not only affect the constant term, but also the coefficient on income. Income was the only variable specified in a continuous form. The regression was run across the entire sample of households for 1973–74.

The regression results indicate the importance of the sociodemographic factors. Age, education, and sex have a statistically significant effect at the .05 level on the constant term. Household size, age, and urbanity each have a significant effect on the income coefficient. When the regression was calculated for married households only, the working wife coefficient was 48.24 with a t-statistic of 1.61. If the dependent variable was then specified as the proportion of total food ex-

---

[1] At the time of this analysis, the income data for households with incomes below \$2,000 and above \$35,000 were withheld. Also, if the household size was greater than six, actual size was not reported. In each situation, the mean value was utilized; \$1,001 for incomes below \$2,000, \$48,457 for income above \$35,000, and 7.93 persons for families of seven members and larger.

penditure spent away from home, the working wife coefficient was .0346 with a t-statistic of 4.02.

The other reason for selecting these six sociodemographic factors is that the U.S. population underwent major shifts in relation to each during the past twenty-five years. The largest relative change was in regard to college education. The portion of the population twenty-five and over with a college education changed from 6.0% in 1950 to 13.9% in 1975, a change of 132%. The smallest shift was in the relative size of the elderly in the population, but there was over a 30% change between 1950 and 1975 even for that factor, from 7.8% to 10.3%. Each of the sociodemographic factors used, therefore, met the twin criteria of having a significant influence on FAFH expenditure and showing a large relative change over time.

Cross-classification by six binary factors yields sixty-four groupings, except if certain of the categories exclude other possibilities. By definition, neither a one-person nor a female-headed household can have a working wife. The forty population subgroups specified are enumerated in table 2. For example, subgroup (1) is composed of urban, not college-educated, under age 65, male-headed, multiperson, wife not working households. Subgroup (40) includes rural, college-educated, over age 65, female-headed, one person households.

There are substantial differences in spending on FAFH among the forty population subgroups. These differences are perhaps most striking when FAFH expenditure is given as a proportion of total food expenditure. Column (1) gives the percentage of total food expenditure that was away from home in 1973–74 for each subgroup. The highest figure was 56% for subgroup (13), urban, college-educated, under age 65, male-headed, one person households. The lowest was 6% for subgroups (29) and (30), rural, less than college-educated, over age 65, female-headed households. The average for all households was 25%. Column (2) presents a similar figure for 1960–61. However, because the definition of FAFH was different in the two surveys, columns (1) and (2) are not comparable. Subgroups (37), (38), and (39) were excluded in 1973–74 because the number of observations was so small, at three, zero, and one, respectively.

Empirical Results

The Effect of Demographic Shifts

The impact of demographic changes depends on both the magnitude of the population shifts and the degree of dissimilarity in disaggregate behavior. During the thirteen-year period analyzed in this study, there were substantial shifts among the forty population subgroups specified in table 2. Column (3) gives the percentage of the total sample population in each subgroup in 1973–74. Column (4) gives the percent figure for 1960–61.[2] One of the more substantial population movements occurred for subgroup (21), rural, less than college-educated, under 65, male-headed, multiperson households with the wife not working, which

[2] The surveys were designed to be representative samples of the U.S. population and some preliminary work indicated that households with various characteristics were represented in the right proportion. However, there is no guarantee that specific subgroups used here may not have been under or over sampled to some degree in either survey.

decreased from 14.51% of the population in 1960–61 to 4.52% in 1973–74. Subgroup (3), on the other hand, increased from 2.12% to 5.14%.

Column (5) gives the average dollar expenditure on FAFH for each subgroup in 1973–74. The largest figure was $880 per year by subgroup (12), composed of urban, college-educated, under age 65, male-headed, multiperson housholds with the wife working. The lowest annual expenditure was $56 by subgroup (30), rural, less than college-educated, over age 65, female-headed, one person households.

Based on equation (9), the effect of demographic shifts was determined by subtracting the population figures in column (3) from those in column (4), dividing the result by 100, then multiplying by the FAFH figures in column (5) and summing over the subgroups. The projected change in household expenditure on FAFH was $29.10 going from 1973–74 back to 1960–61. Demographic shifts among the forty subgroups specified could therefore account for 22.3% of the $130.49 observed change in average household expenditure over the period.[3]

The Effect of Income Distribution Changes

The effect of income redistribution depends on both the magnitude of the changes in its distribution and the dissimilarities in the FAFH-income relationship among demographic subgroups. To derive the disaggregate income effect in equation (9), a marginal propensity to consume (*mpc*) for FAFH was needed for each subgroup. These subgroup specific *mpc*'s were derived two ways. First, regressions were estimated for 1973–74 for each subgroup with at least twenty observations. Second, a *mpc* was calculated for each of the forty subgroups from the regression results in table 1.

The first approach yielded the *mpc*'s shown in column (7) of table 2. For the twenty-nine subgroups with more than twenty observations, a linear OLS regression was run with income as an explanatory variable. Family size was also included as a variable for the subgroups composed of multiperson households. The *t*-statistics are given in parentheses next to the parameter estimates. In cases where the *t*-statistic indicated a lack of statistical significance at the .05 level, the *mpc* was assumed equal to zero in further calculations. For the nine subgroups with less than twenty but more than zero observations, the average *mpc* for all households of .0261 was used in the calculations. This average *mpc* value was estimated in a linear regression run over the entire sample for 1973–74 with the six sociodemographic variables affecting the constant, but not the income coefficient.

The second approach produced the *mpc*'s presented in column (8). Based on the regression results shown in table 1, subgroup specific income coefficients can be derived using the income coefficient and sociodemographic variable interaction terms. The income coefficient presented in table 1 of .0374 is representative of the *mpc* for an urban, less than college-educated, under age 65, female-headed, one-person household. Any interaction effect larger than its standard error was utilized in deriving subgroup specific income coefficients. The income interaction coefficient for sex had a *t*-statistic of less than one, so the *mpc*'s for subgroups differentiated only by the sex of the household head were assumed to be equal.

The largest statistically significant *mpc* in column (7) is .0919 for subgroup (23), rural, less than college-educated, under age 65, male-headed, one-person households. On the other hand, the income coefficient is not statistically different from zero for subgroups (15), (16), or (28). In column (8) the *mpc*'s range from .0374 to .0081. A $1.00 increase in income increases FAFH expenditure by $.037 for subgroups (3) and (5), urban, less than college-educated, under age 65, both male- and female-headed, one-person households. The smallest *mpc* is for subgroups (36) and (39), rural, college-educated, over 65, both male- and female-headed, multiperson households, with the wife not working if the head is male. The differences between the *mpc* estimates in column (7) and (8), where they exist, may be partially due to the different specification for household size in the two approaches. The binary regression simply specified household size as one-person or multiperson. On the other hand, the subgroup specific regressions for multiperson households contained a household size variable.

Column (9) gives the mean household total money income before taxes for the demographic subgroups in 1973–74. Column (10) presents the 1960–61 income figure in 1973–74 dollars. Column (11) calculates the change in

[3] Some thought was given to correcting for family size changes on a subgroup basis. However, the family size changes were small enough that their impact on a subgroup basis could be ignored.

income between 1960–61 and 1973–74. The larger increases are recorded among certain of the rural households. These results should not be surprising since 1973 and 1974 were the two best years in history for U.S. farm income. Some thirteen subgroups actually suffered a decline in real income between the two surveys. These results may be partially explained by the downturn of the overall economy during 1974 preceding the last recession. However, certain of the income changes could possibly reflect an abnormality in the subgroup samples for one or both of the surveys. In analyzing subgroups, the sample size was small enough in many cases that a household with an abnormally high income could have a large influence on the mean.[4]

From equation (9), the disaggregate income change effect was determined by multiplying the income coefficients in column (7) or (8) by the subgroup income changes in column (11). This result was then multiplied by the 1973–74 population percentage weights in column (3) divided by 100. Based on the *mpc*'s in column (7), calculated by subgroup specific regressions, the projected change of expenditure on FAFH was $32.69 between 1973–74 and 1960–61. Based on the *mpc*'s in column (8), derived from the table 1 regression results, the projected change was $29.62 due to disaggregate income changes. The sign is negative in both cases going from 1973–74 back to 1960–61.

The effect of income distribution changes can be isolated by subtracting equation (10) from these results. The average percent change in real income across all households was 12.37%, $1,388 divided by $11,225. Based on equation (10), the 1973–74 subgroup incomes in column (9) were each thus multiplied by .1237. The resulting change in income was multiplied by the income coefficients in column (7) or (8) and the 1973–74 population weights in column (3) were applied.

A 12.37% change in income with a constant distribution produces a change in FAFH expenditure of $37.57 using the *mpc*'s in column (7) and $35.62 based on those in column (8). Subtracting $37.57 from $32.69 yields −$4.88, or $35.62 from $29.62 yields −$6.00. The negative sign means that income distribution changes caused a change in FAFH expenditure opposite in direction from that which occurred. If the distribution of income were the only factor changed, FAFH expenditure would have increased going from 1973–74 to 1960–61 or decreased going from 1960–61 to 1973–74.

The underlying explanation is that some of larger income increases between 1960–61 and 1973–74 occurred for subgroups with below average *mpc*'s for FAFH. An example is the large increases for many rural households due to high farm incomes during the latter survey. On the other hand, some of the smaller increases in real income, even negative in some cases, were for subgroups with higher than average *mpc*'s. One problem in this analysis may be the use of current income, rather than some measure of permanent income, particularly in the case of households with volatile incomes such as farmers.[5]

The multiplicative income and demographic change factor, the third term on the right side of equation (9), produces a change of −$.73 based on the *mpc*'s in column (7), and of −$1.09 based on the *mpc*'s in column (8).

Conclusions

These results may partially explain the lack of consistency among aggregate parameter estimates from cross-sectional data sets collected in different years. Harmston and Hino in analyzing two cross-sectional data sets separated by ten years found a lack of consistency in the aggregate income elasticity estimates. Such a change could be explained at least partly by population and income shifts among subgroups with different coefficients. Agarwala and Drinkwater pursued this line of reasoning for the aggregate consumption function. Carrying this idea further, some of the behavior which economists normally attribute to taste changes can actually be quantified as being a result of compositional shifts.

Ignoring demographic and income distribution shift effects, when they are significant, will lead to specification bias. This left-out variable bias may affect the income and price effect estimates in a time-series regression analysis. As a corollary, long-run projections made on the basis of income and price elasticities so estimated will yield inaccurate pre-

[4] The problem may arise partly because of the nonreporting of incomes over $35,000 in the 1973–74 data, which forced the use of an average income over that level.

[5] The disaggregate income change effect of equation (11) also can be compared to the aggregate income effect, which is typically calculated. Based on the *mpc* for all households in 1973–74 of .0261 and the average change in income of $1,388 in 1973–74 dollars, the projected change in expenditure was $36.23.

dictions, when substantial changes do occur in the demographic profile and/or income distribution.

A possible approach to correcting this misspecification problem might be to use the cross-sectional estimates of the effect of demographic and income distribution changes as extraneous information to obtain a "corrected" time-series data set. The use of cross-sectionally generated estimates as extraneous information in a time-series regression analysis was first pursued by Tobin. This approach would also allow the residual movement in FAFH expenditure, not accounted for by demographic or income distribution changes, to be explained at least partially by changes in aggregate income and relative prices. The simplest correction would be to treat changes in the income distribution and demographic profile as a trend factor. The annual change in FAFH due to these factors could be converted to the correct constant dollar base, placed on a per capita basis, multiplied by the trend value for each year, and subtracted from the annual FAFH time series. The "corrected or residual" FAFH series could then be considered a function of aggregate per capita income and prices. The original intention was to carry out this procedure. However, the severe collinearity between the time-series price and income series precluded this.

Two assumptions are essential to the approach employed in this study. First, the stability over time of the disaggregated parameters is assumed. The *mpc*'s estimated with the 1973–74 data for the sociodemographic subgroups are applied to the 1960–61 period. A check on the consistency of the disaggregated parameter estimates would have been highly desirable. This check could not be made because of the definitional difference in FAFH in the 1960–61 and 1973–74 data available for this research.

Second, but equally as critical, this analysis relies on drawing inferences concerned with changes over time from cross-sectional estimates. A considerable literature exists on this topic (Kuh, Kuh and Meyer, Maddala; Tobin). Kuh argues for caution in applying cross-sectional estimates to time-series processes. Those less skeptical would probably be willing to accept cross-sectional estimates as approximately equivalent to long-run time-series parameters (George and King, p. 68; Kuh and Meyer). Moreover, a long history exists in demand analysis of using cross-sectional data to generate estimates that are primarily applicable to a time-series context, such as the work of Frisch or Pinstrup-Andersen.

A further limitation of this approach is that the sample size for many of the subgroups is extremely small, which affects the reliability of the estimates. For example, the confidence level at the .90 level for the mean FAFH expenditure for all households of $491 is between $480 and $502. For subgroup (22) with 440 observations, the 90% confidence interval is between $441 and $521, with the mean at $481. For subgroup (26) with 157 observations, the mean is $144, and the confidence interval is $106 to $182. The confidence intervals about the estimated values for smaller subgroups became extremely wide. However, there is a mitigating factor. Because the effect of a subgroup on aggregate FAFH expenditure is in relation to its relative size in the population, the possibly less accurate estimates have a minimal influence on the results.

In summary, the limited information content of the data always has been a serious restriction in time-series related analyses. Problems of multicollinearity are prevalent and only aggregate behavior can be studied. On the other hand, large cross-sectional data sets are a rich information source, but most of the practical concerns pertain to time-series processes. The use of cross-sectional information for time-series inferences allows the effect of disaggregate compositional changes on aggregate behavior over time to be analyzed.

Demographic and income distribution shifts can have a significant effect on long-run changes in consumer demand. This analysis suggests that a major portion, 22.3%, of the observed change in average aggregate expenditure on FAFH might be explained by demographic shifts. The suggested effect of income distribution changes is small, but counter to the observed movement of FAFH, interestingly. Moreover, this study has presented a methodology which can be applied to any commodity. Aggregate demand analyses can conceal a considerable diversity in consumer behavior among subgroups of the population. Disaggregate compositional changes may, in turn, have a significant impact over time on average aggregate behavior. In addition, questions concerned with specific subgroups of the population and distributional impacts are becoming increasingly important themselves in our society.

Demographic Change and the Demand for Food: Discussion

R. A. Schrimper

Salathe's and Sexauer's papers report substantial effects of demographic changes on food consumption in recent years even though some of the unexplained residuals are fairly large. Explanations of 50%–70% of actual changes for some of Salathe's categories and 22.3% in Sexauer's analysis are impressive. Although the latter type of comparisons are very natural, they can be misleading when various factors influencing quantities and expenditures for food have offsetting effects. In such circumstances, it is conceivable that observed changes in average consumption or expenditures per capita, or per household, actually can be less than some of the individual components. Hence, a more meaningful comparison might be made by noting the relative magnitude of individual components as in the case of Sexauer's analysis where the effect of demographic shifts was approximately the same size as the aggregate income effect regardless of which set of marginal propensities to consume was used.[1] Similarly, comparison of the magnitudes of various factors analyzed by Salathe may be more meaningful than comparisons to observed changes in per capita consumption.

In addition to empirical estimation of the extent to which changes in various population characteristics affect average food consumption or expenditures, the papers raise some interesting methodological issues. The studies complement each other by illustrating how an identical conceptual relationship can be implemented in different ways with different types of data to examine similar questions. The basic relationship underlying each of the studies is that national average consumption or expenditure per capita, or per household, is a weighted sum of population subgroup averages. The analyses focus on measuring changes in national per capita or per household averages resulting from changing distributions of the population among subgroups and the effect of adjustments in subgroup averages. Interesting questions arise, however, as to how subgroups of the population should be defined, and should a given variable be used to define more detailed subgroups of the population or should its effects be handled by adjusting subgroup or cell averages? Salathe chose to use only age and sex characteristics to subdivide the population into subgroups with the effects of other variables evaluated through modification of subgroup averages. On the other hand, Sexauer used six factors to specify population subgroups and considered income and family size as the only characteristics affecting individual cell means over time. These contrasts in methodology raise a question. Is there some criterion to help decide whether to use a given variable to define additional subgroups or to handle its effects by adjusting group averages?

Another interesting contrast between the two studies is in the specification of variables used to define subgroups or adjust cell means. Age and sex characteristics are used in both cases to define subgroups, but working with household rather than individual intake data necessitated different specifications of these characteristics. For example, Salathe adjusted for consumption differences by age using ten subgroups for each sex whereas Sexauer's analysis used age of the household head to differentiate those 65 and over from those with a younger household head. A question for future research is how much information might be gained by a more detailed specification of life-cycle stages noted by Sexauer.

Income is used in both studies as a significant variable affecting subgroup means. The effect of household size is also included in each study but in a different manner. Race and

[1] Sexauer's income effects may be slightly overestimated because they are based on the change in real income before taxes between 1960–61 and 1973–74 rather than the change in real income after taxes. There may be an offsetting effect, however, to the extent that current income involves errors of measurement for permanent income.

region are variables explicitly introduced by Salathe and considered in some preliminary regression analyses by Sexauer. On the other hand, education, employment, and marital status were included by Sexauer but omitted by Salathe in the set of population characteristics selected for evaluating demographic effects on food consumption. If each study had incorporated a more comprehensive list of variables, the estimated aggregate effects of changes in population or demographic characteristics would have been even larger. This observation, however, begs the question of what variables are to be analyzed or considered to represent the effects of changes in demographic or population characteristics. All of us perhaps need to exercise care in using the term demographic effects because it has become increasingly popular in consumption economics and gets used in so many different ways. In view of modern economic analyses of factors influencing household formation, birth, and mortality rates, it may not be totally realistic to even think about differentiating the effects of classic demographic characteristics of age and sex composition of the population from the influence of economic factors on the demand for food.

Much of the interest in this general research area undoubtedly has been generated by the sharp reduction in birth rates during the 1960s and 1970s documented by Salathe. Subsequent changes in age composition of the population may be partly responsible for the slowing of the rate of reduction in the proportion of income allocated to food with higher levels of per capita income that has occurred since the mid-1960s. Salathe's tabulations vividly demonstrate that the largest impact of changes in the age and sex distribution of the population on per capita consumption of individual food commodities between 1950 and 1990 is associated with beverages including milk, coffee, tea, and soft drinks. A large share of these effects certainly results from the change in birthrates affecting the proportion of children who have quite different beverage consumption patterns from the rest of the population in our economy.

In examining the tabulations further, however, I was surprised that the changing age and sex distribution of the population between 1970 and 1990 is projected to affect per capita cheese consumption nearly as much as that of beverage consumption. Since per capita cheese consumption was relatively unaffected by changes in age-sex composition between 1950 and 1970, the effect appears to be operating somewhat differently than that for beverages and suggests the possible influence of a different demographic factor. One hypothesis is that some of the effect may be related to the increasing divergence in male-female mortality rates that is producing an increased ratio of females among the elderly. Unfortunately, Salathe's results do not provide a separate tabulation of the effects of the changing age distribution from the sex composition of the population to readily check this hypothesis. The reason for suspecting that the changing sex composition among the elderly might be a factor influencing future cheese consumption is that cheese is the only food category considered by Salathe for which daily intake for females by each age group over forty is consistently larger than that for males of corresponding ages. Individual age-sex consumption data for poultry also indicate a rather sharp contrast in relative female-to-male rates over age fifty compared to those of earlier ages even though females consistently consumed less than males. This suggests that per capita poultry consumption also may be affected by differential mortality factors for each sex between 1970 and 1990.

It will be interesting to see if the same contrasts in age-sex patterns of food consumption persist when new intake data from the 1977–78 USDA Food Consumption Survey become available. Comparison of the two sets of data to explain differences in particular subgroup averages will be similar to the challenge Sexauer undertook in trying to relate a segment of the 1960–61 and 1973–74 Household Expenditure Data. One issue worth pursuing in comparing the two sets of individual food intake data is determination of how much of the differences associated with age in any given cross-section are the result of economic influences or partly cohort effects as compared to pure age effects. For example, are variations in eating patterns of older people relative to younger segments of the population the result of physiological differences, perceived nutritional requirements, different economic circumstances, or are food habits partly a product of different generations of influences? In other words, is it reasonable to expect all generations to follow the same transformation of eating habits over their life cycle, *ceteris paribus?* If definitive results could lead to a rejection of cohort effects on

food consumption it would strengthen reliability of projections based on gross or net differences among age groups from a given cross-sectional data source. Searching for empirical evidence to address some of these issues seems to be important in continuing to improve our understanding and analyses of demographic effects on food consumption.

Demographic Change and the Demand for Food: Discussion

David W. Price

The papers by Sexauer and Salathe are to be commended for emphasizing the important but frequently overlooked problem of the effects of changing demographic composition of the population. In some instances, these changes have been so slow that they could be overlooked in any time-series analysis, as confirmed by some of Salathe's results. In a study that I did several years ago (Price), it made little difference in a time-series context whether total food expenditures or expenditures for major food groups were placed on a per capita or on a per adult equivalent basis. That is, the age-sex composition of the population did not change fast enough to be an important factor. The results of Sexauer show that for food eaten away from home, demographic changes are important. The question and challenge that Sexauer and Salathe lay down is, for which commodities and for which demographic variables are demographic shifts important? Their results show that the profession cannot continue to assume that demographic changes are slow enough to be assumed away.

The following remarks were induced by Sexauer's paper as Salathe's paper was not received in time for me to make relevant comments. Even though Sexauer's paper appears to be a thorough job, there are questions that remain. From my own perspective, I found the specification of the age and household size effects unsatisfactory. The only two age categories specified are those over 65 and those under 65. The only two household size categories specified were the one-person household and all others. The usual husband-wife, two-person household should be considerably different in many respects from the household with one or more children. The rationale stated, "there was a need to limit the number of classification factors to a reasonable level," does not seem to be an appropriate defense when there are over 10,000 observations. The discussion leaves the reader questioning whether the other types of households were ignored because their proportion in the total sample did not change between sample periods, they were ignored, or their addition made the model too complex. The results cannot tell us what the effect on food expenditures away from home will be if the proportion of children in the population declines. It would be informative to estimate unit equivalent scales for food eaten away from home. The scales would show the amount spent on food away from home by various ages and sexes as a ratio to that spent by the adult male.

Scales are a convenient expression of age-sex differences. They are a vast improvement over a per capita specification which implicitly assumes that food consumption for a child less than six years of age are equal to that of a teenage boy. If we express food expenditure on a household basis as our dependent variable and use the number of persons as an explanatory variable, we are guilty of using the above oversimplifying assumption. The coefficient on the number of persons variable would be larger for the household with teenagers than the household with younger children. Economies-of-size effects will be confounded with age-sex effects.

The unit equivalent scale is not without its difficulties. The basic idea of Sydenstricker and King was to compare food expenditures of households differing in age-sex composition by only one member. For example, the expenditure attributable to a six- to twelve-year-old child is obtained by subtracting the mean expenditure of a household with two adults and one six- to twelve-year-old child from that of a household with only two adults. The two groups of households need to be comparable with respect to income and other relevant characteristics.

Differing income coefficients between households with children and those without lead to instability in the values of the scales. If

David W. Price is a professor of agricultural economics, Washington State University.

the coefficient for households with children is higher than that for households without, the scale values for children will increase as income increases. For prediction purposes, the values of the income coefficients for each type of household are needed along with the scale. Thus, the scale will completely specify age-sex and other effects if coefficients for income and other similar variables are equal for different types of households. If such coefficients are unequal, the scales express only age-sex differences at mean income levels. If income and other coefficient differences are not large, scales may still adequately express age-sex and other effects. If income coefficients differ substantially, scales are only a rough indication of age-sex and other effects. A specification similar to that used by Sexauer might be used along with the scales to specify sociodemographic effects.

In the broader context of methodology, the Sexauer paper makes progress on the basic problems inherent in forecasting. To forecast accurately, one must have stable coefficients. The procedure of disaggregating into groups which hopefully display stable coefficients is an important contribution. Of course, we are not assured that the groups Sexauer has delineated will display stable coefficients over time.

This problem of stable coefficients can be viewed as a problem of scientific laws. The causal law is of the form "all X's have property Y." For example, for a given group of consumers (X's), as income increases by a given percentage, food expenditures increase by a given percentage (property Y). The X's must be defined specifically so that the relationship holds universally. In the example of household behavior, we need to specify for which household, under what conditions there will be a stable relationship between income and expenditures.

Since we cannot state the relationship between income and expenditure with certainty, this type of relationship can be viewed as a statistical law which is of the form "all X's have property Y with probability p." According to Hemple, little modification is needed in the basic framework of explanation and prediction when statistical laws are used instead of causal ones. Thus, the same problems of the adequacy of the basic laws exist whether statistical or causal.

Viewing the specific relationship between income and expenditure as a scientific law, we must specify the "boundary" conditions under which this law will hold. I am not referring here to the more general form of Engel's law between income and food expenditure, but a specific statement as to the size of the income coefficient or elasticity. For forecasting, we need to specify the boundary conditions for the specific coefficient to be stable. For example, the conditions may consist of the following: a one-person household with the person being employed, with a college education, belonging to social class y, having a psychological need for food of level z.

The above is, of course, little more than a guess as to what the boundary conditions may look like. Our lack of knowledge of boundary conditions demonstrates a major weakness in the profession of agricultural economists (Kelso). We cannot successfully predict or explain adequately economic phenomena without them. Boundary conditions can be specified with the use of theory and empirical experiment. Sexauer's work is a start. To fill in the missing pieces, we need to analyze different data sets which let us look at households under different situations. The theory which suggests what variables affect the income-food expenditure relationship needs considerable improvement. We have little idea if and what any sociological or psychological variables may affect this relationship.

Risk Preferences of Agricultural Producers: Their Use in Extension and Research

Douglas L. Young

Most models of decision making under risk require knowledge of decision makers' willingness to bear risk, or equivalently, knowledge of their risk preferences. This is true both for positive applications of risk theory that explain or predict behavior under uncertainty for purposes of policy evaluation and for normative applications which advise decision makers which decisions they should make given their feelings toward risk.

The specific objectives of this paper are: (*a*) to review and evaluate critically the current state of knowledge on risk preference measurement methods and empirical results for individual agricultural producers, and (*b*) to suggest directions for future research and extension applications requiring information on risk preferences of individual producers. The implications of aggregate (industry) risk preferences as in risk supply response studies will not be included in this review.

Concepts of Risk and Risk Preferences

The behavorial decision model employed determines the appropriate concept of risk in a particular application. The popular Bernoullian expected utility decision criterion utilizes an objective function that is a function of (potentially) all the statistical moments of the (usually profit) outcome of the risky actions, a_i, $i = 1, \ldots, n$, available to the decision maker. In practice, it has been popular among empiricists to assume that the underlying utility function was quadratic or that profits were normally distributed yielding the simpler function of mean and variance only

$$(1) \qquad \max_i \; (EU)_{a_i} = f(\mu_{a_i}, \sigma_{a_i}^2).$$

Accepting (1), variance (or a related measure of dispersion such as standard deviation or coefficient of variation) is clearly the appropriate "measure of risk." Aside from the plethora of conceptual and methodological issues concerning whether the variance should be subjective or objective and how it should be elicited or measured (see Anderson, Dillon, Hardaker), two fundamental potential limitations characterize the "variance as risk" concept embedded in (1). First, if the decision maker is concerned about higher moments of the action-outcome probability distributions, "risk" should be represented by a vector containing variance of profit, skewness of profit, kurtosis of profit, and so on. Secondly, the convenient scalar measure of risk is based on a utility function considering only the single-attribute of profit. Agricultural producers may, in fact, base their decisions upon such multiple objectives as profits, leisure-work consequences, and personal "aesthetic" considerations.

A distinctly different set of risk concepts are implied by the various non-Bernoullian decision models. For example, the "minimax" model would identify the maximum loss of an action, regardless of how remote the probability of its occurrence, as a measure of the riskiness of the action. The lexicographic "safety first" model identifies the probability (α) that random profit (Π) will fall below some critical or "disaster" level (d) as risk, formally

$$(2) \qquad Pr\,(\Pi \leq d) = \alpha.$$

Most formal definitions of risk aversion rely on the Bernoullian conclusion that risk preferences can be encoded in a utility function for money (income or wealth) and the associated expected utility function as in (1). Positive marginal utility of income (i.e., $U'(M) > 0$) is commonly assumed for the utility function. Within the framework of Bernoullian decision

Douglas Young is an assistant professor and assistant agricultural economist at the Department of Agricultural Economics, Washington State University.

This is Washington College of Agriculture Research Center Scientific Paper No. 5395.

This paper draws on two more detailed papers on this topic (Young and Findeis; Young et al. 1979) stemming from the author's involvement on Western Regional Research Project, W-149. Helpful suggestions from several fellow W-149 project participants on earlier versions of this paper are gratefully acknowledged.

theory, the following measures yield equivalent risk preference classifications: (*i*) $U''(M)$, (*ii*) $-U''(M)/U'(M)$, (*iii*) $\partial EU/\partial\sigma^2$, (*iv*) $(d\mu/d\sigma^2)_{EU=\text{constant}}$, and (*v*) the risk premium. A decision maker is classified as risk averse, risk neutral, or risk preferring, respectively, as measures (*i*) or (*iii*) are less than, equal to, or greater than zero. For measures (*ii*), (*iv*), and (*v*), the inequalities are reversed to indicate the respective classifications. A Bernoullian utility function is unique only up to a positive linear transformation; the same action will maximize expected utility for $Z = a + bU$, $b > 0$, as for U. In recognition of this property, Pratt developed $-[U''(M)/U'(M)]$ as a unique measure of absolute risk aversion which yields the same value for both Z and U. Pratt also defined $-[U''(M)/U'(M)]M$ as a measure of relative risk aversion. Definition (*iii*) directly measures the impact of a change in risk (σ^2) on expected utility. Definition (*iv*), attributable to Magnusson, represents the marginal rate of substitution between risk and expected income.

An intuitively attractive measure of the degree of risk aversion is the amount an individual will willingly pay to avoid participation in a fair bet, or the risk premium. More generally, the risk premium for a risky action is the difference between its expected monetary value and its certainty equivalent. The certainty

tween certain outcomes and risky options involving hypothetical gains and losses. After a series of points in U-M space have been identified in the interview, an explicit utility curve can be fitted to the points by regression analysis.

The DEU technique has been criticized as subject to bias arising from different interviewers, preferences for specific probabilities (for example, a 50:50 bet), confounding from extraneous variables, and negative preferences toward gambling (Roumasset, Binswanger 1978b). Choice of an inappropriate functional form for the utility function can lead to undesirable implications (Lin and Chang). Also, utility associated with the outcome of a particular risky action is probably dependent upon more variables than monetary gains and losses alone. Inability to hold these other variables constant while eliciting single attribute utility functions is likely to lead to substantial imprecision.

In my view, even if the above "technical" sources of bias could be removed by refined interviewing and econometric techniques, the representativeness of choices involving hypothetical gains and losses in a parlor game setting could be questioned. Does a utility function elicited in a short interview around a farmer's living room coffee table reflect his attitudes toward risk in real world decisions?

Table 1. Empirical Studies of Risk Preferences of Individual Farmers: A Summary

Source	Description of Sample	Method[a]	Sample Size	Percent Distribution of Sample by Risk Classification: Averse	Neutral	Preferring	Mixed[b]
Binswanger	Indian farmers and landless laborers	EM					
		0.50 real[c]	119	71	0	19[d]	—[e]

Moscardi and de Janvry	Mexican peasant farmers	*OEB*	45	100	0	0	—[e]

[a] *EM* is experimental method; *DEU*, directly elicited utility; *OEB*, observed economic behavior.
[b] "Mixed" indicates presence of both risk-averse and risk-preferring ranges.
[c] Real payoff levels of 0.5, 5, and 50 rupees and hypothetical payoff of 500 rupees.
[d] Percentages do not sum to 100 due to "inefficient" respondents.
[e] Methodology precluded "mixed" classifications.
[f] *DEU* approach used but no explicit utility functions estimated.
[g] *SA* is subsistence assured; *SR* is subsistence at risk.
[h] Halter and Mason only reported "that the number (of classifications) falling into each category was about equal" (p. 105).
[i] I is year, II is year 2; *MVM*, modified von Neumann-Morgenstern method; *RAM*, Ramsey method.
[j] *EF* is expected income versus focus-loss income tradeoff approach; *MVM*, modified von Neumann-Morgenstern method.

chological research, for measuring risk preferences of more than 350 peasants in rural India. This approach involved use of actual financial compensation at significant levels, was conducted in a series of several visits over five or more weeks which permitted the respondent ample time to reflect on each decision and discuss it with others if desired, and required only a simple choice among eight gambles, which outcomes were determined by a flip of a coin. Impressive efforts were made to teach respondents the nature of the game, to elicit responses reflecting true feelings, to avoid interview bias, and to eliminate other sources of error. Binswanger developed the experimental approach after rejecting the DEU interview method. His field checks on the interview method led him to conclude " . . .

that evidence on risk aversion from pure interviews is unreliable, nonreplicable and misleading, even if one is interested only in a distribution of risk aversion rather than reliable individual measurement" (1978a, p. 45).

The realistic experimental approach utilized by Binswanger goes far in remedying some of the more serious measurement flaws of the DEU method. It is less obvious that such games could be funded for realistic levels of gains associated with major farm decisions in the United States. Binswanger spent approximately $2,500 for prize money in his Indian experiment. He estimated a comparable experiment in the United States would require $150,000 for prizes alone—an amount he implies is not unreasonable given the cost of many modern research projects (1978b, p. 54).

Observed Input Demand and Output Supply Behavior

The doubts surrounding the validity of directly elicited utility functions have encouraged researchers to seek indirect measures of risk preferences. This approach compares observed economic behavior with respect to factor demand and output supply to behavior predicted by theoretical models incorporating risk and risk preferences. For example, expected utility maximization under risk leads to first order conditions of the form (Magnusson, p. 65; Anderson, Dillon, Hardaker, p. 163).

$$(3)\quad E(MVP_i) = MFC_i + R_a I_r, \quad i = 1, \ldots, n$$

where $E(MVP_i)$ is expected marginal value product of input i, MFC_i is nonstochastic marginal factor cost of input i, and $R_a I_r$ is a "risk adjustment." R_a is the entrepreneur's local risk aversion coefficient as described by definition (*iv*) above and I_r is the marginal contribution to risk of additional input use. Assuming I_r is positive, risk aversion ($R_a > 0$) implies a positive "risk adjustment"; i.e., a risk-averse, expected utility-maximizing entrepreneur will "stop short" of equating $E(MVP)$ to MFC. (See Wolgin, and Young 1979, for an extension of this approach to the multiple-product firm case.)

Equation (3) indicates a theoretical approach for solving for R_a in terms of empirically observable magnitudes,

$$(4)\qquad R_a = [E(MVP_i) - MFC_i]/I_r.$$

In practice, however, obtaining appropriate estimates of I_r can be difficult without invoking excessively restrictive assumptions on the sources and functional specification of stochastic influences. Pope has proposed an econometric approach, based on the OEB concept, that provides estimates of an assumed constant risk aversion coefficient under certain assumptions. Moscardi and de Janvry have utilized this OEB approach within a safety first framework.

On the supply side, Brink and McCarl derived indirect estimates of risk aversion coefficients of thirty-eight large Corn Belt farmers by comparing their elicited cropping plans to those predicted by a variant of Hazell's MOTAD linear programming model. The value of the parametrically varied risk aversion coefficient that minimized the difference between the model's predicted plan and the farmer's actual plan was selected to represent the farmer's risk preferences.

The OEB approach shares with the DEU method the advantage of furnishing measures of risk aversion that can be incorporated directly into models of economic decision making under risk. In addition, however, the OEB approach escapes the compelling criticism that the revealed risk preferences may not be germane to real world decisions. Unfortunately, the OEB method is vulnerable to serious errors of inference. Because it measures risk preferences on the basis of the difference between actual factor use or output supply levels and the levels associated with the (risk-neutral) expected profit-maximizing solution, it attributes the entire difference to risk aversion. In actual fact, many other explanations such as inaccurate or incomplete technical and market information, different resource endowments, capital constraints, different objective functions, and different subjective probability assessments could underlie some or all of the residual attributed to risk aversion.

Empirical Findings on Individual Producer Risk Preferences

In assessing the empirical evidence in table 1 it is important to consider the quality of the samples represented. Overall, risk preferences have been elicited for a very small number of agricultural producers. Furthermore, there was no attempt in most studies to achieve industry representativeness in sample selection. These sample limitations, combined with previously cited measurement problems,

make generalizations from the evidence in table 1 to the general populations extremely tenuous.

One tentative conclusion is that farmers in less developed countries appear to be more uniformly risk averse than their wealthier counterparts in developed countries. Among the studies of Australian and American farmers, approximately 50% of the sampled individuals manifested risk-preferring attitudes over at least some ranges when the measurement technique did not preclude this possibility. Risk-neutral or risk-preferring attitudes over some ranges among a significant fraction of agricultural producers in developed countries cannot be excluded on the basis of the available evidence. The greater incidence of risk aversion in developing countries is consistent with the widely accepted hypothesis of decreasing absolute risk aversion with respect to wealth.

Only the studies by Moscardi and de Janvry, Dillon and Scandizzo, Binswanger, and Halter and Mason, among those reviewed, focused explicitly on the relationship between producer attributes and risk preferences. Overall, few consistent relationships emerged over all four studies. The one exception was a positive correlation between education and the willingness to bear risk.

Potential Uses of Producer Risk Preferences: Review and Research Recommendations

To recommend directions for future research on risk preferences, it is necessary to ask why it is important to know producer risk preferences in the first place? Recognizing the added cost of measuring risk preferences and the unproven reliability of the measures, it is necessary to evaluate within the context of the specific problem whether attempted measurement is worthwhile. For many problems, some alternative approach may be more appropriate. Implications for future research are discussed below under three important areas of potential application.

Farm Management Extension Applications

The desire to tailor extension farm management recommendations to the current risk preferences of particular farmers provides one potential justification for measuring individual risk preferences. Although this application is recommended by some advocates (Makeham, Halter, Dillon), time, cost, and practical problems associated with direct elicitation of utility functions are likely to limit their use in extension programs. Even if researchers were to hand an extension worker an elaborate set of equations relating risk aversion at all relevant loss and gain levels to personal and business attributes for farmers in his district, the personal and evolutionary nature of attitudes toward risk would probably prevent their confident application to specific individuals. There likely exists considerable heterogeneity in risk preference among individuals with superficially common business and personal characteristics (recall evidence in table 1). Furthermore, evidence from psychological studies suggests that the behavioral predictive power of an individual's willingness to bear monetary risk is likely to change from situation to situation given the multiobjective nature of most decisions (Schneider, pp. 390–96). Changing objectives, information, and attitudes could make an individual's risk aversion coefficient an elusive moving target.[1] Neither farmers nor field extension personnel are likely to consent to obtaining personal updatings of utility functions or safety first margins every time a new recommendation is given.

In light of the above discussion, what should extension specialists and researchers interested in developing materials and models with extension applications do to incorporate risk considerations? Some specific recommendations which do not require elicitation of individual risk preferences are:

(*a*) Extension specialists should provide more and better information on alternative decision options and their objective outcome probabilities. They also should devote more effort to teaching principles of decision making and information utilization as exemplified by the excellent recent national SEA-Extension project, "Dealing With Risk In Farm Decision Making."

(*b*) Researchers constructing normative decision models for use by farmers should use risk aversion indices that are sufficiently simple and intuitive that they can be supplied by the farmer himself. Alternatively, these mod-

[1] An alternative hypothesis is that risk preferences are relatively stable over time, but that changing behavior under risk is due to varying constraints and changing subjective assessments of expected values and variances. The area of expectation formation processes requires more research to resolve satisfactorily this question.

els might incorporate decision rules that depend upon objectively measurable financial ability to bear risk. Hardin and Walker, for example, required that a farmer exceed a minimum equity ratio in order to assume the risk of borrowing in a land investment analysis.

(*c*) Researchers can rank decision options on the basis of rules of stochastic dominance. Meyer's criterion for identifying risk efficient decisions for decision makers whose risk aversion functions fall between certain bounds is a promising method for certain prescriptive models (Robison and King).

Technology Transfer and Rural Development Applications

Estimating single-attribute risk aversion coefficients of peasant farmers and relating them to socioeconomic variables as in Moscardi and de Janvry is probably not the most efficient method of predicting their willingness to adopt new technology or participate in rural development programs. If technology adoption or development program participation is of primary concern, it seems appropriate to use these phenomena as dependent variables directly, and to include all relevant factors as independent variables. A review by Havens of variables commonly used in technology adoption studies listed: (*a*) size of operation, (*b*) education, (*c*) social status, (*d*) contact with information, and (*e*) social participation. Other variables such as age, local group identification, opinion leadership, management practices, and attitude toward credit have also been used but less frequently.

Microeconomic Policy and Predictive Applications

It has been argued that farm management extension and development program planning applications generally do not justify measurement of individual risk preferences, or at least not formal measures based on directly elicited utility functions. In the area of microeconomic policy and predictive applications, however, such measures sometimes are justified. The studies by Baquet, Halter, Conklin; Harris and Nehring; and Lin, Carman, Moore, Dean provide examples of such applications.

A danger in such application is that the difficulty or cost of eliciting utility functions for more than a small, possibly unrepresentative, sample of farmers will reduce the studies to methodological excursions rather than practical policy evaluation tools. This danger seems to have been realized, at least in part, in both the Baquet, Halter, and Conklin and Harris and Nehring studies as reflected in extensive qualifications of their results (see Baquet, Halter, Conklin, p. 519, and Harris and Nehring, p. 166). Researchers must seriously ask themselves, especially for applications where results are not highly sensitive to risk preferences, whether ignoring risk preferences will increase their chances of developing quantitative results for a larger and more representative sample of the population so that their conclusions will be of practical value to policy makers.

A policy area of particular importance at the current time justifying incorporation of risk considerations is the dynamic structural and distributive implications of income instability in agriculture and of public policies to mitigate such instability. What are the relationships between risk preferences and structural features, especially farm size and legal form of ownership? For example, are larger or corporate farmers generally less risk averse than small or family farmers who are sole proprietors? A second, not unrelated, group of hypotheses involves examining the frequently assumed positive relationship between accounting measures of financial ability to bear risk and willingness to bear risk. A related research priority is the need to examine the differential historical capacity of farms of different sizes and types to survive and to maintain profitability under price and yield instability. Studies by Lin and Ingerson, Anderson, and Moore provide tentative evidence that small farms may benefit relatively from increased income stability, but much more empirical work is needed in this area.

Which methodologies appear most fruitful for measuring risk preferences for use in microeconomic policy and predictive applications? If the problem strictly requires risk preferences of individual producers rather than "typical" preferences of designated classes of producers, the experimental method as utilized by Binswanger seems most likely to provide reliable replicable measures of risk aversion, assuming the method is adequately funded and conscientiously executed.

In applications where objectives other than profit alone are likely to be important, serious consideration should be given to utilizing a multiobjective decision model (Keeney and

Raiffa). In certain cases, a certainty multi-objective approach may be preferable to a single-attribute risk model.

If "typical" or average risk preferences of designated classes of farmers are required, two methodological options are available. The first approach is typically carried out in two stages: (*a*) estimate risk aversion coefficients for a large sample of individuals whose members vary according to the class attributes of interest, and (*b*) describe the relationship between risk aversion level and personal or business attributes. Regression analysis and multivariate statistical techniques are statistical tools which can be used to describe these relationships (Binswanger 1978a, Dillon and Scandizzo, Moscardi and de Janvry, and Halter and Mason).

The second (OEB) approach would be to estimate aggregate risk aversion coefficients or risk responses of designated classes of farmers directly with econometric or risk-programming models. Risk response models which bypass the direct estimation of formal risk aversion coefficients to focus directly on the measured impact of risk on the variable of interest should be seriously considered whenever their estimation is feasible. Data availability is likely to pose the greatest constraint to the use of this method. Aggregate time series data are unlikely to be available, for example, to estimate separate risk-response acreage supply functions for small and large farmers.

Analysis of Risk Management Strategies for Agricultural Producers

Harry P. Mapp, Jr., Michael L. Hardin, Odell L. Walker, and Tillak Persaud

Uncertainty is a pervasive phenomenon in production agriculture. Many factors, including weather events, diseases, insect infestations, general economic conditions, the development and adoption of technological innovations, and public and private institutional policies, interact to create a unique decision making environment for the agricultural producer. Institutions and the uncertainty surrounding the development and implementation of their policies have become increasingly important to farm operators. Today, perhaps to a greater extent than they would like, producers must respond to energy policy which affects the availability and cost of fuels, and trade policy which influences exports and imports of agricultural supplies and products. Farmers' decisions are influenced by environmental policy which specifies the types and quantities of pesticides and herbicides available and legislates safe levels of usage. Financial institutions have increased farm borrowers' risk of interest rate increases by adopting floating and variable interest rates.

Each of these factors along with vagaries of nature and markets contributes to the price, yield, or net return variability of agricultural producers. Institutional innovations, such as disaster payments, emergency loans, and federal crop insurance, are designed to shift a portion of the adverse effects of price and yield variability from the private to the public sector. The proposed Farm Production Protection Act of 1979 would provide varying amounts of protection and guarantee compensation for crop losses due to crop failure or natural disasters through an insurance program with the producer's premium subsidized by the government (Miller and Trock). Participation in these programs depends upon the decision maker's perceptions of the potential benefits and costs, and his attitude toward risk.

The specific purposes of this paper are (*a*) to review research both recently completed and currently in progress on approaches being used to assess and respond to production, market, and financial risks in agriculture; and (*b*) to present an evaluation of production and marketing strategies designed to minimize variability of net farm income subject to receiving a specified level of income for a southwestern Oklahoma farm operation; and (*c*) to relate the effects of alternative assumptions regarding beginning equity level, rate of increase in land value, and rate of increase in the cost of agricultural inputs to the probability of "success" of risk efficient farm plans for the southwestern Oklahoma operation.

Review of Recent Research Approaches

A number of firm-level studies have focused on whole farm planning under conditions of risk and uncertainty. An approach frequently used is quadratic risk programming (Fruend; Kliebenstein and Scott). Researchers using this approach usually assume that the decision maker maximizes expected utility and either the utility function is quadratic with respect to expected income and variance of income or net returns of the production activities follow a multivariate normal distribution. Historical price, yield, and cost data provide the basis for

Journal Article No. J-3676 of the Oklahoma Agricultural Experiment Station.

calculating net returns associated with each production activity. The model is solved to determine the set of production activities that minimizes variance of net returns subject to receiving a specified level of income or to develop the efficiency frontier showing tradeoffs between expected income and variance of income.

Hazell developed an approach which minimizes total absolute deviation rather than variance, which may be solved using a linear programming algorithm, and which gives results remarkably similar to those of quadratic programming. This approach, referred to as MOTAD, had been applied successfully to several different types of problems (Brink and McCarl; Nieuwoudt, Bullock, Mathia; Simmons and Pomareda; Schurle and Erven).

An alternative approach to studying the effects of risk and uncertainty at the firm level has involved development of firm level simulation models. Patrick studied the effects of debt levels and loan arrangements on a farm firm survival and growth. Held and Helmers developed a financial simulation model to investigate firm growth, income, and survivorship relationships in wheat farming. Hardin also developed a simulation model to evaluate risk and financial management implications of major capital investments in an uncertain environment.

This analysis uses both MOTAD and simulation models to evaluate risk efficient farm plans under alternative economic futures. The analysis simulates the potential effects of reduced rates of increase in land value, increased costs of production, and alternative beginning equity levels on the viability of risk efficient farm plans developed on the basis of historical data in a MOTAD framework.

Farm Situation and Data Requirements

A typical farm situation for southwestern Oklahoma was defined for the MOTAD-simulation analysis. The farm contains 1,200 acres of cropland and 300 acres of native pasture. Crop activities in the model include alfalfa, cotton, grain sorghum, wheat, barley, and oats. Both models require data on variability for each activity. Experimental plot data from field stations in southwestern Oklahoma were analyzed and a series of trend-adjusted annual yields for each activity was estimated for the period 1965–77.

Activities for steers and heifers on wheat pasture and summer stockers were included in the model. Experimental data did not exist to establish yield variability for the livestock activities. Oklahoma crop and livestock price series for 1965–77 were obtained for each activity in the model. Product prices were adjusted for trend where appropriate and expressed in constant (1977) dollars. Oklahoma crop and livestock budgets were used to establish the 1977 cost of production for each activity. The Index of Prices Paid by Farmers was used to generate the cost of production series from 1977 back to 1965 for each activity. The result was then expressed in 1977 dollars.

Gross margins for each activity were calculated by subtracting the variable cost of production during each year from the appropriate gross revenue in that year. Estimated gross margins for selected crop and livestock activities used in the MOTAD analysis are presented in table 1. Triangular distributions reflecting these relationships along with correlations among activity yields and prices were used in the simulation analysis. The triangular distributions were defined by specifying the maximum, minimum, and modal values for each activity.

Production assets for the hypothetical 1,500 acre dryland farm include land and buildings valued at $855,000 and machinery valued at $70,000. Production liabilities were confined to real estate debt of $270,628. Beginning equity is $654,372 (70%). In part of the study described later, real estate and machinery debt are increased to create a beginning equity of 45%.

Development of MOTAD and Simulation Models

The MOTAD model used to develop risk efficient farm plans is a variation of linear programming. The MOTAD model formulation used in this study was

$$\text{(1)} \quad \text{Minimize } Ld^{-}$$
$$\text{subject to:}$$
$$\text{(2)} \quad A\,X \leq B,$$
$$\text{(3)} \quad DX + Id^{-} \geq 0,$$
$$\text{(4)} \quad C'X = \lambda, \text{ and}$$
$$\text{(5)} \quad X,\, d^{-},\, \lambda \geq 0,$$

where X, A, B, and C represent activity levels, resource requirements, resource availabilities, and gross margin expectations, respectively.

Table 1. Estimated Gross Margins in Constant (1977) Dollars for Selected Crops, Southwestern Oklahoma

Year	Wheat Sale at Harvest	Cotton	Grain Sorghum	Winter Steers	Summer Steers
	($/AC)			($HD)	
1965	23.03	64.51	36.21	31.50	53.77
1966	76.62	−55.84	17.74	69.28	8.08

Mean	36.02	35.31	52.86	47.07	27.27
Standard deviation	48.79	56.99	34.92	37.57	36.78
Coefficient of variation	135.44	161.38	66.05	79.82	134.87

Gross margin is defined as gross return minus total variable cost. The gross margin expectation is the mean of the series. The difference between the observed gross margin and the gross margin expectation in a given year is an element of D, the matrix of deviations. The vector $\mathbf{d}^-$ represents yearly total negative deviations summed over all risky activities. $\mathbf{Ld}^-$ represents the summed total negative deviations over all years. λ is a scalar used to represent the income constraint. The efficiency frontier may be traced out by parameterizing λ from zero to its maximum value.

The simulation model, described in detail by Hardin, traces the operation of the firm thru a specified planning horizon under stochastic prices and yields. The simulation model generates cash flow data used in present value and feasibility analysis for the farm and balance sheet information needed to determine if equity is sufficient to maintain the financial viability of the farm thru the planning horizon. For the alternative plans developed by MOTAD, the simulation model can answer questions such as "Is the plan financially feasible given the farmer's consumption needs, initial financial position, and potential income distribution over the planning horizon?" The simulation model evaluates the effects of interactions between years which is not possible with the MOTAD model. The risk management strategy to be simulated is specified as input data for the model. Alternative assumptions regarding the future economic trends are specified. In this analysis, changes in the rate of increase in land values and input prices were evaluated for alternative beginning equity levels.

Analysis and Results

The MOTAD model was used to analyze a base plan and two risk management scenarios. The base plan (the linear programming solution) assumes the farm operator chooses from a set of production activities which involve sale of the product at harvest and that his objective is to maximize gross margins. In the first risk management scenario, the producer is assumed to minimize total negative deviations from the gross margin expectations, subject to receiving a specified level of income. The second risk management scenario assumes that storable commodities, such as wheat, may be marketed at harvest or sequentially during the crop year. Storage costs are accounted for and the producer may sell any portion of the stored wheat during any month of the crop year. In addition, this scenario permits consideration of forward contracting for a portion of the wheat crop. The forward contracting activity assumes the producer contracts in March for June delivery.

The solutions determined under the base plan and the two risk scenarios are presented

Table 2. Programming Solutions under Three Production and Marketing Scenarios

Activities in the Optimum Solution	Units	Profit-Maximizing Solution—Sale at Harvest	MOTAD Solution—Sale at Harvest	MOTAD Solution—Sequential Marketing and Forward Contracting
Steers	Head	171	233	222
Grain sorghum	Acres	1172	918	866
Alfalfa	Acres	28	28	28
Cotton	Acres		65	150
Wheat—sell in June	Acres		189	
Wheat—sell in December	Acres			60
Wheat—forward contract in March for June sale	Acres			96
Gross margins	Dollars	66,340	65,000	65,000
Standard deviation[a]	Dollars	41,360	36,100	33,605

[a]Standard deviation is estimated by multiplying the objective function value from MOTAD (Ld^-) by a constant K. K is calculated as $K = 2/t\sqrt{\frac{t \cdot \pi}{2(t-1)}}$, where $t = 13$, the number of years in the series, and $\pi = 3.14286$ (Hazell).

in table 2. When production and sale at harvest are the only alternatives, the profit maximizing organization of production is very specialized. Only two crop activities enter the solution—1,172 acres of grain sorghum and 28 acres of alfalfa. In addition, 171 steers are included in the solution. Gross margins total $66,340 and standard deviation is $41,360. Risk is assumed to be of no importance to the producer in the base plan. This solution represents the maximum profit point on the efficiency frontier.

The first risk management scenario assumes the producer wishes to minimize total negative deviations from the gross margin expectations subject to receiving $65,000 in revenue above variable costs of production. Lowering gross margins slightly results in a considerably more diversified farm plan and substantially less risk (table 2). The MOTAD solution still contains grain sorghum (918 acres) and alfalfa (28 acres), but also contains 65 acres of cotton and 189 acres of wheat. Steers remain in the solution, but at a considerably higher level. The efficiency frontier appears to be relatively steep in the vicinity of the profit-maximizing point. Diversification of the farm plan permits the producer to receive gross margins of $65,000 while reducing the standard deviation to $36,100. The coefficient of variation (standard deviation divided by the mean) is reduced from 62.35% under the base plan to 55.54% under the first risk management scenario.

The second risk management scenario introduces the possibility of sequential marketing and forward contracting of wheat. It is on an efficiency frontier different than the first MOTAD solution for gross margins of $65,000 (table 2). The resulting farm plan contains 866 acres of grain sorghum, 156 acres of wheat, 150 acres of cotton, and 222 steers. The production from 96 acres of wheat is forward contracted in March for sale in June. Production from 60 acres of wheat is harvested in June and stored until December when it is sold. Introduction of sequential marketing and forward contracting as marketing alternatives permits the producer to reach a higher efficiency frontier. He is able to generate $65,000 in gross margins while reducing the standard deviation to $33,605. The coefficient of variation for this scenario is 51.70%.

A number of additional risk management strategies are possible. Several of the more interesting include purchase of crop insurance, cash versus crop share rental arrangements, use of the futures market for wheat and cattle, and the utilization of federal disaster payment programs. These alternatives are being explored, but time did not permit their inclusion in this paper. Instead, the analysis focuses on the feasibility of the risk efficient farm plans under alternative assumptions regarding future economic conditions—questions not easily addressed in a MOTAD framework.

Simulation Analysis

The base solution and two MOTAD risk management solutions discussed above were eval-

Table 3. Economic Situations and Strategies Evaluated in Simulation Runs for a Southwestern Oklahoma Farm

	Programming Solution									
	Base	MOTAD 1	MOTAD 2	Base	MOTAD 1	MOTAD 2	Base	Base	Base	Base
Simulation run	1	2	3	4	5	6	7	8	9	10
Percent equity	70	70	70	45	45	45	70	45	70	45
Annual percentage increase in:[a]										
Land values	7.0	7.0	7.0	7.0	7.0	7.0	4.0	4.0	7.0	7.0
Input prices	5.0	5.0	5.0	5.0	5.0	5.0	5.0	5.0	6.0	6.0

[a] The following were held constant at the indicated rates of increase: output prices, 3.75%; family living, 5.0%; and machinery and building prices, 5%.

uated under alternative assumptions regarding future economic conditions. Each of these farm plans was simulated over a twenty-year period under the assumptions that the producer had a 70% beginning equity, the prices of agricultural products would increase 3.75% annually, the prices of agricultural inputs would increase 5% annually, land price would increase at an annual rate of 7%, and family living requirements and machinery and building costs would increase by 5% per year. Each of the farm plans was also simulated over a twenty-year period under the assumption that the land values increase at an annual rate of only 4%, and then under the assumption that the prices of agricultural inputs increase at an annual rate of 6%, all other rates of increase as originally specified. These simulation runs are summarized in table 3.

Table 4 presents ending net worth and farm bankruptcies for each farm plan and economic future evaluated, based on a twenty-year simulation under the indicated situation. At the end of the twenty years there would be substantial amounts of capital gains in land and capital gain taxes to be paid if the land were sold. The ending net worth has been adjusted to reflect the net that would remain after the capital gain taxes are paid, as though the land is sold in the twentieth year. The simulation model will generate cumulative probability distributions of selected variables such as net worth for use with stochastic dominance or other criteria. Only the parameters of net worth are considered here for brevity.

The expected ending net worth under each alternative is presented in the column labeled "mean" in table 4. As expected, the highest

Table 4. Ending Net Worth and Farm Bankruptcies under Alternative Farm Plans and Economic Futures, Southwestern Oklahoma Farm

Situation	Simulation Run	Ending Net Worth[a] Mean	Minimum ($1000)	Maximum	C.V.	Number of Bankruptcies
70% Equity						
Base	1	3135.7	2169.8	3856.4	9.6	0
MOTAD 1	2	3056.0	2320.9	3682.4	8.0	0
MOTAD 2	3	3099.1	2422.1	3668.6	7.3	0
Base (4% land price increase)	7	1801.2	835.4	2522.9	16.7	0
Base (6% input price increase)	9	2991.4	1899.0	3738.2	11.0	0
45% equity						
Base	4	2464.0	1185.6	3344.4	16.8	6
MOTAD 1	5	2330.7	1338.7	3137.0	15.4	2
MOTAD 2	6	2390.0	1448.8	3128.4	14.2	1
Base (4% land price increase)	8	1129.5	−148.8	2009.9	36.7	20
Base (6% input cost increase)	10	2265.2	880.1	3214.3	20.0	8

[a] Ending net worth is based on twenty years of simulated operation of the 1500-acre farm under the run situation indicated and is net of capital gains taxes on the ending value of land (payable if the land were sold).

expected net worth was obtained from the linear programming, profit-maximizing solution (run 1) where risk is assumed ignored. Simulation of MOTAD 1 (run 2) results in lower expected net worth at the end of twenty years and a reduction in the coefficient of variation. Simulation of MOTAD 2 (run 3), the solution on a higher efficiency frontier, results in slightly higher expected net worth and a lower coefficient of variation. The minimum ending net worth is higher and range of ending net worths lower for the MOTAD solutions than for the base solution which ignores risk.

Run 7 simulated the effects on the base solution of a reduction in the rate of increase in land values from 7% to 4%, other factors unchanged. The importance of land price increases on the level and stability of ending net worth is dramatically illustrated. Mean ending net worth drops from \$3.1 million to \$1.8 million and the coefficient of variation increases substantially.

The potential impact on the base solution of a change in the annual rate of increase in the cost of inputs from 5% to 6% is shown in run 9. The expected ending net worth is reduced slightly from \$3.1 million to about \$3.0 million and the coefficient of variation is increased to 11.0%. As expected, the modest increase in the price of inputs has substantially less effect than the reduction in the rate of increase in land values. No bankruptcies occurred under any of the simulation runs when the producer had a beginning equity of 70%.

When the beginning equity was reduced to 45%, the possibility of bankruptcies occurs under all five simulation runs (table 4). The relationships between and among the base, MOTAD 1, and MOTAD 2 solutions under the assumption of 45% equity (runs 4, 5, and 6) are again as expected. The base solution has the highest expected ending net worth, the highest coefficient of variation, and the possibility of six bankruptcies. MOTAD 2 has the lowest coefficient of variation and the possibility of only one bankruptcy.

A drop in the rate of increase in land values to 4% had a drastic effect at the 45% equity level (table 4, run 8). Expected ending net worth is reduced to \$1.1 million, the minimum ending net worth is negative and twenty bankruptcies occur in 100 replications. The impact of an increase in the annual cost of inputs to 6% is less severe. Mean ending net worth over twenty years is reduced only by \$200,000 and the coefficient of variation and number of bankruptcies are increased slightly compared to the base solution at 45% equity.

An approximate comparison of the results of operating the farm over twenty years under each of the plans with other off- or on-farm opportunities is obtained by deflating the ending net worth to reflect present value. The mean ending net worth for the three plans with 70% equity and base assumptions reflected about a 6% compound rate of growth. The expected rate of growth with 45% equity is approximately 5%.

Summary and Limitations

This analysis combines use of a MOTAD model to derive risk efficient farm plans and a simulation model to evaluate the feasibility of those plans under alternative economic and institutional futures. The MOTAD model demonstrates the possibility of reducing relative variability through diversification and sequential marketing and forward contracting of wheat. The simulation model calculates annual net cash income, net worth, net present value, and the chance of business failure when the risk efficient farm plans are subjected to alternative rates of increase in land values and input costs, assuming beginning equities of 70% and 45%. The chance of business failure was found to increase substantially when beginning equity is 45% and land value rises at only 4% annually.

A number of important limitations of this analysis deserve mention. First, we assumed full ownership by the farm operator. Many large commercial farms combine land ownership and rental arrangements. An earlier Oklahoma study suggests that share rather than cash rent is an effective means of spreading risk among tenant and landlord (Walker and Hardin). Farm operators might also use pasture rental arrangements or livestock shares rather than ownership of cattle to reduce their risk. On the input side, machinery rental and/or custom hiring provide input cost flexibility. The impact of these deserves additional attention.

Second, given the ownership situation, only a few risk management strategies are evaluated. On the marketing side, we have considered only sequential marketing and forward contracting. Hedging opportunities are available for both wheat and cattle, but have been ignored in this analysis. All risk crop insur-

ance is an alternative receiving current policy attention. Preliminary analysis in another Oklahoma farming area indicated that, under the insurance arrangements assumed, federal crop insurance decreased the mean income without reducing income variability (Walker and Hardin). In fact, the number of bankruptcies increased, apparently due to the annual drain on cash flows to pay premiums and borrowings to meet cash needs. Other provisions of the proposed legislation discussed by Miller and Trock could also be evaluated.

The disaster payment provisions of the current commodity programs have also been subjected to preliminary analysis revealing that disaster payments improve the income and risk performance of farms (Walker and Hardin). The only cost to the farmer is participation in the commodity programs. The disaster payment sets a lower floor on returns from the commodities covered by the program. The deficiency payment also sets a lower floor on income variability associated with price fluctuations. Other institutional arrangements deserving attention include the impact of variable interest rates and alternative forms of business organization on the ability of the farm firm to survive economic fluctuations.

Risk Management and Risk Preferences in Agriculture: Discussion

David Bessler

I would like to commend the authors of both papers delivered in this session. The papers deal with important topics that deserve our attention. Because my major interest in this area has been the representation of economic agents' beliefs (see Bessler, and Bessler and Moore), I find it appropriate to direct the bulk of my comments to the paper delivered by Young. My comments on the paper by Mapp, Hardin, Walker, and Persaud will reflect only methodological points.

Briefly, the paper by Young reviews several empirical works on the elicitation of economic agents' risk preferences and makes certain observations on the feasibility of incorporating these preferences in various extension and research applications. The paper by Mapp et al., describes the selection of alternative risky production and management strategies using a variant of the mean-variance analysis for a southwestern Oklahoma farm operation. Outcomes from this analysis are then simulated, under alternative equity and price assumptions, over a twenty-year period.

My primary concern with both papers is that they have, for the most part, ignored the problems associated with using variance as a measure of risk and the associated stochastic dominance literature. The concern is quite real for the paper by Mapp et al., because their results are directly based on the representation of risk by variance (or an approximation of variance). My concern also applies to Young's paper. He too directs his discussion to the traditional mean-variance analysis of risky choice. Although he suggests that other procedures might apply, such as Meyer's stochastic dominance theorems, he gives only passing mention of their use in research and extension programs.

Criticisms of the mean-variance approach to analysis of risky choice have been heard for some time—probably the most elegant of these is contained in the dual papers of Rothschild and Stiglitz, written in the early 1970s. Additional work on the subject can be found in Meyer. They demonstrate that the ordering among risky prospects using the mean-variance approach is not necessarily equivalent to that obtained using three alternative rules for ordering. These three alternatives are, however, consistent among themselves. It is, for instance, quite easy to construct reasonable looking utility functions and probability distributions for two risky prospects, say F and G, for which F has a larger mean and a smaller variance than G, and yet have G be preferred to F. The idea is to make G highly skewed to the right.

I refer to these deductive arguments not to suggest that the results of Mapp et al., are necessarily invalid, for my degree of belief would suggest they are valid ($p = .80$). However, the deductive arguments do suggest certain empirical questions which should be answered before we go further with this type of analysis.

The questions involve the measurement of the probability distributions and utility functions relevant for choice among a particular set of risky actions. If the subjective probability assessments of the particular group of economic agents are normal or if their elicited utility functions are quadratic in income (wealth), then the procedures used by Mapp et al., are proper. If both of these conditions do not hold, then I suggest the more general stochastic dominance theorems be applied. This latter course is less desirable because pair-wise comparisons among distributions must be made—this is operationally tedious. Nevertheless, there have been numerous applications of these procedures in the literature (see Anderson et al.).

The paper by Young investigates the measurement of risk preferences. His findings, especially those related to Binswanger's work, are important and should not be taken lightly. The major point which Young's paper brings

---

David Bessler is an assistant professor in the Department of Agricultural Economics at Purdue University.

out of Binswanger's work is the proper one—that is, elicitation procedures carried out with hypothetical rewards and in brief sessions can yield incorrect results. More generally, one might say that we have not had very good experimental controls in much of our past work on utility elicitations. The use of rewards as a control (or assessor motivation) is not new in the general assessment literature. In fact, their use and advantages have been major points of study in the area of probability assessment for some time (see Winkler). However, I have not run across their direct use in utility assessment. Nevertheless, their use should be considered in both probability and utility assessment work.

The fact that Binswanger made multiple elicitations from the same assessor over several weeks is also commendable.

The concern Young shows on the added cost to research from paying assessors is quite real. Yet, if the "interview" method of elicitation does perform so poorly, and if we believe the research we undertake is important, then hundreds of thousands of dollars spent to obtain micro-observations should not necessarily be out of line. On this point I borrow the words of Juster:

> Economists are not accustomed to thinking in terms of these orders of magnitude (millions of dollars), but I suggest we take a page from the books of our brethren in the physical sciences. Particle accelerators and astronomical observatories that cost in the tens of millions are not uncommon, and they are judged to be worth their cost. Yet one is simply a way to generate observations, and the other is a way to measure observable physical phenomena. (p. 15)

Because most of our training and research involves the use of secondary data (designed for purposes not necessarily related to our research), we frequently are able to write project statements with relatively low data collection costs. A project requiring large control expenditures for data collection will most probably be judged extravagant when compared with projects not using these controls. Thus, Binswanger's documentation on the needs for these control expenditures (and Young's bringing it to our attention) is an important bit of information.

I would now like to raise a few specific points on these papers.

Mapp et al., continue to make the distinction between risk and uncertainty. By now, the reader has probably observed that I approach risk analysis from a subjective view. Thus, I find that this distinction is not very meaningful. Given the weight of other authors who sit in the subjective camp, I am curious why these authors continue to make the distinction. What type of analysis would the authors suggest if no exchangeable observations were available upon which to base their probabilities?

Mapp et al., use the triangular distribution to represent the probability distributions of each production activity. I find this representation to be interesting. However, I suspect that in some cases it may misrepresent the tails of the distributions rather severely—especially since the representations are based on only 13 observations. As an extension of their work, it would be interesting to compare these modeled representations with elicited subjective distributions from a sample of southwestern Oklahoma farmers.

The recommendation by Young that we report alternative decision options and their objective outcome probabilities is at first glance a laudable recommendation. However, further study might suggest that markets may already be reporting these options. Before public sector reporting is undertaken, it is necessary to better document its need and value. It is my guess that for many commodities, existing markets do a fairly good job of providing this information. That is, I suspect that market participants are, quite often, very much aware of relevant options and the probability distributions associated with the consequences of selecting any particular one. This point is generally an application of Muth's rational expectations hypothesis. More specifically, before we undertake a project of reporting options and objective outcomes, we must demonstrate that existing private markets are in some way failing to provide this information. Of course, where market failures in providing this information occur, I support Young's recommendation.

Risk Management and Risk Preferences in Agriculture: Discussion

Thomas A. Miller

These papers indicate that the process of individual decision making under risk is at least conceptually clear. When faced with risky situations, farmers choose risk management strategies based on their appropriate risk preferences. Unfortunately public decision making about agricultural risk management is not this well developed. Issues concern both what public risk management programs are needed for agriculture and the likely impacts of such programs. The papers presented here contain a number of intriguing implications about public risk management issues in agriculture, even though they do not directly address these issues. I will focus my remarks on these implications instead of making a detailed review or criticism of the papers.

Agricultural risk is a factor in two important groups of policy issues. One concerns Federal Crop Insurance and disaster payments. At the Western Agricultural Economics Association (WAEA) meetings last year, I discussed the issues concerning the government's role in providing disaster assistance to farmers (Miller and Trock). The U.S. Congress still is debating this question and appears moving toward a greatly expanded federal crop insurance program with some public subsidy to reduce farmer premiums. Answers to questions concerning both farmer needs for this assistance and its structural impacts are critically important if rational economic decisions are to be made on this program.

A second group of policy issues that are related to risk concern the structure of agriculture. Here the policy debate is not cast in terms of risk; it concerns family farms, the structure of agriculture, and the impact of policy on this structure. But risk may be one of the key mechanisms that links policy and structural change. The current U.S. farm programs assume risk through income support and grain reserve provisions, as well as through disaster payments and crop insurance. Raup recently observed that the federal assumption of agriculture risk is the single most pervasive example of how federal policies affect land use—how it is used, where it is used, and who uses it. Others have argued that the risk assumption effect of government commodity programs is a major policy influence on the structure of agriculture—possibly towards large scale, single purpose, nonfamily farms (Pope and Gardner, Sharples). Young cites other studies that suggest the opposite effect.

Simply put, the issues are these. What is the proper sharing of agricultural risks between the public and private sectors? Does federal assumption of agricultural risk have unexpected structural impacts? Do the likely benefits of such programs justify the costs, both public and private? I would like to discuss the papers presented here from the perspective of what they imply toward these issues.

Young has argued that the consideration of producer risk preferences may be necessary to understand thoroughly the consequences of public policies to mitigate instability. While traditional risk-neutral profit-maximization assumptions may be adequate for many research studies, the analysis of the distributive impacts of risk-modifying policies may require reliable risk preference measurements for appropriate groups of farmers. Two groups of hypotheses are of interest here: (*a*) the relationship between producer risk preferences and structural features, especially farm size and the legal form of ownership; and (*b*) the relationship between accounting measures of financial ability to bear risk and the willingness to bear risk. Testing these hypotheses is necessary to undestand the "dynamic structural implications" of public policies to mitigate income instability in agriculture.

Young's paper, therefore, has implications for both groups of policy issues I described at

the outset. Research on the risk preferences of different groups of farmers would increase our understanding of the impact and need of public disaster assistance programs. And because risk apprarently links policy to structure, measurement of risk preferences among different categories of farmers may also be of assistance in developing an effective structures policy for American agriculture.

While not explicitly requiring the measurement of risk preferences, the Mapp et al. paper describes a methodology for analyzing the impact of federal risk assumption programs at the individual farm level. The methodology encompasses much of the complexity of decision making under risk and provides one means of testing some of the hypotheses identified in the Young paper. I encourage the authors to evaluate additional public-supported risk management strategies including all risk crop insurance, hail insurance, direct disaster payments under the commodity programs, and the deficiency payments provided by the current target price mechanism.

The direct results of the Mapp research are consistent with the theory of decision making under uncertainty. Enterprise diversification is an effective risk management strategy. But this strategy, as well as other risk management tools, generally involves an income sacrifice. A farm operator's equity is extremely important in his ability to bear risk and in the long-run ability of the farm to survive and maintain profitability. A continued increase in land values is an important factor allowing farmers to bear risk, due to its favorable impact on equity ratios. Relative stability in input prices is of lesser importance. These preliminary results appear reasonable and suggest numerous additional questions to be analyzed.

Considered together, the two papers provide a number of interesting ideas concerning the impact of federal risk assumption programs. Since some of these relationships do not have a strong empirical basis at this time, it is convenient to describe them as hypotheses for further research.[1] Five major hypotheses cover both natural disaster assistance programs and commodity programs that decrease price and income variability: (*a*) Public risk assumption programs decrease the need for farm enterprise diversification and thus encourage more highly specialized farming operations. (*b*) Public risk assumption increases farm income slightly by decreasing the need for risk management strategies that would otherwise involve a farm income trade-off. (*c*) Public risk assumption programs enable farms to operate at lower equity levels by limiting the bankruptcy risk of highly levered financing. The implications of this hypothesis need to be carefully considered since the social cost of individual farm bankruptcy is unclear, particularly if such farms fail because they are poor risk managers. (*d*) Public risk assumption encourages the flow of outside funds into agriculture, increases the means of farms to grow, and increases the returns of capital relative to management. (*e*) Federal risk assumption encourages large-scale, specialized, low-equity farms financed from outside agriculture—and lessens the comparative advantage of traditional moderate-sized, diversified owner-operated family farms.

I believe that these hypotheses are among the most important that our profession can investigate. Do the likely benefits of public risk assumption programs justify the public cost and the possible structural impacts? The two papers just presented provide us with a basic theory and an operational methodology for testing these and other hypotheses. The future prospects for work in this area are both relevant and exciting.

[1] I have made on additional assumption in stating these hypotheses—that many farmers are already using prudent risk management strategies such as the ones evaluated by Mapp et al.

Risk Management and Risk Preference in Agriculture: Discussion

Steven T. Sonka

As evidenced by recent events, uncertainty about the future has seemingly become a characteristic of American society (Bazelon). The agricultural producer, of course, is subjected to those societal risks but, because of the particular aspects of agricultural production, uncertainty about future outcomes is a more critical concern for these producers. Therefore it is quite appropriate for agricultural economists to select this topic for discussion at these meetings. Although the two papers both address the risk question, the research topics they address have a considerable divergence. In part, of course, this only reflects the different orientations in which agricultural economists view the risk problem area.

Risk Preference

The paper by Young is primarily directed toward the problem of measuring producer's risk preference. Given the standard introductory comments we all make as to the importance of risk for the farmer, the investigation of farmer risk preferences would appear to be a high priority research need. However, for reasons detailed later, reflection and expansion on the issues reviewed by Young lead me to suspect that this research area may not have as high a payoff as it, at first glance, would appear.

Young's compilation of evidence as to risk preferences, which is a culmination of an extensive effort (Young et al.), is a useful statement of our present empirical knowledge base. And I concur with his concern about the validity of risk assessments generated from the direct elicitation and experimental methods.

A major strength of Young's paper, in my opinion, is its final section. In that section the question is asked, "What would we do with these coefficients even if we could estimate them?" This is a most useful question, although many of us may be guilty of not often asking it relative to our own research. Of the three uses suggested, the paper's discussion indicates that the microeconomic policy and predictive applications area has the most potential for utilizing risk aversion parameters.

But would the availability of risk aversion parameters really help us accomplish better policy and predictive work? Although risk is often an important factor which might encourage a decisionmaker to select a nonprofit-maximizing alternative, it certainly is not the only force which may temper the profit criterion.

For example, for several years Reiss has informally interviewed purchasers of farmland as to their reasons for buying land. Some of the motives cited relate to the income potential of the purchased property. However, several do not. Factors such as a son returning to the farm, a desire to own land, or the need for the house on a particular property were also cited as major reasons for buying farmland. Two additional factors often cited were tenure security and hedging against inflation. Although these latter two factors relate to uncertainty they are not captured by a risk aversion coefficient relating to variability of annual income flows (Harris and Nehring). But these variables do affect the bid price of individuals attempting to purchase farmland.

Therefore if we want to predict future behavior it may be as or more important to attempt to model the influence of these multiple objectives as it is to measure risk preferences. This comment supports Young's recommendation to bypass direct estimation of formal risk aversion coefficients, although possibly for differing reasons. It is important that our attempts to model the effects of uncertainty do not lead to our ignoring the effects of other important behavioral attributes of the farm decisionmaker.

Steven T. Sonka is an associate professor in the Department of Agricultural Economics at the University of Illinois.

Analysis of Risk Management Strategies

For farm management recommendations, however, it may often be quite useful to analyze alternatives in terms of their impact on income variability. The research summarized in the Mapp et al. paper utilizes such an approach. They first evaluate risky alternatives considering both expected income and returns variability using a MOTAD programming model. By parameterizing expected returns, they can then trace a curve analogous to an *E, V* frontier for several alternatives (Scott and Baker).

A major strength of their research effort is that they do not terminate their analysis at this point. Instead, by combining the attributes of two modeling techniques, the characteristics of their risk efficient plans can be evaluated in terms of outcomes, i.e., change in net worth and probability of bankruptcy, which have meaning for farm decisionmakers.

The research potential exhibited in the paper is impressive. The attainment of this potential should be applauded and might serve as a model for other groups of researchers concerned with generating information relevant to problem solutions.

On a negative note however, the alternatives analyzed in this paper are rather unexciting. Although the strategies discussed do exhibit the potential of their research approach, several of the risk management strategies cited as candidates for further research, such as crop insurance, nontraditional financing arrangements, and leasing alternatives, would be markedly more interesting than those presented.

Both the Young and Mapp et al. papers address research concepts which are important to researchers concerned with the impact of uncertainty on agricultural producers. Both should be interesting and thought-provoking readings for agricultural economists interested in doing research in the risk area.

Capital Gains versus Current Income in the Farming Sector

Emanuel Melichar

The value of farm assets has increased in most years since the Great Depression, mainly because of rising farm real estate prices. After 1970, annual increases in asset values have each year exceeded annual net farm income (including landlords' net rent), often by wide margins.

This paper examines the magnitude and causes of asset appreciation. It first notes that asset appreciation should be adjusted for general price inflation before it is compared with income. The comparable series, known as real capital gains, has been roughly equal to net farm income during this decade. Next, the primary origin of these significant real capital gains is traced to the fact that, contrary to the popular impression, the current return to farm assets has grown rapidly over the past twenty-five years, even when measured in constant dollars. It is then shown that, according to asset-pricing theory, a farm economy characterized by rapid growth in the real current return to assets will tend to experience large annual real capital gains and a low rate of current return to assets—which corresponds to actual experience in most years since the mid-1950s. This inescapable tendency has serious and paradoxical implications for the structure of agriculture and for farm policy, which are briefly sketched in the concluding remarks.

Capital Gains

At the aggregate sector level, analytical work on increased asset values as a form of return to farming seems to have been stimulated by Hathaway's 1957 observation that significant asset value increases were occurring in most years, and in particular by his technical error in adding asset value increases to net income and publishing the total.

The work that followed thus focused on constructing series that validly could be compared with net income. In the early 1960s, Grove first pointed out that annual net investment in farm assets should have been subtracted, and then Hoover and Boyne independently noted the further need for including gains or losses, on both assets and debt, resulting from changes in the general price level. Since the series constructed by Hoover and by Boyne included gains or losses on the purchasing power of funds owed to others, they could not be called "asset price appreciation"; their authors labelled them "real capital gains." The real capital gains series were next discussed and updated by Bhatia in 1971, and more recently by Brake and Melichar (pp. 445–47) and by Melichar and Sayre (1975, 1977).

Real capital gains are here computed as outlined by Melichar and Sayre (1977, pp. 58–62). First, total net investment and net transfers into the farming sector are subtracted from the annual change in the value of physical assets. This step yields the series known as "nominal capital gains." In the upper panel of figure 1, nominal capital gains are compared with income in a chart similar to that published annually by the U.S. Department of Agriculture (USDA; Evans, p. 17). As already noted, however, this comparison is misleading. If all of net farm income is transferred out of the farming sector (for instance, spent for con-

The analyses and conclusions are those of the author and do not necessarily reflect the views of the Board of Governors or the other members of its staff.

Advice and data on asset values and the return to assets received over a period of years from Carson Evans and Bruce Hottel, ESCS, U.S. Department of Agriculture, are much appreciated by the author. Balance sheet and income data used here are available from ESCS as of July 1979, except that farm income data for 1979 are projected by the author.

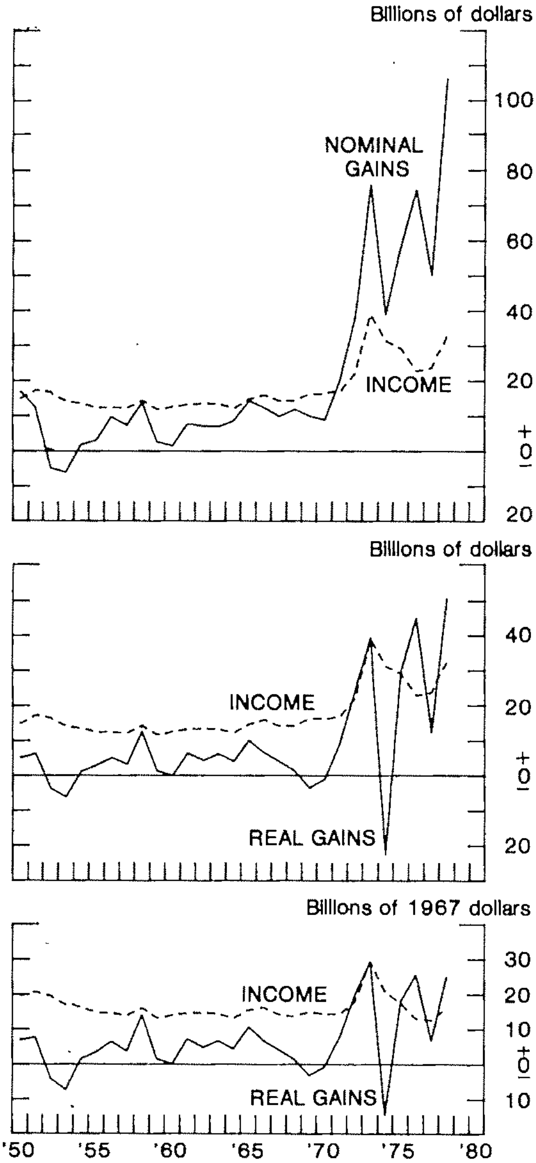

Figure 1. Capital gains compared with net farm income

sumer goods or nonfarm investments) the real wealth position of the sector is not changed. In a time of general price inflation, that also holds for real capital gains, but not for nominal gains.

Real capital gains are computed by adjusting the nominal gains for the gains or losses resulting from each year's change in the purchasing power of the funds tied up in assets or of the funds owed. These adjustments have been huge for recent years of rapid general price inflation. In 1978, for example, nominal capital gains of $106 billion were experienced on assets valued at $713 billion on 1 January. But general price inflation of 9.3% resulted in a purchasing power loss of $67 billion on assets held (9.3% of $713 billion) and a purchasing power gain of $11 billion on debt owed (9.3% of $119 billion).

The final result, real capital gains, is shown in the middle panel of figure 1. In most years, farm real estate has been the primary source of real capital gains and losses. However, cattle price changes contributed large losses in 1952 and 1974 and large gains in 1958 and 1978. Farm debt also has become a significant source of real capital gains, partly because of its rapid growth, but mainly because of more rapid general price inflation. Over two decades preceding 1972, real capital gains averaged about one-third as large as net farm income. Since then, on average, income and real gains have been roughly equal.

To compare recent capital gains (or income) with those of earlier years, it is advisable to express the data in terms of dollars with the same purchasing power, as in the lower panel of figure 1. Even in constant dollars, recent real capital gains are on average significantly larger than in earlier periods.

Origin of the Real Capital Gains— The Current Return to Assets

Many of the policy implications of large annual real capital gains depend on the cause of those gains. It is important to know, for instance, whether real capital gains are occurring because the return to assets is rising or because of some other influences.

The return to farm assets has been growing rapidly over the past twenty-five years; in fact, the return has risen somewhat faster on average than either farm real estate prices or the total value of farm assets (Melichar 1978). The common impression to the contrary has arisen through use of an inappropriate measure of the return to assets.

Typical discussions of land prices have proceeded by stating that, in theory, land prices should be related to "income." They then go on to compare operators' net farm income with the USDA index of farm real estate value per acre. Land prices have tended to rise faster than such income, especially prior to 1968. By that time this concept had become entrenched in much analytical thinking and literature.

There are, however, important defects in-

herent in comparing operators' net farm income with land prices. To begin with, an aggregate return is being compared with a unit price; moreover, the aggregate income is being regarded as a return to real estate alone, ignoring other productive assets. These defects can be remedied by replacing the real estate price index with the aggregate USDA series called "farm production assets" (Evans, p. 15).

Furthermore, operators' net farm income is not an appropriate measure of the return to either land or production assets. First, because a significant portion of farm real estate is owned by nonoperator landlords, their net rental income should be added. Interest paid on farm debt should also be included, as the goal is a return to assets rather than to equity. And, since farm production assets exclude operators' dwellings, that part of operators' net farm income consisting of the imputed return to the equity in these dwellings should be subtracted.

The series derived after making these adjustments is charted as the topmost curve in figure 2. However, as its title indicates, it remains a return not only to assets but also to management and to operators' labor. Thus, over time, comparisons between it and asset values may be distorted by changes in the relative importance of assets, management, and operators' labor in farm production. In view of the well-known reduction in operator numbers and man-hours, often described as "the substitution of capital for labor," one should not be surprised to find that this series is not an appropriate indicator of trends in the return to assets alone.

The upper panel of figure 2 shows the decomposition of the total return, as estimated by the USDA (Evans, p. 16). The lower panel, which shows the percentage distribution each year of the same three components, helps to clarify the significant change that occurred. Over the last twenty-five years, the proportion of the total return that could appropriately be ascribed to operators' labor has dropped from 63% to 17%, while the proportion that could be regarded as a return to production assets has risen from 25% to 69%. Consequently, as shown in the upper panel of the chart, the

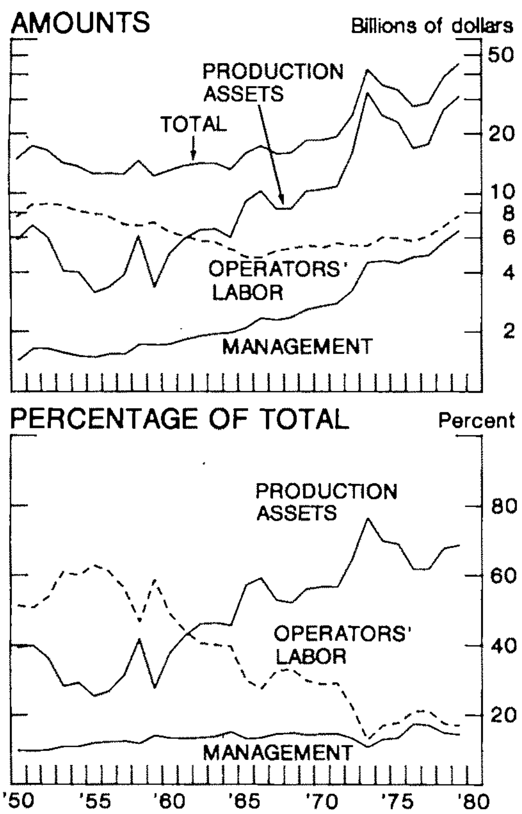

Figure 2. Distribution of the total return to pro duction assets, management, and operators' labor

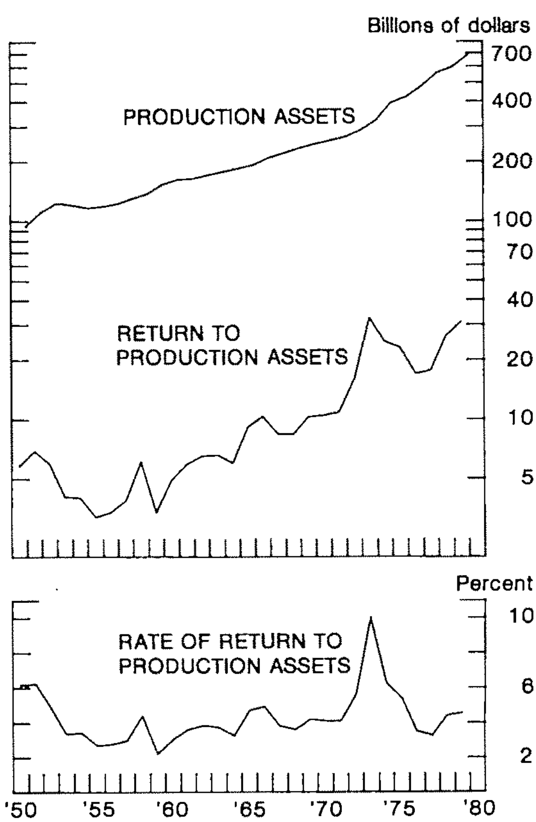

Figure 3. Residual return to production assets compared with value of such assets

estimated return to farm production assets has risen very rapidly over this period.

Figure 3 shows the residual return to farm production assets, the value of these assets, and—in the lower panel—their ratio, the rate of current return to such assets. It is evident that a markedly different picture of relative trends in asset values and returns has emerged. Since the mid-1950s, the return to farm production assets has risen faster than the value of such assets. Thus the rate of return rose from an average of 3.0% in 1955–59 to 4.2% in 1965–69, and again averaged 4.2% in 1975–79 in spite of the slump in 1976 and 1977.

Given the growth exhibited by the return to assets and the dominant position of farm real estate among these assets, there is no question but that farm real estate prices had to rise significantly. For instance, if farm real estate prices had remained at their 1954 level while the return to assets rose as it actually did, the rate of current return to assets in 1978 would have been 12% rather than the actual figure of 4%. Thus growth in the current return has figured prominently in upward pressures on land prices and hence in the occurrence of real capital gains. The arithmetic of this relationship is the next topic.

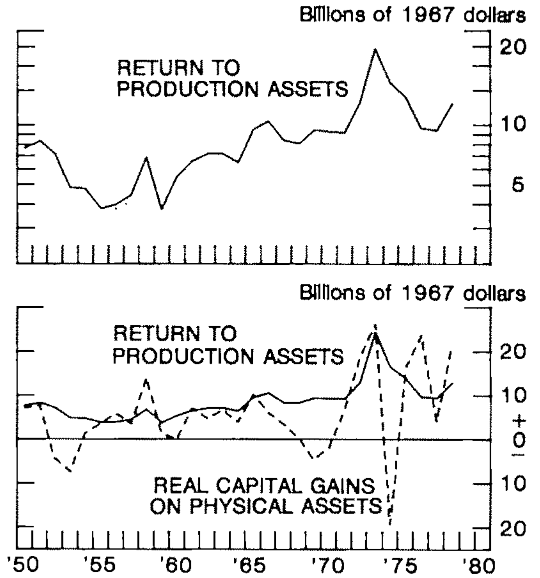

Figure 4. Return to assets compared with real capital gains, in 1967 dollars

Theoretical and Empirical Relationships Among Current Return, Capital Gains, and Assets

Key results of the first two parts of this paper are brought together in figure 4. The upper panel demonstrates that the constant-dollar current return to farm assets has exhibited significant growth since the mid-1950s. Its annual growth rate over the period 1954–78 averaged 4.25%.

In the lower panel of figure 4, annual real capital gains on physical assets are compared with the annual current return to production assets. When discussing real capital gains as a form of return to assets, it is more meaningful to compare them with the current return to assets than with total net income which, as already shown, contained a much greater proportion of labor income in earlier than in more recent years. Note that real capital gains on physical assets were on average nearly as large as the current return from 1954 through 1967 as well as in the 1970s.

In table 1, average values of these data are shown for four periods into which the past twenty-five years have been divided on the basis of differences either in the growth rate of the current return, shown in column A, or in the relative importance of real capital gains, shown in column C. In addition, column B shows the average rate of current return, and column D shows a measure of the average annual real percentage change in farm real estate prices.

For insights into the historical experience and relationships summarized in table 1, it is instructive to examine parallel relationships inherent in the asset-pricing model for an asset with a growing return. In its simplest form (ignoring complications such as inflation and taxes), the formula that relates the equilibrium present value of such an asset to its return is

$$V = \frac{1+g}{1+d} R + \frac{1+g}{1+d} V,$$
$$= \frac{1+g}{d-g} R,$$

where V is the present value of the asset, R is the present current return, g is the annual growth rate of the current return, and d is the discount rate applied to future returns.

For this asset, real capital gains arise in two different ways. First, changes in the value of R, g, or d result in a new equilibrium value V, and the amount of change in V is a real capital gain. Second, if the growth rate g is greater than zero, the equilibrium value V rises each

Table 1. Summary of Historical Constant-Dollar Relationships among Current Return, Capital Gains, and Asset Values, for Selected Periods

	(A)	(B)	(C)	(D)
1954–60	2.4	3.1	91	3.1
1961–67	6.2[a]	4.0	76	3.5
1968–71	2.3[a]	4.0	2	−0.2
1972–78	5.0[a]	5.4	91	4.9

[a] Growth rate from return in year preceding period shown to return in last year of period.

year even though the values of g and d are unchanged; that is, annual real capital gains are an inherent feature of the equilibrium condition.

Panel A of table 2 helps to illustrate the first source of real capital gains. For instance, at a discount rate of 6%, an asset whose return is growing at a rate of 1% annually will tend to be priced at 20.20 times its current return. If the growth rate of the return rises to 2%, the equilibrium multiple rises to 25.50. Thus this change in the underlying conditions causes equilibrium asset value to rise by 5.30 times a single year's current return. If the asset market should recognize and "discount" this growth rate change within one year, the real capital gain recorded that year would dwarf current income in that year. Suppose, however, that the asset market were to take five years to become fully aware of this growth rate change. In each of these years, the ongoing revaluation of the asset would on average result in real capital gain roughly equal to the current return. In the sixth year, the new equilibrium asset value having been reached, real capital gains from this source would vanish. This could come as a shock to analysts who had projected future gains primarily on the basis of the past record of such gains.

Revaluations of this kind are always going on in asset markets. In any historical record of real capital gains, an unknown proportion consists of gains of this essentially temporary and reversible nature.

The last three panels of table 2 help to clarify the second kind of real capital gains, those that occur annually in an equilibrium situation.

Panel B shows that, at equilibrium, the annual rate of increase in the price of an asset is equal to the growth rate of the annual return. For instance, if the equilibrium price of an asset this year is 25.50 times earnings and those earnings are rising by 2% annually, then next year, when those earnings are 2% higher, the asset is again priced at 25.50 times earnings and thus its price is also 2% higher. Therefore the value of the asset grows at the same rate as its return.

Panel C shows the equilibrium rate of current return at various combinations of the growth and discount rates. Note that the sum of the rate of current return (in panel C) and the rate of capital gains (in panel B) is equal to the discount rate. But since the growth rate is the same as the rate of capital gains, it is also evident that the rate of current return is equal to the discount rate minus the growth rate. In other words, the discount rate determines the total rate of return, and the growth rate determines how that total return is divided between a capital gain and a current return.

Suppose that one has an asset whose current return is growing at 2% annually, and that the discount rate of participants in the market for that asset is 6%. Panel C shows that the asset will be priced to yield an annual current return of 4%. For this asset, therefore, the ratio of annual capital gains to current return will be 2/4; that is, each year capital gains will be equal to 50% of current income. This result, shown in panel D, is simply the figure in panel B expressed as a percentage of the corresponding figure in panel C.

Upon scanning panel D, it becomes evident that substantial annual capital gains are inherent in equilibrium situations characterized by growth rates such as those recorded in table 1. In returning to table 1 to make such a comparison of historical and equilibrium capital gains,

Table 2. Equilibrium Constant-Dollar Relationships among Current Return, Capital Gain, and Asset Value, at Various Growth and Discount Rates

it would be futile to assume and misleading to imply that any past period represented equilibrium. But the comparison does show that the substantial real capital gains experienced over most of the past twenty-five years—no matter what their origin—were on the whole no greater than those that would have been expected to occur at equilibrium, given the growth rates exhibited by the current return to production assets.

At equilibrium, the percentage that the growth rate in column A of table 1 is of the rate of return in column B would be equal to the percentage in column C. The actual relative amount of capital gains shown in column C is slightly above such an equilibrium level in the 1950s, considerably below it during the next two periods, and about equal to it during 1972–78.

Alternatively, at equilibrium, the percentage gains in column D of table 1 would be equal to the growth rates in column A. Again, the historical gains were slightly higher in the 1950s, much lower in the 1960s, and about the same in the 1970s.

It thus appears that both recent real capital gains and those of 1954–67 are, in a sense, fully explained by the growth exhibited by the current return to assets. Changes in other land market influences, such as nonfarm demand

and the discount rate, therefore appear to have largely offset one another.

Implications for Agricultural Structure and Policy

The foregoing rates and relationships have serious implications for the structure of the farming sector and for public farm policy. Given a growth rate of 4% to 5% in the constant-dollar current return to assets, the farming sector is doomed, at likely discount rates, to a relatively low rate of current return on the market value of assets. This inescapable consequence is the common root of many of the farming sector's current problems: cash flow difficulties; large increases in debt; troubles of beginning farmers; the attraction of farm real estate for persons of large wealth or high income—all of these stem from the fact that, at such a growth rate, a significant proportion of the total return to farm real estate necessarily takes the form of real capital gains. To borrow the language of the stock market, farm real estate is a "growth stock," best and most easily owned by those who can tolerate its low current return in the first few years after its purchase.

In attempting to respond to cash flow problems and the like, it might appear logical to take policy actions that increase the growth rate of the current return. However, the principal longer-term effect of programs that maintain or increase the growth rate is not on the profitability of farming, but rather on the degree to which profit takes the form of capital gains rather than current return. Policy actions that increase the growth rate will tend to depress the rate of current return to assets, and thus the problems they seek to address are eventually aggravated. The implications of capitalization of an increased growth rate in income are therefore more severe than those of the well-known "capitalization of an increase in income."

A low current return to the market value of assets is not a problem for all farmers. Established farmers, like wealthy stockholders, thrive on the growing and eventually high rates of return on the funds invested in earlier years. But persons of limited means find it difficult to undertake investments with a low initial current return—or may find themselves in financial difficulty shortly after doing so. In the interests of preserving or promoting certain characteristics of the structure of farming, it may be considered desirable to assist these persons in making or in surviving such investments. It is evident that such aid should be provided in ways that do not tend to increase further the growth rate of the current return in farming generally; otherwise, a few years later new entrants are likely to face still lower rates of current return.

There are parallel implications for other aspects of farm policy. Designers of farm programs should bear in mind that, over time, the rate of current return to assets is inversely related to the growth rate of that return. Thus, for instance, programs to reduce the short-run variability of income may need to truncate peaks as well as troughs of farm output prices and to adjust constant-dollar commodity support levels downward as productivity advances; otherwise, their unintended long-term effect may be to reduce the rate of current return.

More generally, farm land price research needs to be reexamined in the context of the foregoing framework. Among the variables popular in recent models, "net farm income" seems clearly inappropriate, while the role and interpretation of "expected capital gains" and perhaps also "current yields on alternative investments" needs to be reconsidered. The present rate of current return (and thus the present level of land prices) appears implicitly indicative of expectations that the constant-dollar return to assets will grow at an average annual rate of perhaps 5% over a lengthy future period. Earlier studies have indicated that technological advances in combination with government commodity programs that maintained output prices were instrumental in establishing a growing real return to assets (Brake and Melichar, p. 442). In this decade, increased foreign demand in concert with government programs appears to have been the primary factor maintaining or increasing the growth rate of that return. Renewed study of these relationships should further advance understanding of past and probable future land price trends.

farm income. However, in 1961, Scofield observed that land prices, which from 1912 to 1940 had moved in an almost parallel fashion with farm income, were diverging from the income trend. He concluded that it was paradoxical for land values to rise without an accompanying rise in income.

In the remainder of this paper, we will attempt to clarify the economics of land valuation and explain what we believe are the underlying forces in the land market. We will also briefly address what is implied for agricultural structure and policy.

We should say at this point that we accept the theory of value which can be stated as

$$V = \Sigma \frac{a_t}{(1 + i_t)^t},$$

where V is the current value of an asset, a is expected value of the annual return in year t, and i is the expected value of the discount rate in year t.

In any year, expected returns are some function of farm commodity and input prices, yields, taxes, interest rates, credit terms, inflation rates, the potential for disposing of the tract for some higher and better use, and a long list of other variables. Discount rates are a function of the time preference for money, risk, and inflation.

Thus, to explain the present value of land we must explain factors which influence expectations of net returns to land and those which explain the formation of expected discount rates. Developing the formula becomes a very complex and somewhat overpowering problem, if all these factors are taken into account. It is tempting to simplify the formula as many appraisers and researchers have done to $V = a/i$ where (a) represents current earnings and (a) and (i) are assumed constant into perpetuity.

Such a formulation frequently has led researchers, lenders, and appraisers to believe that land is overvalued because current returns do not explain current land values. Alternatively, they believe that land earnings are below those in other potential investments. In reality land earnings have not remained constant over time and thus $V = a/i$ has misrepresented actual experience.

Real estate accounts for nearly three-fourths of all farm assets and returns to assets are based on farm income. Thus the relationship between returns to assets and asset values can help in understanding farm real estate

Indexes of Return to Assets and Asset Value

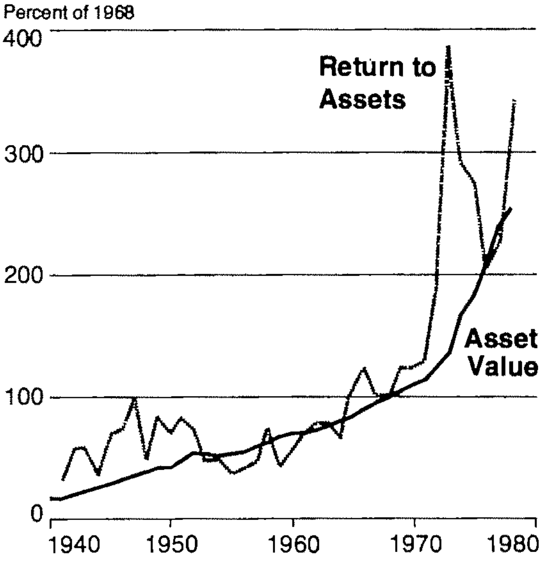

Figure 1. Indexes of returns to assets and asset value 1968 = 100

values (fig. 1). Returns to assets are calculated as a residual by subtracting estimated returns to labor and management from returns to labor, management, and total assets, including borrowed capital and farm assets of landlords. From 1940 through the early 1950s asset returns increased more rapidly than asset values. During the late 1950s and early 1960s values rose slightly more rapidly than asset returns. From 1963 to date the general tendency has been for returns to increase faster than values, even though the increase in returns was interrupted after the 1973 high. Overall since 1940, returns to assets have increased in both absolute and relative terms.

Although data on returns to assets are not available for 1910–40, assets including land are believed to have received a relatively constant share of net income. In that period, land values generally rose and fell with current net income from farming. The share of net returns going to assets rose from less than 30% in the 1940s to more than 60% in the 1970s (fig. 2).

The relationship between cash rents and values also provides evidence that agricultural rents and land values have followed parallel trends in major farm states of the Plains and

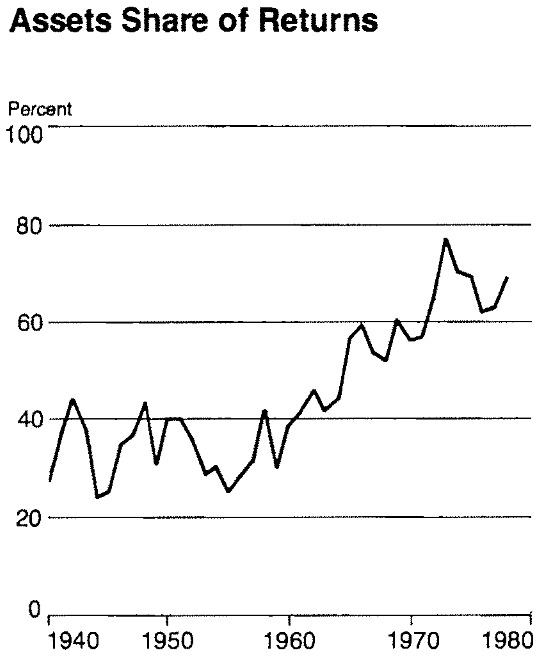

Figure 2. Assets share of returns 1940–78

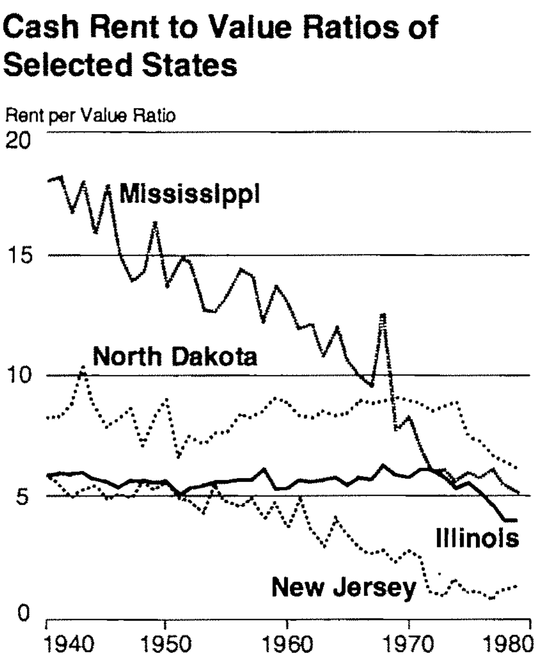

Figure 3. Cash rent to value ratios, 1940–79 selected states

Corn Belt (fig. 3). The ratio of cash rent to value has, therefore, been nearly constant.

In North Dakota and Illinois, for example, the ratio of gross cash rent-to-value remained nearly stable from 1940 to 1970. Trend lines computed for the period show no significant slope. However, since 1970 rent value ratios have declined rather sharply, at a rate of $-.24$ ratio points per year, suggesting that earnings expectations have changed. Apparently, land buyers believed that future returns will exceed current earnings by a substantial margin.

In New Jersey, where agricultural earnings are a minor component of the total expected return from land, agricultural rents have declined in relation to value since 1940. This decline may be explained by the rapid urbanization of New Jersey and by the expectation that future earnings are more likely to come from urban uses than from agricultural production.

Land rents have also declined rapidly in relation to value in Mississippi since 1940. However, the reason for the decline is different from the New Jersey example. In Mississippi, rents in the early years were distorted by imperfections in the land purchase and rental markets. Land was held in very strong hands and many tenants who had few alternatives were competing for the right to rent land. Over time the numbers of tenants declined sharply as nonfarm opportunities increased and production technology changed. Land became more readily available on both the purchase and rental markets. Apparently, a major structural change occurred which brought rent-to-value ratios closer to those of Midwest agriculture.

These data suggest, rather strongly, that an individual buying land at any time during the last forty years would have been in error if he had assumed that earnings would remain constant in the future. Under the conditions which prevailed during this period, it is clear that the ratio of current rents to current values would have represented a substantial understatement of the actual rate of return.

We now ask if it is reasonable to expect land earnings to continue to rise in the future. What factors are likely to determine expectations? If earnings and values are to increase, how will it be possible for new buyers to withstand the substantial cash flow problems that arise in the early years of land ownership with debt financing? We might also question how it

is possible for returns to assets to continue rising in an excess capacity industry.

Assuming that you accept the theory that current land values are determined by expected earnings, we will proceed to explain those factors which have been important in determining expected earnings and, therefore, underlie the demand for land.

Even in a static economy, we would expect land earnings to differ among tracts, areas, and regions, because of soil, climate, population density, mineral resources, and transportation infrastructure. Clearly, such factors impact on earnings expectations and therefore on values. Because much has been written about them, we will say no more about these cross-sectional forces.

The important issue is what causes expectations of earnings and values to vary over time. Perhaps the most important factor, which acts as a demand shifter for land, is population growth. Other things equal, an increase in population will increase the quantity of land demanded at any price. Because the aggregate quantity of land is fixed, earnings will increase as a result of the increased demand for food, fiber, and space. Prices must rise to reallocate land among those who currently own it and those who desire to hold it. Marketing of U.S. agricultural products overseas has an affect similar to a domestic population increase.

Inflation also takes its toll. When prices rise rapidly during a general inflation, production of most goods can be increased at least partly to satisfy the demand, but new land cannot be developed despite strong demand. Thus, land values can be expected to increase more rapidly than the general inflation rate. Buyers also see land as an inflation hedge.

During an inflationary period the tendency is for nominal asset prices to increase as the money supply increases relative to the quantity of the asset. Even if the money supply increases in line with growth in gross national product (GNP), the ratio of money to land is increased and some inflation in land values can be expected. The United States has had a policy of monetary expansion. This policy, we suggest, has been a factor in the increasing land prices.

If the terms of trade in land are modified by changing access to debt financing and interest rates, these changes will shift the demand for real estate to the extent that they modify the ability of buyers with a given set of earnings expectations to bid for land. An extension of the repayment period, a reduction in the downpayment or lower interest rates will each result in an increase in the number of potential buyers at any price. Government guarantees for marginal borrowers, so that lenders are not subject to loss of principal should the borrower fail, have the same effect.

It has often been argued that more lenient credit terms were required to ease the entry of young people into farming. However, such changes in terms benefit only the earliest buyers. Cash flow and equity advantages are soon bid into the price of land. Therefore, with each relaxation in credit terms, land prices can be expected to rise more rapidly, then resume a normal pattern of change with future benefits discounted.

Tax policy also alters the earnings of land through taxation of receipts from production, taxation of appreciation (capital gains), and taxation of real estate values. The government policy of minimizing taxes on capital gains has encouraged investment in real assets, particularly land. Not only have we taxed capital gains at rates well below those on earned income, but we now forgive taxes on the first $100,000 of such gains on residences for those over age fifty-five.

Also, we have increased the size of the inheritance and estate tax exemption and developed procedures to tax estates at "agricultural value" rather than at market value. Such tax laws encourage investment in land and reduce the amount offered for sale.

Preferential or use value assessment of real estate has also changed land values. Depending on how these laws are written they can either increase farm earnings or result in land being held for speculation in nonfarm alternatives, or both.

Among government actions taken to assist farmers are programs designed to increase or at least stabilize farm income. Such programs have directly raised land earnings by increasing the value of the product of land and have indirectly increased earnings by reducing the risk involved in crop production. These programs have operated through direct subsidy to idle land resources and through control of market prices. The net effect of such programs is that earnings and land values which are a function of earnings are higher than they would have been in their absence.

The implications of continuously rising land values for the structure of the agricultural sector are that current land owners will benefit

from wealth changes at the expense of future generations of farmers. If nominal earnings and values rise faster than the general price level, it will become increasingly difficult for prospective farmers to acquire viable farm units. Land ownership and wealth will tend to become concentrated into fewer hands as current land owners add marginal units to existing operations. Entry into farming will occur mainly through inheritance. Few tenants will obtain sufficient capital to become owners. Control of land resources will go to those with the greatest wealth and highest earnings expectations. This process is likely to be aided by policies arising from our concern for the beginning farmer. We can expect continued increases in land values. Our production sector is likely to differ greatly from the Jeffersonian ideal.

Concluding Remarks

If the land market is not allocating land resources and wealth in a manner consistent with economic or social objectives we must consider impacts of present actions and recognize potential consequences of alternative policies.

It would be possible to tax capital appreciation at the same or a higher rate than earned income, reduce the incentive to hold land as a store of value, and slow the accumulation of wealth. Use valuation for real property and estate taxes could be restricted. We could limit borrowing against real estate. This would decrease leverage that current land owners obtain from appreciation in real estate values. We could modify the tax law so that interest payments on real estate were no longer deductible. Commodity income programs could be eliminated or greatly modified to increase market risk and reduce land earnings. All land sales could be controlled by a government agency with redistribution to "worthy" farmers. Acreage limitations could be applied to land holdings. It would be possible to restrict corporate control of farm land to leasing arrangements of thirty years or less, thus placing them on planning horizons similar to individuals.

Such actions would tend to limit concentration of ownership, reduce competition in the land market, increase the risk of farming, and probably limit gains in production efficiency. But which of these policies would be economically, socially, and politically acceptable as means to limit further land price increases and further concentration of wealth? Although we may not like it, if we are serious in our concern over rising land values, we will need to consider such actions.

Implications of Divergence in Sources of Returns in Agriculture

James S. Plaxico

Over the short run, resource prices affect the level and mix of inputs and outputs and determine the distributive share to the factors of production. Over the longer run, resource prices impact on the structure of control in all sectors of the economy. In this paper attention is focused on structural implications of rapid changes in U.S. farmland prices. Land price increases are hypothesized to stimulate consolidation of land control (ownership) with an attendant shift in income and wealth positions within agriculture and perhaps between agriculture and other sectors. Alternative future scenarios are sketched as a means of considering implications and available policy alternatives are suggested.

Ownership Expansion Potential

The changing distribution of farm size is a result of the differential rates of growth among farms. Individual ownership expansion is limited by equity and cash flow considerations. Current income contributes to equity and/or cash flow. Asset price increases provide a base for expanded credit finance, but do not satisfy cash flow requirements.

The potential land ownership expansion rate, based on land appreciation equity, depends on the rate of land price increase and equity requirement. Land price increases can only increase the cash equity requirement for land acquisition for the nonowner. Land purchase potential, based on earnings, depends on the level of earnings, the income tax bracket, the rate of change of land prices, the proportion of earnings available for investment, and the cash equity required. The marginal tax rate affects the potential rate of expansion very little but the cash equity requirement has a major impact.

James S. Plaxico is a professor of agricultural economics at Oklahoma State University.

Oklahoma Agricultural Experiment Station Journal Article No. 3665.

Risk-oriented, established, owner-operators and landlords have the potential to expand land holdings rapidly given rapid land price increases and modest earnings. A 10% rate of land price increase provides the equity base for a 27% per year expansion in ownership to meet an overall 25% equity requirement. This in turn would require a first year annual cash flow of approximately 3.5% of the land value assuming all acres owned are leveraged so that the overall equity ratio is 25%.

Several conclusions appear inescapable. Land price increases create the potential for large owner-operated farms to become much larger and raise barriers to entry into farming of those who have no land ownership base. Given rapid increases in land prices, cash flow requirements constitute the major barrier to ownership expansion. Cash flow declines threaten the financial survival of operators who have expanded at rapid rates. Yet, a moderately favorable cash flow situation with continued land price increases results in very large wealth increases among large farmers.

Ownership patterns and structure need not be directly related, yet in the United States the trend is evident. Breimyer states it succinctly: "More than most farm leaders will acknowledge, fully as much as many farmers sense without being able to articulate, and definitely beyond what most agricultural economists are willing to recognize, the era of cheap land, of land subordinate to operatorship in farming, is fading from the American experience" (1978, p. 10).

The Structure of Farmland Prices

A recent analysis suggests that farm income and expected capital gains were major forces in U.S. farmland prices over the 1940–77 period (Kuhlman). Farm income and expected capital gains were estimated in a second degree polynomial lag structure. The capital gains variable exhibited regression coefficients higher for each of the lagged variables than

was the case for farm income. These results suggest that expected capital gains had a greater impact on land prices than an equal expected income increase. Is farmland in the United States becoming a vehicle for storing and preserving wealth? The question is an important empirical one, for policy alternatives available are dependent on the answer.

Gains occur in nonrevenue generating assets (e.g., gold, art, jewels) presumably because these assets offer a useful vehicle for value storage and preservation. Yet economists often argue that farmland capital gains (FCG) occur solely because incomes are expected to increase. Unfortunately, economists frequently ignore the current value of unrealized capital gains because they think of returns as annual income flows and view managers as maximizing a utility function closely related to annual income flows. Yet capital gains constitute an important source of returns, impact on the aggregate consumption function, and affect investment and production decisions. Wealth accumulation may be superior to income as a simple proxy of the utility surface.

In the national income accounts, capital gains and losses are excluded since the objective is to measure the net annual flow of goods and services, but capital gains and losses have been shown to affect individual consumption (and saving) behavior. Thus capital gains and losses cannot be ignored in evaluating the economic welfare (income) of individuals and groups nor in asset pricing.

Grove argued that it would be inappropriate to add net income from farming (NIF) and FCG to derive an overall income measure because "they are not entirely comparable magnitudes." NIF is largely a realized gain while FCG are mostly nonrealized. Also FCG are likely distributed in a different pattern than is NIF. Bhatia hypothesized that capital gains could enter the consumption function via either an income or a wealth effect. In the Bhatia income approach equations, the coefficients relating to both realized and accrued gains were positive. In the wealth approach equations, the coefficients for both accrued and realized gains were positive and significant but the coefficients associated with expected gains were smaller than those associated with expected income. Bhatia's results suggest that farmers have a high propensity to save from FCG. This is logical since FCG amount to forced saving. Plaxico and Kletke found that accrued FCG values to individuals appear to be similar for both the income and wealth approaches.

If farmland owners place a value on wealth accumulation, FCG could have a value as large as an equal disposable NIF in determining land values. Where cash flow is not a pressing problem, this could be essentially correct. This situation may describe a majority of recent farmland buyers. Bhatia (p. 877) concluded, "in all likelihood, people treat realized gains like any other income." Baquet (p. 76) treats gains as equivalent to income.

The most viable hypothesis at this point is that FCG have a value at least equal to an equal additional disposable income for current farmland purchasers in determining farmland values. Yet the simple sum of FCG and NIF is an inadequate basis for gauging the economic well-being of the farming population because of the different patterns of distribution.

Two Scenarios

Two scenarios are constructed to identify implications of changing sources of return in agriculture. NIF is assumed to remain essentially unchanged (as has been the case in real terms since 1940) while land prices are assumed to increase in the first case while remaining stable or declining in the second case. The scenarios appear consistent with observed relationships, but implications for the future are extrapolations. In both scenarios, hobby and subsistence farm units are likely to increase in number but not in terms of market share.

I-*The Rising Farmland Price*

Farmland ownership (control) will be consolidated rapidly due to growth of already large farms with a corresponding decline in the number of medium size (family) farms. The large units will grow as a consequence of financial expertise and leverage with marketing advantages playing a lesser role. Growth will not be due to scale economies in production. Initially large farms will be predominantly owned by individuals and these owners will be the economic elite in the economy—whether they reside in Boston, Zurich, or Gotebo. Large established units will become attractive acquisition targets for large corporations and for pension fund investments as es-

tates are settled. Corporate-owned farmland will generate modest dividends, but stockholder enchantment will not wane as net worth and stock values rise.

Capital, management, and labor functions will be separated. Initially tenants will farm the land—until a unionized labor force in agriculture emerges. The factor share to land will increase with a concurrent decline in the labor factor share, a continuation of the current trend (Cleveland and Ray). Labor cost rates in agriculture will equal nonfarm wages. Agriculture as a way of life will pass and agriculture will have lost its uniqueness in the American scene (Paarlberg).

Public support of agricultural research and education will decline. Research will be funded by private agribusiness interests and the results will be proprietary and findings will be guarded—not extended. Land grant institutions will lose their unique advantage as teaching institutions as they decline in importance as agricultural research centers—but those with the leadership, foresight, and desire will adjust to new funding patterns and emerge as the "prestige institutions" of the twenty-first century. The agricultural economics profession may be replaced by systems scientists, applied economists, business managers, accountants, and attorneys.

II-*The Stable Farmland Price*

Static land prices will stimulate selling by the highly leveraged, rapidly expanding units where farm debt growth appears to be most rapid (Melichar), and among the smaller low equity operators. Buyers will be conservative, high equity, larger family farms, and a few nonfarm investors.

Average size (however measured) units will continue to increase relative to the present, but less than in scenario I. Ownership will be concentrated among larger scale family farmers. Commodity market structures will be under some pressure but change will come slowly (Rhodes). Public research and education in agriculture will be viable, but formula funding will decline and confusion with respect to direction of research and education programs will be increasingly evident.

Class action suits concerning the apparent distribution of the benefits of publicly supported research will become common. Numerous land grant university agricultural colleges will flounder, fade, and fold, but two groups will survive. One will receive substantial public funding, as grants or contracts, in support of basic and/or public interest research and education. The other will engage in proprietary work in the interest of private agricultural clients. Farm income will be more skewed than is now the case, but less than in scenario I. The factor share to land will increase and that to labor decrease relative to the present but less than under the previous scenario. Agricultural economics as a profession will survive in some public institutions but growth is less likely than decline.

Does It Matter?

Production scale economies are achievable by moderate-sized family farmers, yet per unit costs do not increase as size increases. There are differences among enterprises, most associated with financing and marketing considerations, but structure appears to have little impact on resource productivity, supply or perhaps food production costs. However, changes in the farming structure alter the distribution of income and wealth within agriculture and between agriculture and other sectors of the economy.

Conservation levels and environmental quality appear not to be affected by structure. Small farms may use less fossil energy per unit of output than larger units, but there is no evidence that very large farms use energy more or less efficiently than family-sized units. Both appear to be highly energy dependent, but energy efficient, within the context of current price ratios.

Concentration in agricultural production may impact on food prices. Yet concentration in broiler production appears not to have retarded productivity advances nor resulted in prices above competitive levels, but market behavior associated with a given structure may be different in different industries. Also structure may limit access to markets and disrupt current pricing arrangements, and structural change is likely to be irreversible.

Farming jobs have been eliminated or transferred to the nonfarm sector as a result of a changing farming structure. A further structural shift may further reduce onfarm employment and farming opportunities. Some believe that a farming environment produces superior citizens. A structure of small farms better supports local businesses and institu-

tions than does a very large farming structure. What are the social and individual costs of a changing farming structure which reduces access to farming opportunities, alters income and wealth distribution patterns, changes the backgrounds of future populations, and accelerates the demise of small business communities and local institutions with an attendant shift in economic, social and political control?

Policy Options

Rapid land price increases are a major force leading to a concentrated agricultural production structure. Forces which tend to give wealth increases a greater utility than current income, make farmland prices rise relative to comparable assets, and make it less expensive for heirs of landowners than others to enter farming, are important contributing factors. The impact of commodity programs on long run structural change may not be established (Gardner, p. 842) but Gaffney argues, "The proximate beneficiary of most farm programs is the land owner per se. . . . The collateral of high land values lures more capital into agriculture. . . . A system of instant pleasure and deferred pain lends itself nicely to the demand of the American political process. . . . Land plays the role of Lorelei. The siren song . . . is the lure of the unearned increment" (pp. 1252–63).

If one accepts that the forces identified lead to a more concentrated production structure, and society desires to modify change, the policy objectives are clear. They are: (*a*) modify the rise in land prices, (*b*) reduce the appeal of wealth increases relative to current income, (*c*) make intergeneration transfer of wealth more difficult, and (*d*) design commodity support programs so that benefits accrue to factors other than land. These objectives are not interdependent and in some cases conflict, thus the details of policy options to achieve a desired structure are much less clear. Policies relating to the four objectives identified are outlined. Three of the four objectives relate to overall economic and tax policy. It is increasingly clear that farmers no longer control the agenda germane to agricultural policy.

Modify Land Price Increases

If general inflation leads to the use of land as a store of value, measures to stem inflation will contribute to controlling land price increases. Higher property taxes on land reduce the investment appeal of land. A property tax rebate for owner-operators and a size progressive tax rate are two available specialized instruments. Specific measures could be directed to land price modification but these would require direct controls which many would consider to be unduly onerous. Limiting use of certain land to agricultural production is an example. Restricting sales of agricultural land to operating farmers to discourage speculative holdings is another possibility. An ultimate measure would be the creation of a public trust authority to hold title to agricultural land. The land would then be leased to farm operators on a long-term basis. The trust authority could be financed by investors with rates of return controlled in a manner similar to public utilities and others granted monopoly positions in the economy.

A family farming structure requires new entrants and existing family units must continue to invest to maintain efficiency. Easier agricultural credit increases the demand for farmland, but it is not clear that restrictive credit would contribute to the maintenance of a family farming structure. The question is an empirical one—and an unanswered one.

Make Wealth Increases Relatively Less Attractive

Preferred tax treatment of capital gains is viewed as a means of stimulating investment to enhance productivity and economic growth rates. Price increases in existing assets do not increase national wealth—nor is productivity directly affected. The public interest might best be served by tax institutions that stimulate net new investments in productivity and growth rather than rewarding holding of assets for price gains. The investment tax credit may be one such vehicle and accelerated depreciation allowances also appear to contribute, although application of these to existing assets likely results in a degree of slippage.

Intergenerational Wealth Transfers

Cash accounting systems permit accumulation of wealth which has not been subjected to either current income nor capital gains tax. Current use valuations facilitate the entry of members of farm families into farming, while entry of individuals from nonowner farm fami-

lies is made more difficult. Yet corporate assets are not subject to estate type taxation. Thus it is not obvious that less liberal estate taxation would contribute to the maintenance of a family-farming structure.

Benefits of Farm Programs

Few innovative ideas for altering the distribution of farm program benefits have been advanced. If individuals view land as the limiting factor, the distribution of farm program benefits among the productive factors is unlikely to be affected significantly by farm program changes.

Perspective

Rapid consolidation of agricultural production units is not a phenomenon of the 1970s (Stanton). During the professional lifetime of many members of this association farm numbers have declined by more than 50%. What is new is the sustained rapid rise in farmland prices which provides a base for rapid further consolidations. Over several decades of farm consolidation, the rhetoric of farm leaders and farm legislation has been in support of the maintenance of the family farm (Breimyer 1977). However, the family farm has been defined and redefined with sufficient flexibility that leaders seem to agree that our current structure is a family farm dominated one, albeit a very different one than that of past decades. Will we continue to redefine the family farm to be the mode of current structure, or have we now attained a structure to be preserved for all seasons and all decades?

The paradox that farm leaders tend to seek programs that ameliorate current problems but escalate long-term structural change rates is well known and understandable. Again, near term pleasure and deferred pain are consistent with the short terms of elected officials. Nevertheless, there is a surprising paucity of hard data to permit a real indepth examination of structural change in farm production and to evaluate implications of alternative policies. The structure issue is a political one. There are available ample policy instruments to modify structural change but there is no evidence of a political constituency to cause the rate of change to be slowed.

Our profession is indebted to the small core group that has recognized and identified the structure concern. The challenge before us is to quantify and monitor the changing nature of the dilemma as well as to measure potential policy impacts. The high profile, which recent comments of the secretary have given the structure issue, certainly gives impetus to the work ahead.

Land Prices, Inflation, and Farm Income: Discussion

R. J. McConnen

Melichar's exciting paper points out that the increases in agricultural land prices we have experienced can be explained by examining macrodata in a microframework. In the process of this analysis, Melichar shows, "real capital gains on physical assets were on the average nearly as large as the current returns from 1954 through 1967 as well as in the 1970's." This means that at no time since the mid-1960s has per capita "farm income" been less than per capita nonfarm income—when "farm income" includes current return plus real capital gains on physical assets. In these terms, our agricultural income problem of the past twenty years has been primarily a problem of income distribution caused not only be differences in farm size, education, access to capital, etc., but also by difference with regard to farm ownerhsip. If Melichar's asset pricing model is modified so that g is defined as "the expected annual growth rate of the current returns expressed in terms of certainty equivalence," table 2, section A becomes conceptually useful as a means of interpreting the impact of policy changes which can range from price and income policy to crop insurance programs to multinational trade negotiations. Any widespread change in either the expected annual growth rate of current returns or the level of risk in agriculture would cause dramatic changes in perceived equilibrium land values. For example, if we use an 8% discount rate in table 2 and if the forces of protectionism in world trade were perceived to be gaining ground and the expected annual growth rate fell from 6% to 4%, land values would fall by one-half.

The Reinsels use Gray's 1919 statement to verbalize Melichar's asset-pricing model. Their data on cash rent to value ratios underscore their statement that, "an individual buying land at any time during the last forty years would have been in error if he had assumed that earnings would remain constant in the future." Their concluding section begins, "If the land market is not allocating land resources and wealth in a manner consistent with economic and social objectives, we must consider impacts of present actions and . . . alternative policies." The desirability of policy instruments which would change farmland prices can only be judged in the context of the impact on more broadly based and accepted economic and social objectives.

Plaxico has presented a clear exposition of the role of increasing land prices on the structure of agriculture. Plaxico asks, "Does It Matter?" It does matter, but structure should not be regarded as an end in itself but rather as a means of achieving economic and social objectives we have not as yet been able to agree upon.

Can we predict all of the consequences of the alternatives suggested by the authors this morning? I think not. Politically, how feasible are some of the suggestions? After all, it was Howard Jarvis not Henry George who was the inspiration for Proposition 13. We are at the stage where we must give careful study to the consequences of alternative solutions. When we see the results of these studies, we may elect to accept an unpleasant phenomenon rather than to promote some unacceptable cures.

Thomas Schelling begins *Micromotives and Macrobehavior* by describing the seating patterns at a lecture he once gave. He speculates systematically on the reasons for this seating pattern and states, "The most interesting question is not how many people would like to change their seats after they see where everybody else is sitting; it is whether some altogether different seating arrangement might better serve the purposes of many, or most, or all of them. How well each does for himself in adapting to his social environment is not the same thing as how satisfactory a social environment they collectively create for themselves" (p. 19). Schelling points out that we

R. J. McConnen is a professor in the Department of Agricultural Economics and Economics, Montana State University.

should not evaluate the resulting social environment merely by examining the acceptability of the micromotives. However, we must understand micromotives if we are to design effective policy instruments which we can use to generate acceptable macrobehavior. The micromotives which give rise to the perceived macroproblems with regard to land prices and farm income extend beyond agriculture and rural America. For example, as Plaxico points out, farmland has been a good hedge against inflation. It is unlikely that any policy to hold down farmland price increases would be successful unless there are also changes in generally held expectations about future inflation rates.

An *Economist* article on Britain's Northfield Committee Report on Agricultural Land states that the "phoney problems" of voracious buying of farmland by financial institutions and by foreigners were disposed by the report as unfounded. "The real problem is a quite different one: the voracious buying of farm land by the private, British yeoman farmer. —entrepreneurial farming has become much harder to get started in than other small businesses—and it cannot be desirable that this should become a strictly hereditary occupation. The answer is the landlord; and the committee makes no bones about being thoroughly in favor of him—Rather than special pleading for more special cases, the Northfield committee would have done better to ask what methods of farm finance (yes, and what levels of farm income) would enable the industry to bear its share of this tax burden and yet thrive" (pp. 70–71).

I refer to the Northfield Report for two reasons. First, the United States is not the only nation facing the problems that are the subject of this session. Second, some of the suggestions of the Northfield Report and the comments in the *Economist* are not among those that would be generally popular in the United States. I think both points suggest we badly need to do some comparative studies. I do not think we have much evidence that an agricultural structure based on large farms will be either less efficient or more unstable than the agriculture we have today. I think the real issues of the evolving agricultural structure in the United States are two; one, as Plaxico points out, deals with the distribution of income and wealth and the second deals with our old friend, agricultural fundamentalism. As economists, we can recognize the second issue and provide—I hope—useful information about the first. If we are to inform rather than misinform, we need to do some careful work. I expect that some of our results will not be popular.

The issues raised in these papers will remain important issues. I believe we can expect current returns to continue to grow over the long run. And that will mean continuing increases in land prices. I think the principal reason will be a significant future growth in export markets of the European Economic Community and China for U.S. agricultural products. I think many American farmers would agree with me. We may be wrong, but by the time that is demonstrated, the structural damage will be done. Unless of course we decide, on the basis of income and wealth distribution considerations, to implement policies which will modify the likely outcome.

Land Prices, Inflation, and Farm Income: Discussion

Duane G. Harris

Although the papers presented by Melichar, Reinsel and Reinsel, and Plaxico address different aspects of the land-value, land-income issue, they all attempt to identify factors affecting value and offer policy prescriptions for solving perceived problems associated with the so-called income-price paradox. The purposes of this comment are to critique the conceptual formulations used by the authors and to evaluate the logic of a few conclusions and policy implications drawn by the authors from their respective conceptual models.

Land Valuation Models

As Melichar has noted, the valuation of land can be regarded as analagous to the valuation of a "growth stock" in which part of the return comes to the owner in the form of current income and part in the form of capital appreciation over time. The standard growth stock valuation model (VanHorne, p. 22), therefore, is useful in examining the land-income, land-value relationship. The general form of the growth model is given by

$$(1)\quad V_o = \frac{R_o\,(1+g)}{(1+k)} + \frac{R_o\,(1+g)^2}{(1+k)^2} + \ldots + \frac{R_o\,(1+g)^n}{(1+k)^n},$$

where V_o represents current value, R_o is current income, g is the expected rate of growth over time of current income, k is the capitalization rate and n is the number of years of income generated by the asset. Because the growth model assumes a particular pattern of income over time, it is less general than the valuation model presented by Reinsel and Reinsel. However, the Reinsel formulation, because it is the most general form, offers little insight into the relationship between income and value. The growth model presented in equation (1) also is more conceptually appealing than the Melichar model in which value itself is assumed to grow at a rate g over time.

If we consider land to be an asset with infinite life ($n \rightarrow \infty$) and assume that in the long run the capitalization rate is greater than the expected rate of growth of income ($k > g$), equation (1) can be reduced to the following form:

$$(2)\quad V_o = \frac{R_o\,(1+g)}{(k-g)}.$$

Note that equation (2) is the same final result as that obtained by Melichar with his more restrictive initial assumptions about growth in value. While the Reinsel model allows us only to conclude that land values will depend on factors affecting annual income and the capitalization rate, the growth model emphasizes that value will be dependent as well on factors affecting the growth in income over time.

Additional insights into the valuation process can be obtained by examining the components of the capitalization rate. The capitalization rate can be expressed as a function of the required rates of return on debt and equity

$$(3)\quad k = w_d k_d + w_e k_e,$$

where k_d and k_e represent the required nominal rates of return on debt and equity, respectively, and w_d and w_e are the proportions of the asset portfolio respectively financed by debt and equity. Furthermore, if the individual rates of return are broken down into real rates and inflation premiums, equation (3) can be reformulated as

$$(4)\quad k = w_d(r_d + \theta_d) + w_e\,(r_e + \theta_e),$$

where r_d and r_e represent real rates of return

Duane G. Harris is an associate professor in the Department of Economics at Iowa State University.

Journal Paper No. J-9648 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa, Project No. 2117.

and θ_d and θ_e represent inflation premiums on debt and equity holdings, respectively. Finally, if debt and equity holders all have the same inflationary expectations ($\theta_e = \theta_d = \theta$), then equation (4) simplifies to

$$k = w_d r_d + w_e r_e + \theta, \tag{5}$$

and equation (2) can be rewritten as

$$V_o = \frac{R_o\,(1 + g)}{w_d r_d + w_e r_e + \theta - g}. \tag{6}$$

We now see that land values are formulated to be a function of current income (R_o), expected growth in income (g), real required rates of return on debt and equity (r_d and r_e), the financial mix used to purchase and hold assets (w_d and w_e), and inflationary expectations (θ). As such, the model given in equation (6) is more explicit in its identification of factors affecting land values than either the Melichar or Reinsel formulations.

Models, Evidence, and Policy Implications

The evidence presented by Melichar on the time trend of land values and income, when properly measured, is consistent with the growth model formulation and suggests that ad hoc explanations for the "apparent" historical divergence between income and value may be misdirected. Melichar's data indicate that long-term growth in the real value of land has been accompanied by long-term growth in real income received from land. If we can hypothesize that a pattern of historical growth in real income generates expectations for continued growth in real income, then the growth model can be judged to be a useful characterization of the land valuation process in the marketplace. As such, the model can serve as a starting point for the definition of problems associated with rising land values and for the identification and evaluation of policies that may have an impact on land values and the structure of U.S. agriculture.

For example, the Reinsel and Reinsel postulate that population growth is a factor that will cause land values to continue rising in years to come is conceptually consistent with the growth model. Their contention, however, that general inflation will cause land values to rise is not so easily substantiated by the model. It is not clear that general inflation will necessarily lead to an increase in the income received from land. Also, if general inflation generates inflationary expectations, equation (6) suggests that an increase in inflation premiums demanded by debt and equity holders (θ) would, *ceteris paribus*, cause land values to decline.

In addition, Reinsel and Reinsel and Plaxico identify government tax policy as a factor affecting the value of land. However, the impact may be neither as direct nor as obvious as the authors would suggest. It is important to appropriately introduce taxation into the land valuation modeling process (Adams) in order to draw quantitative implications of changes in tax policy.

Finally, it is likely that any governmental policy designed to enhance or stabilize farm income will be inconsistent with an objective of stabilizing land prices. Especially aggravating to land value stability are policies linking support prices to costs of production (Harris, Boehlje and Griffin). Thus, as Melichar points out, we should seek out those policies that do not tend to increase the long-term growth in return to farming.

Returns to Public Irrigation Development and the Concomitant Costs of Commodity Programs

William E. Martin

Development of agriculture and associated agricultural problems have had a prominent place in congressional deliberations virtually throughout the history of the United States (Benedict). Early policy stressed land development, and the Reclamation Act of 1902 was in such spirit. It was "An Act Appropriating the receipts from the sale and disposal of public lands in certain States and Territories to the construction of irrigation works for the reclamation of arid lands." With later modifications of policy to provide greater sources of income for works construction, Congress continues to support the Bureau of Reclamation's water development output-increasing activities.

Yet, since 1929, with time out for war, the federal government also has effected commodity programs designed to reduce the supply of major agricultural commodities so as to maintain product prices "at levels that would be above the market price in a free and reasonably normal market situation" (Benedict, p. 517). Such a situation would tend to strike most economists as peculiar (inefficient). Howe and Easter estimated the annual costs of commodity programs directly related to reclamation irrigation in the range of $83 million to $179 million during the period 1944 to 1964 (p. 143). Some of the "facts" generated by these apparently contradictory policies are the subject of this paper.

In the past two decades resource economists, including myself, have severely criticized Bureau of Reclamation project evaluation procedures. Young summarized these criticisms and concluded that if we explicitly adopt a national accounting stance such that benefits and costs are evaluated from the point of view of the whole nation ("to whomsoever they may accrue . . ."), and if we assign a dominant role to economic efficiency in our assessment, "there would have been only a very few, if any, projects initiated in the past two decades which would have met the B-C criterion" (p. 260).

I will not dwell on all the criticisms, but there is one issue that is of particular importance to returns to irrigation development and associated costs of commodity programs. Water development projects traditionally are evaluated outside of a general equilibrium context, and it is assumed that each single project will have no effect on commodity prices. While the elasticity of demand for agricultural output may be close to infinite for the Bureau's smallest, 221-acre project, it could not be infinite over all of its 9.3 million irrigated acres. It is because of the existence of downward sloping demand curves that there could be a rational economic reason for simultaneous irrigation development and agricultural income support programs if questions of welfare and distribution are considered. Thus, in this paper, I first develop a simple conceptual framework of the costs and benefits of public irrigation development, then examine some of the relevant empirical data, and finally draw some rough conclusions as to our country's relative economic rationality.

A Conceptual Framework

Traditional B-C analysis has looked only at the producer side of the issue. As in figure 1A, demand has been assumed to be infinitely elastic while irrigation development shifts supply from S_1 to S_2. There is no consumers' surplus before development and none created by de-

---

William E. Martin is professor of agricultural economics at the University of Arizona, Tucson.

Arizona Agricultural Experiment Station Journal Article No. 3030.

The author benefited from conversations with Russell L. Gum and Dennis C. Cory.

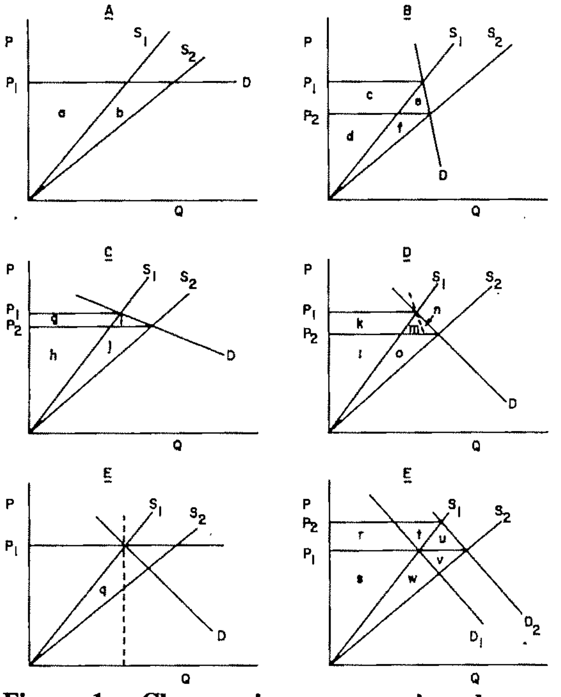

Figure 1. Changes in consumers' and producers surpluses resulting from irrigation development (hypothetical)

velopment. Producers' surplus is assumed to increase from area a to area $a + b$ through development. Area b would be available for producers to repay project costs. Consumers would have no interest in the whole process if they were not usually required to provide a subsidy.

In fact, the situation is as shown in figure 1B. Given a downward sloping demand, project development will create additional consumers' surplus equal to $c + e$. Producers lose c to the consumers, but gain f. The water is there on the farm, $f - c$ may or may not be positive, but the water will be used, output will increase and $c + e$ is always positive.

A distributional problem is created. As with b in figure 1A, f in figure 1B accrues to the recipients of the new water and is available to repay project costs. The loss, c, comes from all producers, old and new. Even if all loss comes from producers outside of the project development area, f is smaller than b and repayment ability will be smaller than computed under the assumption of constant prices.

As is evident from figures 1B and 1C, the relative gains to consumers and gains or losses to producers depends on the elasticity of demand. With an inelastic demand, gains to consumers ($c + e$, figure 1B) are large and losses to all producers are probable. With an elastic demand, consumers gain less ($g + i$, figure 1C) and all producers have a chance of a net gain ($j - g$). Producers in the project area have a chance at project repayment, since j (figure 1C) is not too much smaller in size than b (figure 1A).

A caveat is required on the measurement of consumer gains. If we assume that consumers have a right to their original position (p_1, figure 1D) rather than their subsequent position (p_2), and that the income elasticity of demand is not zero, the more accurate concept of gain is that of compensating variation (Hicks; Currie, Murphy, and Schmitz) rather than simple Marshallian consumers' surplus. For a price fall, compensating variation is the maximum consumers' willingness to pay to achieve the subsequent equilibrium condition. Because of income effects, this amount is less than simple Marshallian consumers' surplus. Compensating variation is shown as $k + m$ in figure 1D, less than consumers' surplus by n. Willig argues that for small changes in consumers' surplus for goods with an income elasticity in the range of $\pm$ 1.0, n is negligible.

We thus have a case for a consumer subsidy to producers where an irrigation project lowers the prices of agricultural products. While we may be sacrificing national economic efficiency, the consumer should be willing to pay up to a maximum of $k + m$ (figure 1D) to gain the distributional effects of increased quantities at lower prices. This amount will be larger where the project produces products for which there is an inelastic rather than an elastic demand. The subsidy could be in the form of zero interest on irrigation project repayment charges—past and current practice under reclamation law or through direct support payments on the commodities. ("Current projects are subsidized to over 80 percent of costs, if the interest on a normal repayment period is factored in" [Young, p. 262]). However, it is important that output be allowed to increase and prices allowed to fall. If the original price is maintained through production controls (figure 1E) there is no consumer gain to provide a subsidy. While there is a total gain in producers' surplus of q, since all producers must be limited if the project is to produce, project farmers will gain at other producers' expense. In this case it is hard to argue that either efficiency or distributional equity would be served.

We may go further in the argument for a

consumer to producer subsidy if we allow demand to shift to the right as would be expected with population growth. Assume an original position at the intersection of S_1 and D_1 (figure 1F). With demand projected to rise to D_2, consumers should be willing to pay up to $r + t$ to avoid the price rise. (See Burns for surplus estimation with shifts in demand.) If prices actually rise to p_2 with the shift in demand, consumers could pay $r + t + u$ to regain their former position of p_1. Of course, the anticipated or actual shift in demand, with the accompanying growth in producers' surplus of $r + t$, should create pressure for irrigation expansion by producers under a market solution. However, project costs could exceed $w + v - r - t$ or there simply could be market failure (Young, p. 3).

Public Investment in Irrigation Development

Bureau of Reclamation facilities do not comprise the entire investment in U.S. irrigation. In fact, Bureau of Reclamation facilities serve only 9.3 million acres while "other project facilities" serve 13.3 million (U.S. Department of Agriculture 1979). ("Other" projects include BIA and Corps of Engineers projects as well as state and private development.) Private on-farm facilities serve another 22.7 million acres for a net farm irrigated acreage of 45.3 million out of 367 million acres in "planted crops and fallow" in the United States (pp. 28, 39). But the net value of the capital investment in Bureau projects in 1975 was \$8.960 billion out of \$9.005 billion net federal investment, with other group projects valued at only \$2.370 billion. Private individual facilities were valued at \$4.640 billion (p. 27). Thus, in terms of federal investment, Bureau projects comprise 99.5% of value. In the context of the issue of federal commodity programs versus federal irrigation development, I will concentrate on the acreage in and output from Bureau projects.

U.S. and Bureau of Reclamation Acreages

In table 1 U.S. acreage and Bureau of Reclamation acreage are compared by crop. Of the cereals, barley and rice are the only crops with Bureau acreage exceeding 1%, with 6.1% of U.S. barley and rice acreage each. Total cereal acreage on Bureau lands is less than 1.1% of the U.S. total. Bureau lands are 6.6% of U.S. alfalfa acreage, but probably less than 1% or 2% of total forage acreage. Thus, we find that while forages and cereals are grown on 62% of all Bureau lands (37% and 25%, respectively) (U.S. Department of Interior 1978b), they are but a percentage point or two of U.S. forage and cereal lands.

Field crops are a different matter. Twenty-four percent of the dry bean acreage is on Bureau lands, 30% of sugar beet acreage, 10% of cotton acreage, and 72% of all hop and mint acreage. But with soybean acreage negligible, total miscellaneous field crop acres on Bureau lands are less than 2.4% of the U.S. total.

The speciality crops—vegetables, fruits, seeds, and nuts—are the major crops on Bureau lands when compared to U.S. acreage. Vegetables are on only 9% of Bureau lands but account for close to 18% of U.S. acres. Fruits and nuts are on 8% of Bureau lands but account for 21% and 32% of U.S. fruit and nut acreage, respectively. Seeds are but 2% of Bureau lands but approximately 11% of U.S. seed acreage.

To summarize, lands currently irrigated by Bureau of Reclamation projects are only 2.5% of total U.S. cropland, but they contain a significant percentage of vegetable, fruit, nut, seed, and miscellaneous field crop acreage, as well as a significant acreage of barley, rice, and alfalfa.

The Incremental Output from Federal Investment

More important than mere area is the productivity of the irrigated lands. In table 2 is shown the 1977 production of major crops grown on Bureau lands, the index for yields from wholly irrigated lands as compared to unirrigated lands, and the implied increment in production due to irrigation on Bureau lands as a percentage of 1977 total U.S. production. Also shown is total Bureau production as a percentage of total U.S. production.

Two assumptions are crucial to the estimates of the increment from irrigation. First, it is assumed that cotton, dry beans, vegetables and melons, and orchards would not be grown in the absence of Bureau irrigation. Thus, for these crops total production is equal to incremental production. Second, for all crops it is assumed that no other irrigation water was available; that is, that the Bureau was required

Table 1. Total U.S. and Bureau of Reclamation Cropped Acreage, by Major Crops, 1977

Crop	U.S.[a]	Bureau of Reclamation[b]	Bureau of Reclamation as a Percentage of U.S.

to develop full water service rather than merely supplemental water service. Both assumptions obviously cause an overestimate of the increment from irrigation, since 54% of all lands irrigated by the Bureau receive supplemental rather than full water service (USDI 1978b).

Given these caveats, we see that the greatest increases in production caused by Bureau water are for vegetables, melons, orchards, and dry beans. Other significant increases are for cotton, rice, barley, alfalfa, and potatoes. The increments in corn, oats, sorghum, wheat, and soybeans are each 1% or less.

Now let us examine recent participation in the major commodity programs. In table 3 are shown the quantities of commodities pledged to the commodity credit corporation under the commodity loan programs, as percentages of total U.S. production for the years 1972 to 1977. (Flaxseed, honey, naval stores, peanuts, rye, and tobacco—not produced on Bureau lands—are excluded. These commodities, along with storage facility and equipment loans comprised 16% of the 1977 loan pro-

gram.) If we take these quantities as a rough measure of farmer and congressional perception of excess agricultural production, we might compare them with production increments associated with public irrigation investment. These increments, developed in table 2, are also presented as the last column of table 3.

A portion of all of the cereal grains consistently has gone under loan during this recent six-year period. In 1977, 10.8% of the barley crop was pledged while the public irrigation increment was 6.3%. Only 0.5% of corn production was pledged—but the irrigation increment was 80% of that amount. Oats and sorghum were each pledged at about 6% of production even though the irrigation increment was minor. Less rice was pledged in 1977 than the Bureau increment, but large quantities had been pledged in previous years. Wheat was heavily under loan (20%) even with only a 1% public irrigation increment.

The two commodities with the largest production increment from public irrigation investment, dry beans and cotton, while pledged in earlier years, apparently were clearing the

market at "satisfactory" prices in 1977. No beans were pledged in 1977 although the irrigation increment was 39.1%. Only 0.3% of cotton was pledged while 11.6% of U.S. production was attributable to public irrigation investment.

Costs and Benefits

How might these data be interpreted? Clearly the grains have generally been and continue to be in "excess" supply relative to congressional intent. But irrigation development seems not to be a major culprit, except perhaps with barley. The problem would exist even without public irrigation development. On the other hand, irrigation investment to grow these crops is obviously unnecessary. The problems with cotton, dry beans, and soybeans seem to be lessening. At least with dry beans, one might see a need for having developed production. Still, overall one could hardly argue the necessity of public water development from the point of view of the U.S. producers of these commodities. That the commodity programs exist is enough evidence that water has not increased net income. Benefits, if there are any, must be on the consumers' side. A consumer should be willing to pay to have larger quantities with lower prices. Unfortunately, the mechanism for subsidies generally has not allowed the consumer to receive full benefits.

Consumer benefits surely have been achieved with investment in water for fruits, nuts, vegetables and melons, potatoes, and perhaps even alfalfa. While many of these crops, with the exception of alfalfa, have been under marketing orders, with the obvious intention to restrict output and raise prices, the very magnitude of their position in total U.S. production suggests a positive benefit. The problem is, of course, that even though demands for most fruits and vegetables are more elastic than for the basic commodities, they still are inelastic. Therefore, a downward shift in supply tends not to benefit consumers greatly—perhaps not enough for project and producer subsidy.

Let us work backwards to see what consumer benefits would have to be if the federal water projects were to be beneficial. The 1975 Bureau of Reclamation gross real investment in irrigation project facilities was $9.1 billion (USDA 1979). This value "represents the estimated cost of reproducing all existing irrigation . . . works at unit costs prevailing in [1975]" (p. 43). If consumers were to receive the full value of the irrigation investment, an annual total return of $910 million would be required if the investment were evaluated at an interest rate of 10%. With a 1975 estimate of "number of people eating from civilian food supplies" of 211 million (USDA 1978a, p. 552), the required annual per capita consumer's surplus would need be only $4.31. Given the large amounts of vegetables, fruits, and nuts that are incremental in Bureau of Reclamation Project acreages, I do not find a $4.31 consumer benefit unbelievable.

In fact, annual per capita subsidy costs of Bureau project construction have been at most about $3.50 in 1975 dollars. I make this estimate as follows. Given the 1975 estimate of $9.1 billion for reproducing all existing irrigation facilities, and assuming amortization at 10% for 50 years (the normal payback period), total principal and interest would equal $45.891 billion. North and Neely estimate that current projects are subsidized to about 80% of costs, when the interest in the normal repayment period is included. Eighty percent of the total is $36.713 billion, or $734 million per year (of which only 20% is principal). With a 1975 population of 211 million, the annual per capital subsidy would be $3.47. Of course projects have been constructed over the past seventy-five years. In any given year only a portion of the 153 projects actually would be under repayment.

However, because of commodity programs for cereals and field crops, there is the additional cost of government payments to farmers. Since World War II, total payments have varied from 0.6% (1974) to 7.9% of total farmers' cash receipts from marketings on a national basis (USDA 1978b). In 1969 a per capita consumer contribution of $19.06 is implied, in 1974 the contribution was only $2.52, and in 1977 the contribution rose again to $8.47. The problem here for consumers is that they are paying for the privilege of not having higher quantities and lower prices on cereals and field crops. Thus, the costs must also be absorbed by any benefits to vegetables, fruits, and nuts.

What might be the total incremental benefits to these crops? Per capita food expenditure in 1977 was $1,136 (USDA 1978c). Ten percent of this expenditure was on fruits and vegetables (USDL). Given a price elasticity of demand for fruits and vegetables of around

−0.75 (George and King, p. 49), and assuming an increment in U.S. production of fruits and vegetables of 26% (table 2), the incremental consumer's surplus attributable to public irrigation would be $34.26 per capita. Perhaps Bureau projects really have been worth the associated commodity program costs.

The data presented have summarized the past and presented the current status of public irrigation investment and commodity programs. What of the future? I cannot help believing that because the less expensive project sites have already been developed, future development will be slight. People slowly are beginning to realize that water naturally runs downhill and to reverse that phenomenon requires energy. For example, Arizona's Salt River Project, the first construction activity of the Bureau, is a major producer of electrical energy. Currently, the Central Arizona Project is under construction. It will require a quarter of the output from the three 750-megawatt coal-fired units of the Navajo Generating Station to lift the water more than 2,000 feet uphill (University of Arizona).

Let us examine the recent trends in construction activities and the crops grown on these new irrigated acres, as a possible clue to the future. The twenty years for which Young suggests negative benefit-cost ratios should serve. Since 1960, in the last 27% of the Bureau's history, 35% of its 153 projects have come on-line, but these projects irrigate only 10.6% of its land. Since 1970, 15% of Bureau projects began producing on only 3.4% of Bureau land. Apparently we are not running out of projects, only land on which to put them. Further, while between 1960 and 1968 acreage developed with full water service was 1.3 times that developed with supplemental service, since 1970, 4.4 times as much supplemental service has been developed than full service (USDI 1978a). Supplemental service may well reduce fluctuations in crop yields, but surely develops a smaller production increment than full service development. I suspect many of the supplemental-water projects are so called "rescue" projects, such as the Central Arizona Project, where the marginal cost of not having the "rescue" water is very small (Kelso, Martin, and Mack).

Finally, we may ask what crops are being grown on these newer project acreages. Economists, including myself, have generally argued that projects should be evaluated in terms of the MVP's of the lowest valued crops—the grains and forages, and that higher valued crops—fruits and vegetables—would be grown in any case if a market were available. From an efficiency point of view the correctness of this argument seems clear. However, the data show that since 1960, the total Bureau land increase of 10.6% was associated with a 10.9% increase in project vegetables, a 23.4% increase in project nuts, an 8.7% increase in project fruit and 9, 11.5, and 10.6% increase in project cereals, forages, and miscellaneous field crops, respectively. In other words, all crops tended to increase proportionately to land in projects. In the years since 1970, the 3.4% increase in Bureau lands include a 21.7% increase in project nuts, a 5% increase in project fruits, a 4.6% increase in project vegetables, almost proportional increase in project forages and field crops, but only a 1.4% increase in cereals.

These data, however, could be misleading. An increase in project fruits or vegetables need not mean a net increase in fruit or vegetable acreage of the same size—especially on supplemental-water projects. As shown above, recent projects are mostly supplemental. Still, one might suspect a positive distributional effect toward consumers.

Conclusions

While it is clear that recent public irrigation development projects are economically inefficient from a national accounting stance, logical economic arguments can be made, at least for past projects, on the basis of distributional gains to consumers. Such gains are probable even in the face of the costs of our national commodity programs. The gains could be substantial if output were not restricted and if any farmer income support were handled through direct income payments.

Arguments for future development are much weaker. Low-cost project sites no longer exist. Projects now use energy rather than develop it. Alternative uses for water in high MVP uses are growing. The increments from the development of supplemental water are not as large as from the full service projects that made the deserts bloom rather than merely "rescuing" marginal acreages. If the intent of Congress remains to provide inexpensive food to consumers while supporting producer incomes, new directions in both

water development policy and farmer support policy are clearly necessary.

On Augmenting Community Economic Performance by New or Continuing Irrigation Developments

Herbert H. Stoevener and Roger G. Kraynick

Having been asked to present a paper at this meeting on the above topic reflects the continuing existence of an unresolved issue among agricultural economists: the nature and extent of regional development impacts of irrigation developments. We do not want to foster the expectation that our paper will resolve this problem. Instead, we shall attempt to sort out some of the major policy issues involved, classify relevant empirical studies on this subject, and make some suggestions for research approaches in this area.

The concern for this issue is old and relates mainly to two subjects which are interdependent yet in some respects are analytically separate from one another. First, there is the question whether or not irrigation developments convey to the subregion in which they take place regional development benefits which matter from a national benefit-cost accounting stance. In traditional benefit-cost analysis these are referred to as "secondary benefits." Second, there are circumstances under which it is important to compare benefits and costs from the standpoint of the region in which irrigation developments are to take place. We shall turn to a discussion of these two viewpoints.

The Concept of National Secondary Benefits (Once Again)

Considerable effort has gone into studying the kinds of secondary benefits which are allowable in the evaluation of public investment. This effort did not begin in earnest until after World War II. However, there continued at that time a significant degree of satisfaction with the phraseology, "to whomsoever they may accrue" in regard to the categorization (and thereby distribution) of net benefits.

The *Proposed Practices* in both the original (May 1950) and the revision (May 1958) consider the deficiency in the above dictum (U.S. Inter-Agency River Basin Committee). The 1958 version states specifically that "secondary benefits . . . usually have little significance in project formulation, economic justification and array." That these local secondary effects in the region in question would be offset by effects with the opposite sign in other regions had become well established.[1] There are only two conditions under which secondary benefits could arise. The first deals with the issue of surpluses (in, say, fixed as well as variable capital stock) in with- and without-public investment situations. The surpluses which could be incorporated into additions to the local capital stock are relevant because (the official reason) some regions may have a comparative advantage over others when implementing such additions and because (the reason proposed below) the process by which such surpluses are implemented may be influenced significantly by the nature of the primary investment itself. The second condition under which the nationally relevant secondary benefits could arise involves the capacity utilization of the existing resources. The extent to which unemployed and underemployed labor resources in a potential area can be employed has emerged as a bona fide benefit category for federal programs. As men-

Herbert H. Stoevener and Roger G. Kraynick are professor and research associate, respectively, in the Department of Agricultural and Resource Economics, Oregon State University.

This is Oregon Agricultural Experiment Station Technical Paper No. 5253.

[1] The official procedure now in effect for reporting local secondary benefits is spelled out in the November 1973 Principles and Standards and remains unchanged in the May 1979 version. Agencies still have the discretion to display secondary benefits in project authorization requests: The Bureau of Reclamation has claimed 18% of gross irrigation benefits, Soil Conservation 10% of total net benefits, while the Corps of Engineers does not display calculated secondary benefits. As noted below, the Area Redevelopment Benefits claimed for proposed projects are currently permitted. (See U.S. General Accounting Office.)

tioned below, capacity utilization of other existing resources has not received as much attention.

The surplus issue has not received the attention that the unemployed resources issue has, but would seem nonetheless to be a key element of whether these kinds of national secondary benefits are to be of any real relevance. Kneese and Margolis, among others, have each mentioned the process by which the surplus-related secondary benefits may emerge. In the former, it was termed a "dynamic" secondary effect, with inference to the kinds of jump steps or lumpiness in the fixed and/or variable capital stock of a local community. Margolis, on the other hand, combined the surplus issue into one involving the fact that a project in sparsely populated regions will result in more efficient use of existing social overhead capital. Whether or not one finds these significantly different from the general class of external economies depends on whether the process by which surpluses accrue to the community in a public investment situation is important.

The evidence on process of making a surplus addition to the fixed and variable capital stock of a local region is not encouraging. First of all, for those economists willing to discuss it at all as something outside the realm of gravity models (and other locational techniques), the term "agglomeration" has tended to be more of a handicap than a help, a point which has been recently expanded by Papageorgiou.

Some economists have expressed belief that conventional economic models may be limited in dealing with socioeconomic processes within rural communities. In particular, it is thought that much of the performance of small towns with respect to issues such as rapid growth are shaped by the nature of key groups of individuals. Tweeten and Brinkman cite the literature in this area much of which refers to "legitimizers" who are "the people in almost every community that seem to have the right, authority and prerogative to sanction activities" (p. 262). Furthermore, as Powers observed, these top influential leaders have the following characteristics: they are usually over fifty years of age with above average education, are in higher income groups having access to or control of money, credit, jobs, mass media, and are longtime residents of the community who are self-employed, owners, or executives.

Most applied regional economists and community development specialists have some personal experience with a power structure in a locality or region. It is frequently observed that in addition to confirmation of the above premises many of the influential community leaders are involved in a multiple of development activities. Powers also notes that many of the influential leaders hold a significant proportion of their assets in real estate. There is some evidence that in a land-intensive investment project economic returns increase to the affected land itself and spill over to other land. Under these circumstances we hypothesize that a process of "venture capital formation" may take place in the local private sector. The resultant availability of local capital may release some previously existing constraint on regional economic development.

These observations parallel some made by Barkley in discussing the variations in water/community relationships. We would suggest that many of the variations that he discusses are due to whether or not surpluses that accrue locally are used locally. Barkley also makes a point about the mining project(s)-community relationships which occurred in many places in the West in the nineteenth century. Those towns that were abandoned are, of course, examples of surpluses which were unwisely invested in local fixed capital.

Testing the hypothesis that the process of local venture capital formation is a significant element of irrigation-related regional growth poses some problems in data gathering and analysis. The reporting of local (perhaps sub-county) financial indicators is limited: annual reports of private bank and other financial institutions can provide some comparisons between areas. The frequency and magnitude of building permit applications and observations on the value of residential and commercial construction and property exchanges may reveal information on the source and extent of finance which can be generated in relevant localities. In any case, necessary data are limited requiring careful consideration of models to be tested.

The unemployment-underemployment issue in the determination of national secondary benefits has been treated in a definitive manner by Haveman and Krutilla. Empirical estimates of the true opportunity cost of labor were made by relating the major occupational categories employed in public project construction

so as to generate the unemployment rates in these particular categories. Based on 1960 conditions, it was concluded that the opportunity cost of project construction from 1957 to 1965 was between 65% and 85% of the nominal expenditures on construction. Although Haveman and Krutilla build their analysis of unemployed labor resources on a national and major regional basis, it is reasonable to draw similar conclusions for small regions or even communities where water development is taking place. It is less convincing, however, to argue that local idle capacity in industry, commerce, and the service sectors will become fully employed because of public investment activities in a small region. Often new capacity-reflecting changes in technology and consumer preferences become installed, a process of "leapfrogging" over the existing idle capacity. Although economies of scale may be realized in these new investments with respect to all new development, the unit costs tend to be made higher than comparable ownership costs in the vintage capacity. It is difficult to gauge whether these growth effects per se are relevant in the sense of Haveman and Krutilla. As indicated above, the process by which they take place as a result of a public investment stimulus is important to understand.

The most recent decade has seen at the national level to some extent a revival of interest in the analysis of regional economic benefits under the framework of multiple objective planning. This is perhaps mainly because of the Water Resources Council's planning guidelines which view regional development as an objective to be considered side by side with national economic development, environmental quality, and social well-being. Major (1969, 1977, and Major and Lenton) has been the principal intellectual proponent of the approach, arguing that national and regional net benefits can be viewed like competitive products (with a range of complementarity) in a production possibilities framework. According to Major the slope of a social indifference function can be inferred from past legislative action. This yields the choice criterion and appropriate weights on the objectives, allowing the set of projects yielding the optimal combination of national and regional net benefits to be chosen. A similar argument is also developed by Schramm.

Major's suggestions have been criticized, perhaps most pointedly by Freeman and Haveman. They challenge the categorization of regional development benefits, as they are likely to overlap with national benefits, making their representation in a production possibilities framework impossible. They also have less faith than Major in the possibilities of deriving weights for multiple objectives from legislative records. Instead, they insist on an explicit specification by the decision maker of the relative "deservingness" of the various regions. Only in this manner could coefficients be derived by which net regional benefits could be weighted.

Local Social Overhead Capital

Before turning to our second topic, let us comment briefly on the subject of regional costs. The costs of expanding public services in rural communities to accommodate growth stimulated by irrigation development have been found to be significant by several authors (e.g., Whittlesey and Butcher 1978). These, of course, should be weighed against the gross regional benefits of irrigation projects. In doing so, one should be cognizant of any potential scale economies in local government, the possibilities for incorporating cost saving technologies in service delivery, and the value of public service outputs generated by the additional expenditures.

Although most of the evidence on scale economies in public services has emerged with respect to urban services, Hamilton and Reid have suggested that such economies are possible in rural areas because the evidence suggests that marginal costs are below average costs. Evidence for specific areas of government services has recently been summarized by Fox et al. Scale economies in public service provision are found not to be mythical, but one should be careful about generalizing these results to the case of rural community growth. In such cases, for example, large one-time incremental costs of service expansion can occur. Relevant monetary measures for values of many types of public sector outputs are still unavailable.

We would like to conclude this section by stating that the short answer to the existence of regional benefits from water planning is negative. There are, however, complex conceptual issues involved which do not rule out the existence of such effects in certain circumstances. Their measurement is generally difficult.

The Local Viewpoint on Regional Benefits

Whether or not regional benefits relevant to a national water-planning standpoint can or should be estimated is only one question of our paper. Our other interest lies in the contribution which irrigation development may make toward the development of the region, as such a contribution is perceived by the region itself. The logic for the existence of such benefits is much clearer than for the case of nationally relevant secondary benefits. Their empirical estimation is, however, a different matter. We believe that there is some confusion in the literature on this point. We shall turn next to these empirical questions, focusing on each of three measurement approaches.

Young discusses federal irrigation development and regional economic growth in a recent paper. While he is explicit about adopting a national accounting stance he refers to the "mythology" of a strong linkage between irrigation water development and regional economic growth to explain pressures by western political leaders for further developments of this kind. Note that the enthusiasm of regional representatives for capturing regional benefits does not depend upon the existence of such benefits from the national accounting stance. They merely need to exist from the viewpoint of the region in question. Nor does Young argue against regional benefits on logical grounds. He refers instead to empirical studies to challenge their existence. We shall turn briefly to two of these, the ones which appear most closely directed at western irrigation development.

The first of these is a study by Cicchetti, Smith, and Carson. It is succinctly summarized by Young:

> Two analyses were performed: A Cobb-Douglas production model and a linear growth equation model. Deflated subregional income and deflated value of farm output were the proxy measures of output. In the production model, variables representing Bureau investment in irrigation facilities were not found to have any significant impact on regional income and only a small and not convincingly significant impact (t-value = 1.62) on value of farm output. The growth equations showed sub-regional incomes to be positively related to some USBR investments as well as to state and local government expenditures on education, health, and so on. However, irrigation investment did not enter as a significant variable in any of the growth equations. Coefficients for those Bureau investments which were significant, hydropower, flood control, and recreation, were often unstable between periods of analysis and in the case of hydropower, with negative sign. (p. 264)

We should add that in the production function model, subregional farm output is explained by three variables: farm employment, and capital stock measures for Bureau of Reclamention investments in irrigation, and hydropower. Average subregional income is viewed as a function of nonfarm employment and capital stock variables for Bureau investments in hydropower and flood control. Cicchetti, Smith, and Carson caution us in the interpretation of their equations as they "have not fully specified all inputs to the production process" (p. 3), a statement with which we must agree wholeheartedly.

The "growth equations" approach is slightly more complex. Even here what starts out as a reasonably specified conceptual model results in an attempt to explain changes in the value of farm output, for example (over the two ten-year periods between 1950–60 and 1960–70), by Bureau investments in hydropower, state and local expenditures on highways, and the change in farm employment. Various equations are estimated, with 1950–60 data "pooled" with those for the 1960–70 decade and for the two time periods separately. There are large apparent differences in many of the regression coefficients depending on how the data sets are aggregated. In one instance, four out of five regression coefficients have the opposite sign in the equation based on 1950–60 data from the ones based on 1960–70 data.

Another study cited by Young is the one by Fullerton et al. We concur with Young's judgment that this study was done with care and rigor and that it does not offer support for the hypothesis that regional economic growth is caused by investment in water resources. But it is easy to overdraw the conclusions from this study. We should heed the authors' cautioning. With respect to their large area statistical analysis they say: "Although we have argued that the statistical findings do not support the hypothesis that regional growth is induced by water investment, we have been somewhat reluctant to offer them in support of the alternative hypothesis, i.e., water resource investments do not result in economic growth impacts. In other words, it is conceivable that such investment does have regional growth effects but that our data and analysis have

failed to pick it up because of a variety of problems" (p. 43).

Fullerton et al. then go on to describe various data and analytical problems which beset cross-sectional studies of this type. They mention the problem of various data being observed at different time periods, water resource investment data not being available with sufficient specificity about timing and geographic incidence of possible impacts, and, finally, the possibility that the impacts of public investment projects may simply be swamped by other developments which affect a much larger proportion of the agricultural land base.

We do not want to appear excessively critical of the multi-area statistical approach to measure regional economic development impacts from irrigation investments. In the recent past we have been encouraged that some independent research in the classroom has focused on this very problem. But the conclusion appears almost inescapable that this approach allows little to be said definitively about the phenomenon in question.

Normal constraints on research resources force reliance upon secondary data, and the problems described by Fullerton et al. are likely to occur. To the latter we would add that especially for large federally sponsored irrigation projects there is the additional problem that the other purposes of such projects, especially flood protection, hydropower production and recreation may have their own regional impacts which may be distributed differently from those of irrigation with respect to space and time. Finally, the focus of the studies cited has been on public investments in irrigation development. In several ways one would expect private developments of this type to have the same impacts as those under public sponsorship. One type of development may even be a substitute for the other. Failure to take account of private irrigation development and other public and private means to intensify agricultural production in areas where such developments are important is likely to make statistical analyses of this type unproductive.

Observations on Land Valuations to Estimate Returns to Irrigated Land and Adjacent Communities

In the late 1950s, Renshaw suggested the use of land values as indirect or proxy measures of the *ex ante* benefits of irrigation projects. The analysis of land values had been popular in the preceeding decade, but rarely with the purpose of determining irrigation-related benefits. A study by Selby in 1945 is a notable exception.

The hypothesis tested by Renshaw is, of course, built on the premise that farm land value represents a capitalization of expected net income derived from production on the land. The term "value" obviously can be interpreted in many ways; Renshaw's definition in one model involved capitalization of repayment streams received by the Bureau of Reclamation from irrigation districts. Another model used average data on land values for states, a third used census data, and a fourth involved questionnaire data. Renshaw's models all involved regressing these land value measures against crop value or some indices of crop value. As such, Renshaw was unable to pursue any questions of the value of water applied to the land.

Milliman's review of Renshaw's work revealed that there are possibilities of obtaining more information on the benefits of irrigation than in conventional budget approaches. In particular he notes that the number of variables to consider is reduced, land values already entail an implicit discount rate reflecting local points of view on risk and uncertainty, and the possibility of double counting of benefits is reduced.

The use of crop values as the sole independent variable as in Renshaw omits some important determinants of irrigated land prices. The basic premise is, of course, that any increase in land values resulting solely from the provision of additional irrigation water represents a market capitalization of the

$$\begin{pmatrix}\text{present discounted value}\\ (PDV)\text{ of expected future}\\ \text{stream of value received}\\ \text{from water}\end{pmatrix}$$
$$\text{minus}$$
$$\begin{pmatrix}PDV\text{ of stream of}\\ \text{actual water service}\\ \text{costs}\end{pmatrix}.$$

In formulating a model based on this premise, according to Milliman, one should take several qualifications into account. With respect to costs, agricultural land is treated as the only fixed factor in production. Furthermore, water is assumed to be the primary causation of production which requires treating all other vari-

ables as a part of the land factor or not at all. Another cost issue which is particularly relevant to federal irrigation development is whether the cost stream being evaluated understates the "true" cost stream involved. If so, one would expect a surplus to be capitalized in the land value. With respect to the stream of benefits, it is necessary to account for any potential loss of security in the agreement to purchase water or in the inherent rights to the use of water. Similarly, taking account of potential transfers to other uses, particularly for residential development, will complicate the land valuation model.

Milliman extends this latter point to a discussion of external economies, particularly the enhancement of land values on commercial and residential property surrounding irrigation development. It also has been demonstrated that external economies of the pecuniary type can be significant in the evaluation of irrigation development such as in the pending completion of the Columbia Basin Project and the proposed irrigation of Desert Land Act and Carey Act lands in southwestern Idaho as demonstrated by Whittlesey and Butcher and U.S. Department of the Interior, Bureau of Land Management, respectively. In both cases the externality is encompassed in product prices and in certain factor costs stemming mainly from the increasing cost of electricity.

How accurate are land value techniques for assessing net primary benefits attributable to irrigation development? Beale's multivariate model of land values on four existing Bureau of Reclamation projects reveals considerable apparent disagreements between this method and the conventional *ex ante* budget determination of net primary benefits. Whereas *ex ante* benefit-cost (B-C) ratios calculated by the budget method (primary benefits) ranged from 0.82 to 1.9, the land value method yielded a range from 0.27 to 0.78. The differences were explained in a minor way by the difference between *ex ante* and *ex post* operation and maintenance (O and M) charges. The principal difference, however, arises because of the rates used in discounting the stream of benefits: a given rate (2.5%) in the budget method and a set of implicit rates (ranging from 7.9% to 11.4%) in the land value method. If these latter rates are representative of the opportunity cost of capital in the region applied to somewhat risky ventures, then the two methods may be assumed to be yielding similar evaluations. The Bureau rate, of course, significantly underestimates not only the opportunity cost of money, but also the risk premium implicit in private lending rates.

Beale's observations on land values were taken from the 1960s when fairly stable relationships existed between land values, net returns to irrigated agriculture, and the general rate of inflation. Since 1972, however, land prices have accelerated sharply, net farm income has been very volatile, and nonland production costs (now being led by higher energy costs) have increased faster than the general price level (Lee and Rask). Decisions to invest in farm land have become significantly more complex with buyers having to consider not only net returns to land and the opportunity cost of money but also the specific terms of both purchase and taxation and a crucially important estimate of selling price at the end of a suitably long planning horizon. As a result, the estimation of returns to irrigation of land using land value observations in the recent decade may become considerably more complicated than in previous periods.

The other point to be addressed here is whether irrigation development per se accounts for any significant land value changes in off-farm areas. Cross-effects between newly irrigated land and potentially irrigable dryland will of course depend on the relevant crops grown, the availability of water, and the sizing of supply facilities, among other things.

There will be a tendency for off-farm areas both within and on the fringes of rural communities to experience some land value appreciation or at least a bolstering effect against outmigration influence. Most of the empirical work in this area, however, involves cases in which recreation or flood control and irrigation were co-objectives (e.g., see Knetsch; Ricci, Laessig, Glaser; Struyk; and Boodt). Most studies report on the extent to which local real estate markets are sensitive to the planning and implementing of reservoir projects. As a result there has been an emphasis on the analysis of time-series data relevant to property surrounding a reservoir or in the protected flood plain, as the case may be. Any study aimed at determining the extent of land value enhancement in areas further removed from lands receiving direct benefits will have to identify the linkages which are involved. In many instances a proximity linkage will be significant due to encroachment of an urban area into the irrigation project.

Such encroachment is very likely if water development is at the onset near a large metropolitan area such as the Tualatin Project (USDI Bureau of Reclamation) southwest of Portland, Oregon. However, the more representative irrigation projects are usually proximate to smaller communities whose growth potential may be affected by not only the normal income expenditure effects but perhaps also the possibility of implicit options for future water supply. Looking for the existence of these particular effects in land values is likely to require significant effort.

Economic Base Study Approach to the Analysis of Individual Existing Projects

One other major study approach needs to be mentioned. It focuses on the analysis of individual projects to trace out the interrelationships between irrigation developments and measures of regional economic growth, usually regional income, employment, or overall economic activity. There is also a long history to studies of this type. Some of the early work was reviewed by Kimball and Castle in 1963. More recent analyses are contained in the proceedings of a NRED symposium (USDA), in the study by Fullerton et al. cited earlier, and in work by Long, Nelson, and Potratz, in Idaho.

Most recent studies in this area employ input-output models. While this does not constitute a general equilibrium approach, these models allow a reasonably complete accounting of interactions in the economy and thus a comprehensive view of certain economic impacts from water developments. Whenever such models are employed, they generate estimates of positive impacts on outputs of certain other sectors of the local economy and of magnitudes for the various kinds of multipliers in excess of one. Note that this is a clear example of one of the cautionings about research provided in the presidental address at this meeting. Instead of making possible the test of a hypothesis, the mathematical specification of the model restricts the outcome of parameter estimates to a certain range. Economic analysts are, of course, not in agreement on the interpretation of the results of their analyses. Most of them are reluctant to make unequivocal statements about the use of the input-output parameters to derive economic impact estimates from irrigation developments or even from an existing irrigation project. This is not surprising. Given the very restrictive assumptions required for predictions from static input-output models, their use is defensible only for marginal changes in final demand. Major irrigation developments hardly ever have marginal impacts upon the economy of interest. What would be required is an identification of the structural changes which occurred in the economy as a result of the development. To derive such structural changes one would like to have input-output models for two states of the economy: with and without the irrigation development, but the same in all other respects.

Conclusion

Where does this leave us with respect to our ability to say something definitively about regional economic impacts from irrigation developments? Our review of the literature on this subject turned up no new arguments which would challenge the view that from the global viewpoint a special accounting of regional impacts is irrelevant except under special circumstances. Our discussion of the "local venture capital formation" hypothesis may enlarge slightly the set of the latter circumstances. From a local point of view, such impacts cannot be ruled out on logical grounds. The difficulty here lies in their empirical estimation.

We reviewed three approaches to the estimation of these impacts. As agricultural and resource economists we are naturally reluctant to discourage the profession from the study of agricultural and other land values. Yet the immediate payoff from the land value approach to this application does not appear promising. To make this approach productive would require not only a general understanding of farm land values but also the mechanisms by which agricultural productivity is translated into changing values for other real estate assets. Nevertheless, even limited success with this approach would shed light on certain distributional consequences associated with irrigation developments which are not likely to be discovered using other methods of analysis. We are thinking here about sharing benefits from these developments between the group of original residents in a community and those who may be attracted by the development.

The input-output approach has two strengths.

It lends itself to prediction of the regional impact of marginal changes in the level of irrigation development. The specificity of the estimates of the distribution of impacts may also facilitate the design of more comprehensive financing and cost-sharing schemes than are currently employed. It is going to be difficult to say very much about the overall magnitude of regional development impacts from this approach. Comparisons among input-output models to ascertain how the structure of a regional economy has changed because of the irrigation development are likely to be frustrated because of the violation of the *ceteris paribus* assumption.

It may be too early to abandon the multi-area statistical approach. While it has not distinguished itself in the past, there are no overwhelming conceptual difficulties with this approach. Data limitations appear to have been the effective constraints in the past. Additional resources should allow a sufficient data base to be developed. Most likely the study area would have to encompass more than one state and would require research cooperation and support from institutions in several states. We realize that there is not a long list of successful endeavors of this kind.

Finally, we anticipate that someone will question whether our analysis is the equivalent of building deck chairs for that famous ocean liner which sank after hitting an iceberg nearly seventy years ago. Even the casual observer of the federal interest in water resource developments will have perceived the end of an era. But even in the balance of a strong federal interest in new developments there is a growing program in the Bureau of Reclamation for "Rehabilitation and Betterment" of existing projects. Repayment capacity, not national net benefits, is the decision criterion for these federal expenditures. Furthermore, the states of Oregon and Washington recently have adopted loan programs for irrigation developments. Aside from these active roles in irrigation developments, the states will have to be equipped to make allocative decisions between irrigation developments (existing and potential) and competing water uses. There is likely to be a continuing interest in the comparative regional impacts of irrigation and other types of developments.

Returns to Public Irrigation Development and the Concomitant Cost of Commodity Programs: Discussion

Harold O. Carter

Martin addresses himself to what many economists as well as others have viewed for years as seemingly contradictory and inefficient government policies: namely, that the federal government has simultaneously supported the Bureau of Reclamation's water development, output-increasing activities and in Martin's words "effected commodity programs designed to reduce the supply of major agricultural commodities . . . ."

The underlying question being posed by Martin differs somewhat from what one generally would expect to encounter in considering this apparent contradiction. Most previous assessments of Bureau activity are specific to particular projects and use a standard benefit-cost framework of analysis. Benefit calculation assumes a perfectly elastic demand curve for commodities to be produced by the single marginal project being evaluated. One does not need great analytical ability to conclude that, generally, an acreage control program operating within the project area would be at cross-purposes at least in the short run, with respect to societal efficiency in the production of agricultural products. Martin, however, poses a different question. He is saying, essentially, what is done is done and is unlikely to be changed. But how do the aggregate costs and benefits of federal irrigation development over the past seventy-five years compare? And in aggregate, have federal projects really had a significant effect on commodity program costs? Quite rightly, Martin argues that while the elasticity of demand for agricultural output may be close to infinity for the Bureau's smallest, 221-acre project, it could not be infinite over all of its 9.3 million acres. Martin then formulates the conceptual framework for the problem in terms of the familiar Marshalian consumer-producer surplus paradigm with a downward sloping demand curve.

The empirical section of the paper presents some first approximations of consumer and producer surpluses, net of governmental costs both in irrigation development and for commodity programs. Conclusions of a tentative nature are drawn that viewing all past projects in the aggregate "rational economic arguments can be made on the basis of distributional gains to consumers even when netting out costs of national commodity programs." In fact, Martin states in the concluding section that the gains could be substantial if output were not restricted. Incidentally, this later claim appears to be at odds with an earlier statement to the effect that irrigation development was not a major culprit in surplus grain production except perhaps with barley.

Curiously, Martin attempts to extend into the future for current or on-line projects his analysis about the benefits and costs of all federal irrigation development. This, of course, gets us back to assessing the benefits and costs of the marginal project where the elasticity of demand approaches infinity. Some of the observations made by Martin seem quite valid but are not well-related to the primary thrust of the paper.

For the remainder of my comments, I want to elaborate on and emphasize some of the underlying assumptions made by Martin, most of which explicitly appear in the paper. Then I will comment on the methods and assumptions used in deriving the empirical approximation central to the main question posed in the paper.

Market Imperfection

The assumption of the downward sloping demand curve is crucial to establishing the existence of a positive consumer surplus. Equally

---

H. O. Carter is a professor in the Department of Agricultural Economics, University of California-Davis.

important is the implicit assumption of competitive markets in all stages of the food chain that allows consumers to reap the benefit from lower prices as the supply curve shifts to the right. Traditional pricing mechanisms are known not to be perfect for most commodities. Increased concentration in the farming sector is well known. Average farm size has about doubled in the last thirty years. Similarly, the number of food and kindred product manufacturing establishments declined one-third between 1958 and 1972 and increased in size. Grocery store chains with over 101 stores captured 29% of the sales in 1954, 40% in 1972. Because grain is heavily involved in government commodity programs, it should be noted also that best estimates suggest five major export firms account for well over 90% of U.S. grain exports.

If market concentration increases, the gains from irrigation development or any new technology can be captured by a small group rather than the general consuming public as the model implies. Unfortunately, we have little empirical information on which to judge the amount of consumer surplus captured through market imperfection. If the consumer loss is significant, the case is obviously weakened for a public subsidy to producers in the form of zero interest on irrigation project repayment charges, which is the past and current practice under reclamation law. And as Martin points out, if the original price is maintained through production controls, there is no consumer gain to provide a subsidy.

The Incremental Output from Federal Investment

In order to assess the extent of a possible commodity price decline from irrigation development, it is necessary to gauge the shift in the supply curve as well as the supply elasticities. Martin's approach is to estimate the implied incremental output from federal investment as a percentage of 1977 total U.S. production. This essentially involves an estimate of what Bureau land would produce farmed dryland, according to Martin, assuming the same cropping plan that exists with irrigation water. The difference between the implied dryland production (with irrigated crop plan) and the Bureau lands' current production is the increment from irrigation. Further, Martin assumes that cotton, dry beans, vegetables and melons, and orchards would not be grown in the absence of irrigation water which, in 1977, accounted for 3.5 million acres (about one-third of the Bureau's total acres). For these crops all of Bureau production is counted as the increment from irrigation. If I understand the procedure, the implicit assumption is that these 3.5 million acres remain idle without irrigation water rather than being planted to a dryland crop, say barley or wheat, when assessing the "before" and "after" situation. If we could assume that these 3.5 million acres were planted to dryland cereal crops in the "before" situation, the increment from irrigation conceivably could be negative for these particular cereal crops. On the other hand, as all good economists say, the irrigation water attributed to the Bureau resulted in greater production of cotton, beans, vegetables, and orchard crops probably at the expense of farmers in non-Bureau land. For example, some farmers in Alabama may have been forced out of cotton production and into a next best crop, say soybeans. What this lengthy and possibly confusing comment comes down to is to say that the agricultural economy is dynamic and adjusts to changing conditions both in and out of Bureau project areas. Measurement of the Bureau impact is even more complex (both on inputs and outputs) than what Martin's paper suggests using a simplified comparative statics approach. Accordingly, unless one can assess properly the dynamic "before" and "after" situation, little definitive can be said about the Bureau's impact on particular commodity programs, not to mention the other social and economic impacts (structural change in different regions). My impression is still consistent with Martin's contention that irrigation is not the major culprit in oversupply of cereal crops and the problem would exist without public irrigation. Probably of more importance has been technological change resulting from mechanization, hybrid seeds, and chemicals.

In summary, Martin has suggested to us that Bureau water projects in total can be evaluated in the context of a land-saving technological innovation in a general equilibrium framework. Proper assessment of the benefits and costs attributable to a single "innovation" are complex, as the literature attests, and empirical approximations are rough at best. Yet it is still worthwhile to make the attempt. We have a challenge to sharpen the methodology and refine the empirical analysis.

On Augmenting Community Economic Performance by New or Continuing Irrigation Developments: Discussion

W. Cris Lewis

Stoevener and Kraynick have offered a review of some of the considerations in identifying and estimating secondary benefits of irrigation and related developments and the proper role of those benefits in feasibility analysis. The issue is particularly timely for at least three reasons: (*a*) the much closer scrutiny being given to water resource investments by the federal government; (*b*) the importance of secondary impact estimation in impact statements concerning a range of federal government actions, especially in the West; and (*c*) the continuing use (and misuse) of the secondary benefit argument by local development officials to generate local support for water projects. With regard to the latter, such arguments often include exaggerated claims about the magnitude of the secondary impacts and, furthermore, usually offer no rationale for their role in logically supporting property tax financing.

As I see it, three questions are raised: (*a*) Do irrigation and related projects generate significant secondary benefits? (*b*) If so, how should these benefits be estimated or measured? (*c*) Once measured, should those benefits be included in benefit-cost analysis; and, if so, how? As a corollary, if they are not to be included in the benefit-cost ratio, as I and many others would argue, should they be reported separately so that the decisions regarding interregional wealth transfers might be made on a slightly more rational basis?

The paper focuses on the second question. It raises a variety of issues on the question of secondary benefits and reviews a number of relevant studies. The authors review three methods of secondary benefit estimation: (*a*) the econometric or statistical approach, (*b*) input-output analysis, and (*c*) the land value approach.

Although the authors "waffle" slightly in their evaluation, they apparently find significant value only in the input-output alternative. For example, they state:

> As agricultural and resource economists, we are naturally reluctant to discourage the profession from the study of agricultural and other land values. Yet the immediate payoff from the land value approach to this application does not appear promising.

On conventional statistical analysis, they argue:

> We do not want to appear excessively critical of the multi-area statistical approach to measure regional economic development impacts from irrigation investments. In the past, we have encouraged our own graduate students to practice their quantitative skills in this area. But the conclusion appears almost inescapable that this approach allows little to be said definitively about the phenomenon in question.

My evaluation of the relative merits of these three techniques would be just the reverse. The statistical or econometric analyses have been used to test countless hypotheses not only in economics but throughout the sciences. That they would not find significant application in questions revolving around the impact of water resource investment seems highly unlikely. To be sure, some of the data problems are severe, particularly in trying to measure the level of investment made in some small area, but these data problems pale into insignificance when compared to the data problems surrounding input-output analysis.

On an *ex post* basis, the land value approach must have significant theoretical merit. Certainly the value of irrigation investment should be capitalized in land values. To the extent that appropriate kinds of data can be developed on changes in land values of properties with and without new irrigation development, the land value approach ought to enhance our

W. Cris Lewis is a professor in the Department of Economics, Utah State University, Logan.

Utah Agricultural Experiment Station Journal Article No. 2478.

ability to measure the benefits of water resource investments.

With regard to input-output analysis, the strengths and weaknesses of that construct are well-known and need not be reviewed. Suffice it to say that as the spatial unit of analysis gets smaller, the questions regarding the use of input-output techniques become larger. The relative importance of external flows and the limited data availability combine to weaken the argument for its use. Stoevener and Kraynick also argue that because of the "specificity of the estimates," input-output analysis may "facilitate the design of more comprehensive financing and cost-sharing schemes than are currently employed." Frankly, the tremendous and, in some cases, excessive detail provided by input-output analysis tends to obscure the more fundamental questions on quality of those predictions.

For example, the assumption of constant coefficients of production, which we all know in economics to be untrue, leads me to believe that the predictions made by input-output analysis are likely to be wrong. It is simply not true that in production relations, the marginal and average functions are coincident. Furthermore, the input-output analysis may be well-suited to questions of prediction but has limited value in hypothesis testing on an *ex post* basis.

In conclusion, Stoevener and Kraynick have chosen a particularly appropriate time to review some of the important issues surrounding secondary impact measurement. The review should be useful in encouraging the necessary additional work on these questions, and, in that sense, the paper makes an important contribution. Unfortunately, they have not gone beyond a brief review of standard benefit measurement techniques, and further, I would disagree with the main thrust of their conclusions regarding the relative merits thereof.

Abstracts

Symposia

Commodity Price Forecasts: Experience and Accuracy. Gordon C. Rausser, chairperson (University of California, Berkeley), Dean Chen (Wharton Econometric Forecasting Associates), Richard E. Just (University of California, Berkeley), Ed Whitacre (Data Resources, Incorporated), and Abner Womack (CES, ESCS, USDA)

Commercial forecasts of spot commodity markets have been available for a number of years. These forecasts are quarterly, refer to specific cash markets, and cover a number of commodities. The firms that generate and sell these forecasts, largely to agribusiness companies, include Chase Econometrics, Data Resources, Inc. (DRI), Doane, and Wharton Econometric Forecasting Associates. The forecasts are based upon large-scale, U.S. agricultural sector models which specify formal links among individual commodities.

The purpose of the symposium was to compare and evaluate the price-forecasting experience and accuracy of these commercial venders from commercial, academic, and government perspectives. The first participants in the symposium, representing major econometric forecasting firms, described their service and clientele. They then discussed their forecasting records with the objective of illuminating the current contributions of large-scale econometric models and identifying where additional improvement is needed.

The second part of the program addressed the issue of accuracy of the major forecasts by computing selected measures of information content for the Chase, DRI, Wharton, and several other econometric firm forecasts of average quarterly cash market prices over the period 1976–78. The question addressed included the following. Does the comparative accuracy of different models depend upon the forecast horizon, e.g., is one more accurate for, say, a one-quarter forecast and another more accurate for a two-quarter or longer term forecast? What is the value of information provided by the econometrically based forecasts, and does this value compare favorably with those afforded by futures markets?

As a third part of the program, the large-scale forecasting efforts of the USDA were described and used as a backdrop against which to compare the commercial forecasting efforts, experience, and accuracy.

Variation of root-mean-squared errors among econometric forecasters was fairly large. Also, there was no clear dominance of one forecaster or vender over another when all horizons were considered. Over all commodities and horizons, the average rank for futures market forecasts was approximately 2.5 suggesting that, at the mode, the econometric models did not forecast as well as the futures markets. Finally, the composites of the econometric forecast and a futures market price were shown to be significantly more accurate than the individual component forecasts.

Agricultural Pollution: Are We Asking the Right Questions? Daniel W. Bromley, chairperson (University of Wisconsin), Klaus Alt (USDA, Iowa State University), Pierre Crosson (Resources for the Future), Gerald Horner (USDA, University of California, Davis), Tom Waddell (Environmental Protection Agency, Athens, Georgia), and Basil Sharp (University of Wisconsin)

Our national capacity to produce food and fiber in sufficient quantity to permit large agricultural exports has been facilitated by an artificial reckoning of the full social costs of domestic agricultural production. Can we continue to ignore environmental costs in order to maintain, or expand, our productive capacity?

The regulatory process has been one of seeking cooperation from farmers rather than mandating standards as in industrial and municipal discharges. If regulation becomes more stringent, do we have the analytic ability to offer guidance? Have we developed useful performance criteria? Have we seriously considered the regional and interregional issues inherent in a more concerted regulatory approach? Have we been sufficiently critical of the purported benefits of public participation programs?

Our models assume minimal institutional lag, perfect compliance, and few enforcement problems. Are our recommended policies consistent with the time perspectives of those formulating policy? Have we rigorously analyzed the incongruous policies that favor expansion onto marginal agricultural lands and yet call for reduced erosion?

These issues will require the attention of the best economists if national policy on agricultural pollution is to be coherent in scope and in content.

Needs and Strategies for Improving Graduate Training for Work in International Agricultural Development. Harold Riley, chairperson (Michigan State University), Darrell Fienup (Michigan State University), Kenneth Nobe (Colorado State University), and Russell Stevenson (Agricultural Development Council)

Fienup reported the results of the AAEA International Committee survey of LDC agricultural economists who have taken graduate work at U.S. universities and a related survey of U.S. professionals who, at the time they completed their graduate programs, were strongly oriented toward careers in

international development. The studies indicate that a high percentage of the LDC alumni have employment in the field of agricultural economics in their home countries and for the most part they have found their training to be useful and relevant. The demand for U.S. graduate training in agricultural economics is expected to continue at a high level, but several program modifications are being suggested to make the training more useful in the LDCs, especially in the least developed countries. Nondegree training, both in the United States and in developing countries with additional emphasis on research methodologies, planning, project evaluation, and public administration, are areas where alumni desire further training.

Although a high proportion of the young U.S. professionals surveyed have significant job involvements in international development, they hold the view that many of their peers are actually deserting this area due to the uncertainty of their positions and lack of support within universities.

The validity of the survey results and the possibility of additional analysis of the data were points of discussion in the symposium. There was a high degree of interest in the results of the surveys and several suggestions were made for strengthening graduate training both in the United States and in the LDCs. A publication summarizing the results of the study and a related set of recommendations will be available later this year.

Agricultural and Water Quality Improvement—What Are the Implementation Costs and Policy Issues? Lee A. Christensen, chairperson (ESCS, University of Georgia), George Casler (Cornell University), Edward Michaelson and David Walker (University of Idaho), John Miranowski (Iowa State University), Klaus Alt (ESCS, Iowa State University), and Lawrence W. Libby (Michigan State University)

This symposium dealt with costs and policy issues related to alternatives for agricultural nonpoint source pollution control and water quality improvement. Discussants highlighted research results, but focused on information needs.

Issues raised included the appropriateness of the term "best management practices" and whether the water quality problems addressed are properly defined, especially if too much focus is on erosion control as a surrogate for water quality improvement. More evidence is needed identifying the long-run benefits to farmers from erosion control and showing the relationship between reduced erosion on farmland and reduction in nutrients, pesticides, and sediment deposited in lakes and reservoirs.

More information is needed on the long-run effect of erosion control on yields, the effectiveness and yield effect of alternative tillage practices, and the measurement of benefits of increased water quality.

Research on erosion control in the wheat producing areas of the Pacific Northwest indicated that application at the farm level of a program of restricted summer fallow, minimum tillage, contour tillage, divided slopes, and seeding critical areas was more effective than a combination of changing crop rotations and relying on minimum tillage.

Another topic discussed was criteria for selecting appropriate policy instruments for controlling nonpoint pollution and how policy costs influence the choice of policy instruments. Important selection criteria needed for such alternative policy instruments as user charges, subsidies, marketable rights, and direct regulations are efficiency and equity. Choice among efficient options can be enhanced by minimizing the social cost of an error in the level of abatement. Greater attention needs to be given policy costs such as the costs of information, administration, and enforcement when establishing the optimum level of pollution abatement and selecting policy instruments.

Food Regulation. William T. Boehm, chairperson (ESCS, USDA), Tanya Roberts, Clark Burbee, and Chuck Handy (ESCS, USDA)

The discussants at this session presented the results of recent economic research in the food regulation area. A diversity of research methodologies was discusssed.

The origins of federal milk-marketing-order price regulation of close substitutes for fresh drinking milk were discussed by Tanya Roberts. The regulations now make these substitutes (such as reconstituted milk) subject to a tax equal to the Class I-Class II price. Roberts concluded that the congressional and judicial branches of the U.S. government were not involved in that decision. The actions ultimately taken by the administrative branch were initiated by cooperatives supplying the drinking milk market. All other economic interest groups potentially affected by the rule opposed it.

Handy investigated the economic impact of a proposed change in weight labeling for meat and poultry. After conducting tests to determine the amount and variability of liquid in chicken packages under alternative regulatory options, he concluded (*a*) alternative net weight rules would not affect the real price per pound, (*b*) the proposed rule would enable consumers to make better per pound price comparisons, and (*c*) industry would incur costs of \$59 to \$116 million for improved quality control.

Burbee and Boehm analyzed the economic effects of banning the use of sodium nitrite as a meat-curing agent. As a consequence of such a ban, food prices probably would increase, reflecting the somewhat higher costs of pork processing, lower hog production, and increased demand for other meats. Net income from farming would also be lower. The All-Food CPI would be 0.3% to 0.7% higher.

AAEA Annual Agricultural Outlook Survey. Glenn Nelson, chairperson (University of Minnesota), Gene Futrell (Iowa State University), John Ikerd (Oklahoma State University), Glenn Grimes (University of Missouri), Charles Erickson (Cargill), and Gary Benjamin (Federal Reserve Bank of Chicago)

This symposium was based on information provided by the AAEA membership in the second annual survey of agricultural outlook. Estimates of supplies and prices were included for the years 1979 and 1980 for the major agricultural commodities including both livestock and crops. Outlook information also was summarized for agricultural costs and returns and for selected general economic indicators.

The symposium began with a review by Futrell of results from the first AAEA outlook survey in 1978 as compared to subsequent actual events. In general, actual prices so far in 1979 on livestock, poultry, and crop items have averaged above forecasted levels, and actual net farm income is also above the forecasted level.

Ikerd presented an overview of the procedures used in the 1979 survey and the characteristics of respondents. The detailed results of the survey were discussed by Grimes, Erickson, and Benjamin who also gave their personal views of the outlook. A major portion of the symposium was devoted to open discussion among the speakers and others attending the symposium.

Are Agricultural Markets in Disequilibrium? Robert G. Chambers, chairperson (Ohio State University), G. S. Maddala (University of Florida), L. Joe Moffitt (USDA), Richard E. Just (University of California, Berkeley), and Robert D. Emerson (University of Florida)

In recent years there has been an increasing amount of attention given to the formulation and estimation of disequilibrium econometric models. These models attempt to portray markets that do not always clear in the neoclassical sense; phenomena that are particularly characteristic of markets that are subject to minimum (maximum) price or quota regulation. Existing models that have failed to take this aspect of the modeling problem into account will in most cases be inconsistently estimated and, thus of little practical value for policy analysis. It is important, therefore, to identify the most important aspects of disequilibrium models and how they apply to agriculture.

Maddala (presented by Emerson) focused on a theoretical review of the literature on disequilibrium econometrics while discussing several modifications of the standard models which may be appropriate for such agricultural markets as the various futures markets. Chambers and Just discussed their experience in applying disequilibrium techniques to the U.S. beef import market, the California retail milk market, and the U.S. cattle industry. Moffit reported some very interesting results he has obtained in modeling the market for gasoline in a disequilibrium framework while emphasizing some important findings on agricultural demand for gasoline.

Curriculum—Meeting the Needs of Our Changing Clientele. Carl O'Connor (Oregon State University) and Raymond J. Folwell, cochairpersons (Washington State University), E. Bruce Godfrey (Utah State University), Daniel D. Badger (Oklahoma State University), Thomas A. Brewer (Pennsylvania State University), and Howard Madsen (General Foods)

The major emphasis of the symposium was on student needs in a curriculum, given present employer expectations. The specific topics were: (*a*) curricula requirements ane marketable skills; (*b*) intern and/or trainee type experiences; (*c*) the needs of the farm and nonfarm student; and (*d*) the skills sought by potential employers.

Arguments can be given for general and specialized curricula and most agricultural economics curricula contain both elements. The greatest need in most departments is neither more theory nor specialized classes, but increased use of a set of marketable skills that apply the principles of economics. An applied curricula is difficult to obtain, however, because it requires imagination, is time consuming, and offers relatively little reward when compared to other efforts.

For the student to compete effectively in the job market in the 1980s, agricultural economics majors will need increasing opportunities for intern and/or trainee experiences. A poll of twelve universities in the Southwest and Midwest indicated that such opportunities are expanding. Many benefits accrue to student participants. Coordinating with employers and supervising the intern participants requires considerable faculty time. The internship program, a well as curricula, must be modified in accordance with the background of the students and the farming and agribusiness communities in the locale of the university. The skills sought in agricultural economics majors are those of basic economics, management, and communication skills.

Will Large Dairy Farms Be the Most Effective in the Future? John W. Wysong, chairperson (University of Maryland), Bernard L. Erven (Ohio State University), Gayle S. Willet (Washington State University), John Holt (University of Florida), and Sherrill B. Nott (Michigan State University)

Entrepreneurship and capital availability together with dairy production, marketing, and input acquisition know-how have been major factors in the development of large dairies in some southern areas of the United States. The objectives of increased managerial income flows and enhancement of financial asset stocks and income flows have been of greater concern than attempts to minimize costs

per unit of revenue generated. Substantial opportunities for economic gains have existed in selected areas from economies of feed procurement and preferential milk marketing arrangements for large dairy farms once major per unit cost reductions have been attained.

Recent data on modern milking systems indicated that this cost component averaged only 12% of total milk production costs, and the major cost reductions could be attained by herds of 100 to 200 cows (although some cost reduction of the one-man milking systems studied occurred up to the 500-cow level). The newer, more labor-efficient milking systems with high cow milking capacity per hour have higher investment costs which require large aggregations of milk cows at one feeding, milking, and housing site to reduce per cow costs to levels comparable to the smaller capacity milking systems. Major gains were available from use of automatic teat-cup detachers irrespective of size and design of the milking system.

The problems of cow management on large dairy farms are compounded with increased problems of labor management in the areas of recruitment, retention, labor relations, labor productivity, salary and wage determination, and other financial and nonfinancial worker incentives. Labor training has tended to be a short-term apprenticeship arrangement on the actual employing dairy farm firms.

No consensus existed on the question of possibilities for greater crop or livestock specialization in major milk production areas. This is an area of future needed research to determine potential gains in human resource productivity and in net value added per employee.

Foreign Aid Reorganization and the Profession. Charles E. Hanrahan, chairperson (ESCS, USDA), Nicolaas Luykx (Institute for Scientific and Technological Cooperation, IDCA), Quentin West (Office of International Cooperation and Development, USDA), Morris D. Whitaker (Board for International Food and Agricultural Development, IDCA)

The U.S. foreign aid program is being reorganized with the creation of an International Development and Cooperation Administration as the policy-making entity for U.S. foreign assistance. IDCA's director will report to the President. IDCA groups into one agency, AID and the Institute for Scientific and Technological Cooperation (ISTC), a newly established agency which has responsibility for research collaboration between the United States and research institutes in other countries. This reorganization has potentially important implications for the participation of the agricultural economics profession in U.S. development assistance programs.

Among the most promising aspects of the reorganization is the establishment of the ISTC, which agency offers the possibility of direct institution-to-institution collaboration in research, training, and extension, traditional activities of agricultural economics departments in the Land Grant system. Linking the Joint Committee on Research of the BIFAD to the ISTC could enhance the research role of the colleges of agriculture in U.S. agricultural development programs. Some skepticism was voiced by university and USDA agricultural economists about the effectiveness of the reorganization in dealing with what they identified as a fundamental problem with the U.S. agricultural development program: an inadequate supply of agricultural economists with training and experience in international development, declining opportunities for professional involvement in international development, a serious reduction in the number and quality of agricultural technicians and scientists in AID, and a limited ability of the foreign aid agency to transfer and/or build technical capacity for carrying out agricultural development in LDCs.

Great Plains Droughts: Are There Effective Management Strategies? Wayne D. Rasmussen, chairperson (USDA), J. Eleonora Sabadell (Department of the Interior), Donald A. Wilhite (University of Nebraska), and Marvin Duncan (Federal Reserve Bank of Kansas City)

The formal presentations represented an interdisciplinary summary and evaluation of a three-day symposium held at the University of Nebraska under the leadership of Norman Rosenberg. Rasmussen reviewed past impacts of drought and said that the report of the Great Plains Committee in 1936 set criteria by which programs still may be judged.

Sabadell listed thirteen major factors presently contributing to vulnerability to drought. These related mainly to water use, energy, changing soil quality, and program management.

Wilhite discussed how technology might be divided into short-term or reactive strategies and long-term or drought-proofing measures. He emphasized innovative technologies that would better utilize available moisture.

Duncan pointed out that many firms and communities have underestimated their vulnerability to drought. This has hindered both planning and the building of flexibility into economic systems at all levels to deal with drought problems.

In a wide-ranging discussion with a number of participants, present federal programs, the usefulness of innovative technologies, and current farming practices were attacked. Crop diversification, careful management of water for irrigation, and a reemphasis on soil conservation were urged. There is a need to reconcile the economic interests of the individual firm and of the nation.

Is Integration of Research and Extension Possible? Marilyn H. Grantham, chairperson (Virginia Polytechnic Institute and State University), Russell C. Youmans (Oregon State University), William R.

Lassey (Washington State University), and Kenneth R. Terfertiller (University of Florida)
Title V of the Rural Development Act of 1972 mandated a joint research/extension effort through the land-grant universities intended to address the most serious and difficult to handle long-standing problems of the rural areas of the United States. The development of Title V work in the respective states resulted in many diverse kinds of specific efforts. However, the common thread throughout was the attempt to integrate or link together the research and extension phases of the work being done. Participants in the discussion reflected upon their respective experiences with Title V Rural Development efforts. Some of the reflections were that although integration of research and extension can be stopped by legislation, it cannot be created solely by legal means and that integration has been easier on the extension side, possibly because there are more rewards for the extension professional in carrying out his efforts than for the researcher. Some of the suggestions offered for accomplishing integration of research and extension were choosing personnel with sufficiently similar backgrounds to be able to interchange roles, developing personnel capabilities in order for them to serve as linkers between researchers and extension educators, and establishing a responsive administration structure and sufficient level of supplemental state funding to insure that rural development is given the impetus to occur.

Applications of Economics in Plant and Animal Breeding. George W. Ladd, chairperson (Iowa State University), Bryan E. Melton (University of Florida), Gerald A. Carlson (North Carolina State University), A. Steven Englander (Yale University), and Robert E. Evenson (Yale University)
Melton summarized some basic concepts and relations used in animal breeding and discussed selection of animals for breeding programs. One means of selection is a selection index, whose construction reaquires the use of economic values of traits. Economic value measures effect on profit of improvement in a trait.

Melton and Ladd presented two procedures for measuring economic values of traits. The procedures start with an "interdisciplinary production function": one containing quantities and characteristics of inputs. They reported an empirical application to beef cattle.

Carlson reported a study of market prices of dairy bulls' semen. One feature of breeding is the uncertainty in transmission of traits to offspring by an individual parent. He found prices to be positively related to expected gain in milk value, and negatively related to uncertainty in milk value gain.

Englander and Evenson considered economic issues that arise from variable environments and interactions between invironments and genotypes. They presented a model for determining efficient locations of experiment stations, and for selecting and screening the results of a crop improvement program, and presented measures of some variables needed to apply the model.

Are Fisheries Economists Asking the Right Questions? Richard C. Bishop, chairperson (University of Wisconsin), Daniel R. Talhelm (Michigan State University), Nancy E. Bockstael (University of Rhode Island), John P. Nichols (Texas A&M University), Richard Marasco (National Marine Fisheries Service, Seattle), and Frederick J. Smith (Oregon State University)
Talhelm pointed out that recreational fishing demand analyses should give more attention to defining recreational products. Analyzing recreational supplies from the consumer's point of view holds much promise as a way of identifying different products. Bockstael suggested that current commercial fishing research is overemphasizing work related to Fisheries Management Plans. Too much attention is being directed toward descriptive details and too little toward theoretical and methodological research. According to Nichols, not enough questions are being asked on the marketing side. Industrial organization research, cost and efficiency studies, and demand and market development analyses are badly needed. From the National Marine Fisheries Service perspective, Marasco stated that too many past economic studies have been overly general and preoccupied with optimization. Specific studies dealing with such issues as the benefits and costs of regulations, how to manage for risk and uncertainty, and transboundary problems should receive higher priorities. Smith argues that rather than "spoon feeding" information to clientele groups, marine extension programs should focus on the true goal of education, to prepare people to better control their own destinies by teaching new skills, developing talents, and providing new knowledge to help them deal with their economic environment.

Federal Water Policy Reform and Its Implications for Irrigated Agriculture. Leonard Shabman, chairperson (Virginia Polytechnic Institute and State University), Harold Stults (ESCS, USDA), Arnold Miller (OPBE, USDA), Robert Young (Colorado State University), and Norman Whittlesey (Washington State University)
Federal water policy reform proposals of the Carter administration were discussed. Particular attention was paid to revised guidelines for estimating irrigation benefits, the focus of the policy reforms on water conservation, and the likely changes in water costs to irrigation farmers as a result of the policy changes. Revised evaluation procedures can result in improved estimates of the irrigation benefits of new projects. Changes in cost-sharing and repayment policy will have little effect on prices paid by

irrigators and, therefore, little effect on water use in agriculture or the politically expressed demand for new projects. The concept of water conservation will need further clarification to be a useful policy tool.

The discussion focused primarily upon traditional federal water project construction activities. Concern was expressed that the water policy reforms should have focused less on traditional project construction programs and more upon emerging issues such as integrating water quantity and quality planning and economic adjustments to declining groundwater tables. There was a consensus that agricultural economists should continue to do sound analyses of water projects, programs, and policies. Such analyses can provide an analytical basis for improved social decisions even though the specific recommendations from such research often appear to be ignored.

Agricultural and Food Policy Education: Is the Profession Meeting the Needs of Its Clientele? B. H. Robinson, chairperson (Clemson University), R. G. F. Spitze (University of Illinois), D. M. Hoover (North Carolina State University), J. B. Wyckoff (Oregon State University), and R. J. Hildreth (Farm Foundation)

The speakers felt that the profession had been meeting the needs of the clientele groups as evidenced by such indicators as the expanding cadre of professional policy workers and the number of both scholarly publications and policy publications addressed to lay audiences. However, each pointed to weaknesses in our current policy education programs. There seemed to be consensus among the speakers that the events of the current decade had stimulated a shift in the demand for policy education. The shift seemed evident irrespective of the clientele group.

Spitze proposed three major areas in need of remedial attention in graduate education: (*a*) training in public policy theory, (*b*) participatory experience in policy critique and dialogue, and (*c*) organized instruction in analysis of policy alternatives.

Hoover argued that undergraduate instruction should include analysis of the aggregate impacts of policy decisions to stress the societal relevance of economics and potential conflicts between private and social optima. He also stressed the need to build on the management aspects of policy decisions to enlist student interest. Hoover feels that policy instruction should be kept simple.

Wyckoff noted that the most successful extension policy-education programs have involved agents in the planning process. The participatory experience in extension education programs was noted by Spitze as a deficiency in graduate education.

The basic policy education model is similar for all clientele. The discussions suggested that educators can benefit from the successes and failures experienced by others irrespective of their primary clientele.

The Impacts of the Proposition 13 Movement. Dale Colyer, chairperson (West Virginia University), James Cothern (University of California, Davis), Phillip Gardiner (University of California, Riverside), Harold Guither (University of Illinois), and James Hite (Clemson University)

Proposition 13 in California has lead to movements to limit taxes and government spending. The movement surfaced from dissatisfaction with such matters as constantly rising taxes, feelings of waste in government, and lack of confidence in public agencies. Tax limitations are not new. Specialized limitations such as use value assessments, circuit breakers, homestead exemptions have been passed by many states in recent years. During the thirties, several states including Washington and West Virginia passed general property tax limitations. Examinations of such laws indicate three broad effects: reduced services, substitute taxes, and shifting of responsibilities to state levels. The initial impacts tend to be mitigated through time but some persist. Once passed, the limitations are not apt to be repealed due to their popularity. In states such as California the impacts may be lessened or postponed due to used surpluses to replace local collections. Immediate impacts included reduced public employment, reductions in school programs, and no pay increases. In some states, a rate limitation actually may result in increased taxes as assessment levels are raised from fractional to full market values. Proposition 13 also has been symbolic, causing legislative and administrative bodies to reevaluate tax and expenditure plans due to apprehension that public action will result in such restrictions.

Commodity Pricing Systems: Issues and Alternatives Bruce W. Marion, chairperson (ESCS, USDA, University of Wisconsin), V. James Rhodes (University of Missouri), Marvin L. Hayenga (University of Wisconsin), Lee F. Schrader (Purdue University), Dennis R. Henderson (Ohio State University), Thomas L. Sporleder (Texas A&M University), and E. Dean Baldwin (Ohio State University)

The three papers presented at this symposium examined current commodity pricing issues and possible solutions. The experience and recommendations of the Secretary of Agriculture's Meat-Pricing Task Force were reviewed by Rhodes, a member of that task force. Hayenga and Schrader discussed formula pricing in five commodities (beef, pork, cheese, turkeys, eggs), including the extent of an incentives for formula pricing and the benefits and

problems derived form formula pricing. The final paper examined the feasibility and impact of electronic markets, particularly in thinly traded or poorly performing markets. The three papers have been published as NC-117 Working Paper 39, Department of Agricultural Economics, University of Wisconsin-Madison.

Editor's note:
Abstracts for publication in the *Journal* were not presented for two symposia sessions: "Emerging Rural Employment Policy Issues," and "Teaching Decision Making under Risk and Uncertainty," led by Lee Bawden (Urban Institute) and J. Roy Black (Michigan State University), respectively.

Abstracts

Contributed Papers

Research Methods (Robert L. Christensen, University of Massachusetts, Chairperson)

"Six Alternative Methods for Linking Normative and Positive National Agricultural Models." Wen-Yuan Huang and Reuben N. Weisz (ESCS), Kenneth H. Baum (Virginia Polytechnic Institute and State University), Lloyd Teigen (ESCS), and Earl O. Heady (Iowa State University)
This paper discusses the pros and cons of six alternative procedures for linking normative and positive U.S. agricultural policy analysis models. A current experiment interfacing the CED Cross-Commodity Forecasting System with the ISU linear programming model is described.

"The Preference of Purchases Data over Sales Data in Primary Data Input-Output Models." Edward E. Ives (Ohio State University and Ohio Agricultural Research and Development Center)
Five arguments are made, based on statistical properties of estimated direct coefficients and the relative ease of handling certain other difficulties, that purchases data are preferable to sales data for generating primary data input-output models.

"Comparing Polynomial and Rational Lag Models." L. J. Butler and S. R. Thompson (Michigan State University)
This paper compares and attempts to evaluate polynomial and rational lags, both theoretically and empirically, by estimating the same lag structure both ways. Comparison is achieved by eliminating the unknown nature of the lag by using data generated from a simple economic model of known lag.

"Elasticities and Flexibilities in Systems of Simultaneous Equations." Jean-Paul Chavas (Texas A&M University), Zuhair Hassan (Statistics Canada), and S. R. Johnson (University of Missouri)
The interrelationships between elasticities and flexibilities have not been given a solid basis for interpreting applied results. The paper provides a derivation of the price and quantity responses obtained in linear simultaneous equation market models. It shows that, abstracting from estimation problems, the connection between price flexibilities and price elasticities can be made so as to allow an unambiguous interpretation of applied results.

"Information, Option, and Existence Value." Jon M. Conrad (Cornell University)
An intergenerational model of resource development is constructed to examine the concepts of option and existence value. These concepts are seen to relate to a more fundamental concept: the expected value of perfect information. The analysis would suggest that when sequencing irreversible resource developments both uncertainty and the expected value of information should be considered.

Policy, Concepts and Conflicts (Frederick L. Leistritz, Texas A&M University, Chairperson)

"An Analysis of U.S. Dairy Price Supports Based on Parity Versus Cost of Production." Andrew Novakovic (Cornell University) and Emerson Babb (Purdue University)
Analyses based on a spatial model of the U.S. dairy sector indicate that the current parity based price supports could lead to large and increasing federal expenditures on dairy products over a five-year period, whereas support prices based on the full cost of production would imply much lower expenditures.

"Measuring Farm Operators Nonfarm Wealth (or, Where Has All the Money Gone?)." Dean W. Hughes (USDA, Texas A&M University)
The "Balance Sheet of the Farming Sector" makes no attempt at reporting the nonfarm equity position of farm sector participants. This study estimates the size of such holdings for farm operator families and finds them to be significant, conservatively accounting for about 20% of reported assets in 1977.

"Prices Paid Indexes for Major U.S. Crops." Ed Fryar and James P. Houck (University of Minnesota)
Commodity-specific Prices Paid Indexes and Prices Received/Prices Paid ratios are calculated for corn, cotton, soybeans, and wheat. These indexes are then compared to the current USDA Prices Paid Index and Prices Received/Prices Paid ratios. Target prices are recalculated using the commodity-specific Prices Paid Indexes and then compared to the actual target prices for the 1976–78 period.

"Conflict within a Changing National Agricultural Policy-Making Process: Major Agricultural Legislation in 1977 and 1978." Jerry R. Skees (Michigan State University)
The new macropolitical dimensions of agriculture and food policy have resulted in an increase in the number and diversity of groups involved in the national policy-making process and in the potential for conflicts. This paper examines the political dynamics of the development of major agricultural legislation in 1977 and 1978, with particular attention to where the potential for conflicts existed and how they were resolved.

"Discontinuous Policy and Distorted Choices: The Case of Acreage Control." Robert D. Weaver (Pennsylvania State University)

Past acreage response studies have failed to recognize that government control policies have typically introduced taxes and subsidies which are discontinuous over acreage planted. The nature of this discontinuity is reviewed and its impact on profit maximizing choice analyzed. A general model suitable for econometric estimation which would accommodate this discontinuity in policy is introduced.

Teaching and Information Delivery (Kelso L. Wessel, Ohio State University, Chairperson)

"Editorship Location and Authorship Affiliation in the AAEA *Journal*." Rod F. Ziemer and Kostas G. Stamoulis (University of Georgia)

This paper presents an analysis of the relationship between editorship location and the distribution of authorship affiliation in the AAEA *Journal*. Nonparametric test results indicated that changes in editorship location have been accompanied by significant changes in the distribution of authorship affiliation over the period 1944–78.

" 'Hands-On' Models: Innovations for Teaching Economic Theory to Undergraduates." Josef M. Broder (University of Georgia)

The abstract nature of economic theory creates challenges for introductory agricultural economics courses. Current techniques designed to teach theory tend to be labor intensive or prohibit active participation in learning theory. This paper discusses recent experiences of designing, constructing, and presenting multiple dimensional and mechanical models into classroom learning.

"An Alternative Method for Training Non-English Speaking Students." Wilmer M. Harper and Martin J. Blake (New Mexico State University)

This paper evaluates a program designed to permit international students with English deficiencies to begin their graduate training while simultaneously taking an intensive course in English as a second language. The results indicate no significant performance difference for students in this program compared to students beginning training with English capabilities.

"An Intermodal Delivery System for Agricultural Marketing and Weather Data." Larry D. Jones and Joe T. Davis (University of Kentucky)

A project entitled "Green Thumb" has been initiated in Kentucky to provide farmers real-time weather and marketing data. This project represents a major departure from past dissemination systems in that it provides for rapid, continuous transmission of data directly to farmers' homes, utilizing computers, telephones, and television to access and deliver data.

"Budgeting the Impact of Dairy Investments." Gerald D. Schwab and Sherrill B. Nott (Michigan State University)

A whole farm budgeting and cash flow analysis of sixty-cow and 100-cow dairy farms investing in new barn and milking facilities is reported. At medium investment levels, a sixty-cow farm would need eighty cows or 15,000 pounds of milk per cow to maintain profit levels.

Livestock Management (Brent Spaulding, University of Arkansas, Chairperson)

"Estimating Learning Benefits from Research and Development in Anaerobic Digestion Systems for Animal Waste Disposal and Energy Recovery." James L. Anderson, Jr. (University of California-Davis) and Marilyn A. Altobello (University of Connecticut)

Learning functions relating cumulative investment in research in anaerobic digestion systems and costs of methane production are estimated and used to determine breakeven points for animal production units adopting this technology, potential net benefits, and regional distribution of benefits. Results indicate greatest benefits accruing to large-scale units in cattle-feeding states.

"Alternative Cost-Sharing Arrangements to Induce the Adoption of Improved Manure Handling Techniques: An Empirical Study." Douglas Southgate, Basil M. H. Sharp, Steven Lovejoy, and Nicolaas W. Bouwes, Sr. (University of Wisconsin)

In this paper, empirical observations constitute the basis of a model of farm operations. The model is used to estimate the minimum cost-sharing rate necessary to induce farmers to implement less-polluting manure management systems. The estimated rate is considerably below rates offered by current cost-sharing programs.

"Taking Account of Variation in Feedstuff Nutrient Values and in Animal Requirements in Ration Formulation." Neal Peterson, J. Roy Black (Michigan State University), and Danny G. Fox (Cornell University)

Choice of safety factor to use in formulation of rations for growing and finishing cattle is discussed. The subtraction of a nutrient's standard deviation from its mean for each feedstuff is superior to adding a safety factor to the animals' requirements for the nutrient. Appropriate safety factors, when the objective is to minimize expected (in a probability sense) cost, are .67, 1.1, and 1.2 standard deviations for 500-, 700-, and 900-pound average framed cattle, respectively.

"The Role of Market Price-Weight Relationships in Optimal Beef Cattle Management Models." Steven T. Buccola and Warren B. Jessee (Virginia Polytechnic Institute and State University)

Optimal beef cattle diet and rate-of-gain analyses normally ignore the relationship between the animal's market price and its weight. Theoretical and empirical models are developed to show that optimal daily weight gain tends to be less than the feasible maximum when market price per pound falls rapidly with weight increases.

"The Suboptimality of the Beef Cycle." Greg Hertzler and James H. Cothern (University of California-Davis)
The supply of beef is investigated using spectral analysis. The two and one-half year lag from herd build up until production is realized requires decisions based on future prices. Producers react instead to past prices, and the cycle results. Optimal control applied to an investment model shows the cycle to be suboptimal.

International Agricultural Production (T. Kelley White, Purdue University, Chairperson)

"An Analysis of Factors Affecting the Limited Utilization of Dry Season Irrigation in Northeast Thailand." Joe T. Davis, Russell H. Brannon (University of Kentucky), and Charles T. Alton (Kentucky Development Cabinet)
Although the government of Thailand has made substantial investment in irrigation infrastructure in northeast Thailand, there is still relatively little dry season irrigated farming being carried out in that region of the country. This study investigated the characteristics of dry season farming and farmers and suggested and tested some hypotheses for explaining this low utilization of dry season irrigation.

"Mitigating the Effects of Multicollinearity Using Exact and Stochastic Restrictions: The Case of an Aggregate Agricultural Production Function for Thailand." Ron C. Mittelhammer, Douglas L. Young, Damrongsak Tasanasanta, and John T. Donnelly (Washington State University)
Mixed estimation and OLS were each used to estimate an aggregate agricultural production function for Thailand for which data were highly multicollinear. The final mixed model obtained using minimax regret in the pretest appeared to outperform significantly OLS in terms of precision and overall reasonableness, mitigating a serious multicollinearity problem.

"The Potential for Self-Sufficiency in Food Production in Six Latin American Countries: Some Projections for 1985 and 1990." Marshall A. Martin and Anoosh Noori Esfandiari (Purdue University)
Based on the assumptions and empirical results of this study, most Latin American countries, with the possible exception of Argentina and Colombia, will find it impossible to become self-sufficient in food production in the 1980s. Fertilizer and food imports will be required in most Latin American countries.

"The Philippines Agricultural Sector in 2000 A.D. Result from the MAAGAP National Model." David E. Kunkel, Gil Rodriguez, Jr., and Leonardo A. Gonzales (ESCS, Republic of the Philippines)
A mathematical programming model of the Philippine agricultural sector was used to look at alternative scenarios for the year 2000. Model results indicated an expanding agricultural sector able to meet the needs of the Philippines. However, improved technologies for corn, feed grains, and vegetable crops are required if higher relative prices for these and livestock products are to be avoided.

"Examining Productivity Differences and Identifying the Efficient Farm Size: A Brazilian Example." James R. Sieber and Douglas L. Young (Washington State University)
Examination of Brazilian data over farm size classes revealed substantial variation between observed and theoretically efficient (implied by econometric production functions) input combinations and average costs. Given the likely persistence of imperfections preventing achievement of theoretical efficiency, use of an "empirically efficient" farm size identified by proposed procedures is encouraged.

Risk and Firm Growth (Robert E. Lee, A. D. Little, Chairperson)

"Firm Growth and Survival Versus Income and Cash Flow: The Influence of Land Appreciation." Larry J. Held (University of Wyoming) and Glenn A. Helmers (University of Nebraska)
A financial simulation model was developed to study the influence of land appreciation upon a Nebraska wheat farm. Results showed sizeable tradeoffs between increased firm growth and survival versus lower net income and larger cash flow deficits at higher rates of appreciation, raising serious questions regarding management goals.

"Effects of Different Measures of Dispersion on Risk-Efficiency Farm Plans in a MOTAD Framework." Tillak Persaud and Harry P. Mapp, Jr. (Oklahoma State University)
In this paper variations in net returns were measured in terms of deviations from the mean of the series and negative deviations from equally- and unequally-weighted moving averages in a MOTAD framework. Results indicate that differences in production activities, expected net returns, and relative variability of the farm plan occur depending upon the method used to measure dispersion of net returns.

"Risk-Returns Criteria in Selecting Farm Machinery." William Edwards and Michael Boehlje (Iowa State University)
Risk preferences can be introduced into machinery selection by estimating the mean and standard deviation for total costs, including timeliness costs,

associated with various machinery sets. Risk-returns criteria tested included *E, V* and *E, S* frontiers, cost-variance, upper confidence limits, and maximum affordable cost.

"A Return-Risk Analysis of the Decision to Participate in Government Price Support Programs." Eddie H. Kaiser and B. H. Robinson (Clemson University)
Farm planning decisions have been subjected to increasing risk and uncertainty during the last decade. Recent government farm programs have been designed to reduce instability in prices and supplies. This study employs MOTAD models to analyze the risk associated with alternative farm plans and the risk-reducing contribution of government farm programs.

"A Simulation Study of the Effects of Credit Terms Upon Maximum Feasible Farm Debt Burdens." Jerry Thompson and Greg Hanson (University of Minnesota)
Cash income data obtained from farm records is decomposed with a regression technique suggested by portfolio theory. Farm debt structure is simulated and maximum feasible relative debt burdens are estimated for several one- and two-enterprise farm types. Sensitivity of the maximum debt burdens to changes in credit terms is explored.

Energy Resources (Michael Hanemann, University of California-Berkeley, Chairperson)

"An Economic Feasibility Study of Crop Residues as an Auxiliary Fuel Source for Iowa's Coal-Fired Power Plants." Burton C. English, Cameron Short, and Earl O. Heady (Iowa State University)
The costs of crop residue for direct combustion in power plants are estimated in 1975 prices. These costs are incorporated into an Iowa agricultural linear programming model. This model is used to evaluate the impacts of energy price increases and increased sulfur restriction levels on the feasibility of crop residues.

"Impacts of Fuel Pricing and Nonprice Allocation Scenarios on High and Low Risk Crop Producers." Douglas C. Farthing (Texas A&M University) and James B. Kliebenstein (University of Missouri)
The study summarizes, through use of a quadratic program, the impacts of government nonprice fuel allocation levels versus fuel price increases on high and low risk crop producers. For high risk crop-producers fuel price increases had little or no impact on their fuel usage levels. Both fuel prices and nonprice allocation strategies were effective in cutting fuel usage by low risk producers.

"The Demand for Natural Gas and Electricity for Nine Northeastern States in the Residential, Commercial, and Industrial Sectors." James G. Beierlein (Pennsylvania State University), James C. McConnon (Iowa State University), and James W. Dunn (Pennsylvania State University)
Classification of energy demand into groups with homogenous uses and motives and the use of simple demand theory resulted in six demand equations that have a preponderance of correct signs and significant variables. Differences in price and income elasticities are found between sectors with the residential sector being more elastic.

"Derived Demand for Energy in Agriculture: Effects of Price, Substitution, and Technology." Edward K. Mensah and John A. Miranowski (Iowa State University)
The derived demand for energy and nonenergy inputs in U.S. agriculture is estimated based on a translog cost function. The estimated coefficients are used to derive own-price and cross-price elasticities of demand and Allen partial elasticities of substitution. The implications of these elasticity estimates for energy modeling are evaluated.

Commodity Demand and Prices (Clyde Greer, Montana State University, Chairperson)

"Univariate Residual Cross-Correlation Analysis: An Application to Beef Prices." Stephen E. Miller (Clemson University)
This paper provides a discussion of univariate residual cross-correlation analysis. This methodology allows an empirical assessment of lead-lag relationships between economic time series. For illustrative purposes the methodology was used to analyze lead-lag relationships between beef value changes at the retail, wholesale, and farm levels.

"Estimation of Income-Expenditure Relationships for Beef Using Spline Functions." Chung-Liang Huang and Robert Raunikar (University of Georgia)
Household expenditure data for ground beef, beef roasts, and steaks were fitted by spline functions. The results indicate that there is a unique expenditure pattern for each type of beef and there are sharp contrasts in marginal propensity to consume for specific types of beef among different household income levels.

"A Trend Projection of High Fructose Corn Sweetener Substitution for Sugar." Hoy F. Carman and Peter K. Thor (University of California-Davis)
High fructose corn syrup substitutes directly for sugar in many food processing applications. Its continued rapid acceptance has economic implications to sweetener industry participants and others. A nonlinear trend projection indicates that because of substitution, per capita and total U.S. sugar consumption likely will decrease during the next decade.

"U.S. Potato Demand: Static and Dynamic Characteristics." Edmund Estes, Leroy Blakeslee, and Ronald Mittelhammer (Washington State University)

Aggregate demand relationships for the U.S. potato industry are estimated by two-stage least squares. Demands were found to be price inelastic suggesting that abrupt changes in production cause major inverse price effects. Secular demand shifts are relatively rapid. Together these suggest opportunities for expanded production but a need for careful planning to avoid price depressing effects from even moderately excessive production growth.

"Demand and Prospects for Cocoa in the 1980s." Aja Okorie and David Blandford (Cornell University)
Estimated demand equations for the major consuming countries/blocs are used to project consumption and revenue in 1985 under alternative price/income scenarios. On the basis of recent production trends it is concluded that from the producers' perspective the prospects for cocoa in the 1980s look very promising.

International Trade (Cathy L. Jabara, ESCS, Chairperson)

"Trade Adjustment Assistance and Labor Displacement in the U.S. Sugar Industry." Lloyd Harbert and David Blandford (Cornell University)
If the price of sugar was reduced to the minimum under the International Sugar Agreement, wage payments to farm labor would be reduced by $39.7 million and to processor labor by $54.7 million. Only one-quarter of the 11,300 displaced processing workers would be eligible for compensation under the existing adjustment assistance program.

"Economic Effects of Selected Trade Restrictions on World Sugar Trade." Mark A. Edelman and Walter H. Gardiner (Purdue University)
A spatial equilibrium approach was employed to analyze the short-run consequences of selected trade restrictions of major importing and exporting countries on the world sugar market. International sugar trade is examined in terms of global welfare, volume, value of receipts, and payments price per unit, and trade flows.

"An Analysis of the Impact of Exchange Rate Changes Using Price Linkages." William H. Meyers, Elizabeth J. Gerber (ESCS), and Maury E. Bredahl (University of Missouri)
A partial equilibrium model is derived for the computation of exchange rate effects. The model incorporates foreign internal demand elasticities and price transmission elasticities which take account of price insulating policies. The appreciation of the Japanese yen relative to the dollar was analyzed for wheat, feed grains, and soybeans.

"A Comparison of the Current United States and Canadian Wheat Marketing Systems." David L. Watt, Donald O. Mitchell, and John Ross (Michigan State University)
The U.S. and Canadian wheat marketing systems are compared over the 1971–78 period. Quantities exported relative to wheat supplies available for export are examined using annual data. Monthly price data is also used to examine the price behavior of U.S. and Canadian wheat exports.

"A Monte Carlo Analysis of the Estimation of Export Demand." James K. Binkley and Lance McKinzie (Purdue University)
A simple two-country trading model was used to compare three methods of estimating export demand: OLS, TSLS, and TSLS applied to domestic curves from which were derived excess demand. Estimator performance depends primarily on relative error variances around excess supply and demand. The third method was generally superior.

Marketing, Temporal and Spatial Issues (Jon A. Brandt, Purdue University, Chairperson)

"Congestion in the Agricultural Marketing/Transportation System: A Case Study." Mechel Paggi and Stephen Fuller (Texas A&M University)
This paper focuses on the problem of congestion in the agricultural marketing transportation system. The purpose of this study is to (*a*) examine methodology for evaluating the cost of congestion, (*b*) relate appropriate research techniques for modeling traffic-congested systems, and (*c*) carry out analysis of congestion arising in the truck-to-ship intermodal grain transfer systems at the Port of Houston. A stochastic network simulation model was constructed to carry out the queuing analysis.

"Integrating Static Approaches to Location Problems into Dynamic Analyses." Virgilio A. P. Machado, Daniel S. Tilley, and Richard L. Kilmer (University of Florida)
A mixed-integer programming model with multiple products and economies of scale in processing is integrated with dynamic programming to allow dynamic analyses of plant location problems. The model is illustrated with an analysis of fresh citrus packing in Florida.

"A Multi-State Approach to Agricultural Issues: The Northwest Agricultural Development Project." James Youde, Robert McKusick, and Bruce Prenguber (Northwest Agricultural Development Project—Vancouver)
The project develops information on tradeoffs among development objectives and future resource and market requirements and constraints. Linear programming and input-output techniques are linked to analyze agricultural production and resource use by multicounty production areas and to estimate state income and employment impacts. The model considers numerous agricultural policy issues.

"Economic and Epidemiologic Policy Implications

from the National Brucellosis Technical Commission Study." Stephen H. Amosson, Raymond A. Dietrich, and John A. Hopkin (Texas A&M University)
This paper analyzes policy implications arising from the National Brucellosis Technical Commission Study. A systems simulation model was designed to estimate physical losses resulting from alternative bovine brucellosis programs. Benefit-cost ratios were calculated by program alternatives for determining economic and epidemiologic implications.

"Temporal Implications of Limitations on Annual Irrigation Water Pumped from an Exhaustible Aquifer." Daniel C. Hardin (Texas Water Resources Institute) and Ronald D. Lacewell (Texas A&M University)
Economic waste caused by uncontrolled pumping of groundwater is of major concern on the Texas High Plains. A recursive linear programming model is used to evaluate various annual limitations of aquifer depletion. Choice of an optimal temporal allocation of groundwater depends greatly on the interest rate chosen for the analysis.

Natural Resources and Environment (Ivery Clifton, University of Georgia, Chairperson)

"Estimating a Potential Cropland Supply Function for the Mississippi Delta Region." Robert N. Shulstad, Billy E. Herrington, Ralph D. May, and E. Moye Rutledge (University of Arkansas)
A potential cropland supply function is constructed under conditions of alternative product prices, crop rotations, factor costs, management levels, and discount rates with special emphasis on the conversion costs of woodland and pastureland. The research will help provide a projection of regional resource use in U.S. agriculture and form the basis for projected expanded input use and the resulting environmental pressures of such expansion.

"Further Evidence on the Effectiveness of the California Land Conservation Act." Daniel J. Dudek and Richard E. Howitt (University of California-Davis)
The effectiveness of use-value assessment in maintaining open space and in deterring the conversion of prime agricultural land to urban uses is evaluated in the San Joaquin subbasin for the period 1958–74. Results indicate that the act is a significant policy variable exhibiting the intended effects upon idle and agricultural land stocks, but that it is ineffective in controlling the growth of urban stocks on prime land.

"Optimal Sequential Sampling of Natural Resource Stocks: An Application of Kalman Filtering." Bruce L. Dixon (University of Illinois) and Richard E. Howitt (University of California-Davis)
For sequential estimation of resource stocks, partial replacement sampling is conventionally thought to give stock estimates with lower standard errors than estimators using simple random samples. Viewing resource production scheduling as dynamic, stochastic optimization, partial replacement sampling is shown to be inefficient in certain instances compared with simple random sampling.

"Analysis of the Economic Impact of Water-Based Recreation in Eastern Oklahoma." James C. Chang and Daniel D. Badger (Oklahoma State University)
The McClellan-Kerr Arkansas River Navigation System provides many water-oriented recreation areas and facilities. The objective of this paper was to estimate the impact of water-based recreation on various industries in Oklahoma. Recreation on the navigation system will generate an additional output of goods and services of $115 million, 7,400 additional jobs, and $38 million in additional income for all input-output industries in Oklahoma.

"Integrated Pest Management in Corn Rootworm Control: An Economic Assessment." John A. Miranowski (Iowa State University)
Integrated pest management in corn production provides cultural and chemical strategies for corn rootworm control. Economics can aid in selecting the optimal management strategy. In selecting the optimal strategy, this study considers both expected net returns and risk. Under current price and cost conditions, cultural control strategies dominate.

Marketing Issues (Alden Manchester, ESCS, Chairperson)

"Quality Choice in a Product Market." John Spriggs (Purdue University)
The paper presents a simple method for measuring the welfare loss from a suboptimal quality choice. The measure of welfare loss may help determine whether moving to the optimal quality choice is worthwhile. By way of illustration the method is supplied to the corn export market.

"The Influence of Alternate Pricing Methods on Ex-Vessel Shrimp Prices." John P. Nichols and Larry Johnston (Texas A&M University)
The relationship between ex-vessel pricing methods and interport price differentials for shrimp was examined. Ex-vessel prices were found to be significantly higher in ports using a pack-out method of establishing the value of landed shrimp when compared to box-weight ports. This differential was shown to vary by seasons and in direct relationship to the weekly change in prices in pack-out ports.

"Revisiting the Advertising-Concentration Issue." Ronald W. Ward and Robert M. Behr (University of Florida)
Advertising intensity is shown to be positively related to SIC four-digit measure of concentration. Advertising within the consumer nondurable industries is particularly influenced by increased concen-

tration. Likewise, the advertising-concentration relationship has intensified over time, suggesting an increase in nonprice competition especially for the food and related industries.

"An Imperfectly Competitive Market Model of the U.S. Lettuce Industry." Michael D. Hammig and Ron Mittelhammer (ESCS)
A simple econometric model of the U.S. lettuce industry is constructed based on an imperfectly competitive market structure with uncertain profit outcomes at the grower level. The model is simulated to provide insight with respect to impacts on the industry of higher wages for hired farm labor.

"Vertical Coordination through Spot Market Contracting and Integration." Richard L. Kilmer and Ronald W. Ward (University of Florida)
Economists have assumed the spot market is a most efficient allocating mechanism. The welfare differences resulting from transactions costs from a spot market, contract or vertical integration, are explored. As increased control over supply is achieved, a tradeoff emerges between increased utility from increased demand and decreased utility from higher costs. The resulting differences in welfare from using each alternative market are shown.

Farm Management Extension (Garnett L. Bradford, University of Kentucky, Chairperson)

"Impacts of a Computerized Management Decision Making Model on Farmers." Charles L. Moore, Sr., David L. Debertin, Larry D. Jones, and Angelos Pagoulatos (University of Kentucky)
This paper examines the impacts of a computerized decision making model on farmers' decisions. A questionnaire completed at the conclusion of the workshop measured farmers' intentions. A follow-up survey one year later assessed the extent to which these intentions were realized.

"The Implications of the FACTS System for Farm Management Extension and Research." Ed Carson (Purdue University)
The FACTS system is an interconnected system of "smart" computer terminals linking the counties of Indiana and the agricultural departments at Purdue University with each other. The system is expected to multiply the farm management extension program significantly. The system must perform well and gain agent and farmer acceptance and staff support.

"Use of the Programmable Calculator in Agricultural Economics Extension." James M. McGrann (Texas A&M University) and William M. Edwards (Iowa State University)
The programmable calculator is a recent addition to the set of tools available for aiding extension professionals, farmers, and agribusiness firms in management decision making. Multidisciplinary programs have been developed and distributed through a subscription library. The programmable calculator is valuable for extension workers in preparation of materials, instruction during meetings, and direct farmer assistance.

"Swine Farm Simulation: An Effective Extension Model." Allan E. Lines (Ohio State University)
The paper presents a unique model that simulates present, selected, and near optimal growth and organization strategies for the swine farm over a five-year planning horizon. Decisions made by the user on the model include product size, growth, management system, scheduling, and building type.

"An Evaluation of Southern Cooperative Extension Programs Aimed at Small and Part-Time Farmers." David Orden and Steven T. Buccola (Virginia Polytechnic Institute and State University)
Results of a model developed to explain farm sales changes of participants in southern extension small-farm programs indicate that sales revenue increases are affected by the initial level of farmers' resources, the extent of their program participation, characteristics and training of the field staff, and output price changes and environmental effects on yields. Policy implications are considered.

Futures, Hedging, and Pricing (James A. Niles, University of Santa Clara, Chairperson)

"Futures Prices of Beef Cattle and the Theory of Nonstorable Commodities." Steve Blank (University of Hawaii)
The long held hypothesis of independence between futures prices of individual delivery month contracts for nonstorable commodities is tested for live cattle and feeder cattle. The hypothesis is rejected for both sets of data. It is also suggested that the volume of trading, composition of trading activity, and characteristics of traders in a market will influence prices generated by that market.

"The Potential for Using Midwest Futures Contracts to Reduce Risk and Increase Storage Returns on Pacific Northwest Wheat." Joe Dewbre and Leroy Blakeslee (Washington State University)
Procedures are developed for forecasting weekly cash prices for white wheat and the basis separating white wheat prices and Midwest futures prices. Forecast variances of each are supplied. A procedure is developed for choosing from among marketing options having uncertain outcomes. Operating results are simulated for the 1972/73–1977/78 storage seasons.

"Incorporation of a Price Forecasting Equation into Selective Hedging Strategies for Corn." David E. Kenyon and Craig D. Cooper (Virginia Polytechnic Institute and State University)
December futures prices during the growing season for corn were predicted as a function of estimated

ending stocks and production. Predicted futures prices were incorporated into hedging strategies. Strategies using predicted futures prices were superior to routine hedging, but not superior to strategies using technical price indicators.

"Market Equilibrium with Random Production." Bruce Gardner and Jean-Paul Chavas (Texas A&M University)
The conditions for competitive equilibrium in a market with random production are examined. It is found that a mean-preserving increase in yield variability changes the competitive equilibrium output even when producers are risk-neutral. This fact creates problems for a common specification of equilibrium in the price stabilization literature.

"Price Disequilibrium Versus Price Equilibrium: A Question of Modeling Approaches." Harry S. Baumes, Jr. and Abner W. Womack (ESCS)
Price equilibrium and price disequilibrium are two modeling approaches that have been used to represent the underlying economic and/or operational structure for agricultural commodity models, particularly field crops. This paper compares both of these model structures as applied to the U.S. corn industry and discusses the implications of each.

Marketing Cooperatives and Cartels (Anne E. Peck, Stanford University, Chairperson)

"Wheat Cartelization in the Presence of a Market Intermediary." Colin Carter and Nancy Gallini (University of California-Berkeley)
This paper examines a von Stackelberg behavior of an intermediary firm in the wheat market. It demonstrates that the intermediary acting as a leader in the market will oppose the formation of a wheat cartel. Although the marketing charge does not change with the introduction of the cartel, volume traded decreases thus decreasing total revenue to the intermediary firm.

"International Trade, Cartels, Customs Unions, and Centrally Planned Economies." Robert G. Chambers (Ohio State University)
A simple 2×2 model of international trade is used to demonstrate that an international cartel or customs union, with monopoly power in trade, may prefer autarky to tariff-protected trade if a distortionary wage differential exists.

"Analysis of Factors Associated with Over-Order Prices in Federal Milk Orders." E. M. Babb, D. A. Bressler, and J. W. Pheasant (Purdue University)
Data on over-order pricing in U.S. federal milk orders are related to measures of cooperative and processor concentration, milk utilization, costs of alternative milk supply, and cost of production in a time-series cross-section regression analysis. The data suggest a strong relation between over-order price and costs of alternative supplies. No definite relation is found between the other variables.

"Existence, Correlates, and Perceptions of Selected Conduct Patterns in the Dairy Industry: Implications for Industrial Organization Research." Robert D. Boynton (Purdue University)
Industrial organization research has found the conduct variable elusive. This situation is nowhere more critical than in regulatory policy, specifically in the dairy industry. Primary data from dairy cooperatives and proprietary firms was used to measure the existence of and attitudes toward selected behaviors and explain their bases.

"Gibrat's Law and Growth of Agricultural Marketing Cooperatives." Robert A. Skinner and Thomas L. Sporleder (Texas A&M University)
Gibrat's Law is that growth rate and size are independent. Various empirical tests of the validity of Gibrat's Law for regional marketing cooperatives in the United States are presented. The empirical tests do not support Gibrat's Law and support the hypothesis of minimum efficient size among marketing cooperatives.

Farm Size and Organization (James K. Whittaker, Oregon State University, Chairperson)

"An Improved Procedure for Evaluating Alternative Farm Sizes." James W. Richardson and Gary D. Condra (Texas A&M University)
The methodology used in existing farm size studies fails to consider explicitly the following factors: time, risk, and uncertainty; alternative financial arrangements; income taxes; changing land prices; increasing input costs over time; and year-to-year net cash flows. A procedure that incorporates these factors is described in this paper and demonstrated by evaluating four alternative farm sizes.

"Some Evidence on Pecuniary Economies of Size for Farm Firms." Bernard V. Tew, Wesley N. Musser, and Bill R. Miller (University of Georgia)
This paper presents an empirical analysis of the assumption of constant variable input prices, which is generally made in studies of economies of size in farming. The empirical analysis supports this assumption even though some responsiveness of price to quantity of input was found.

"A Conceptual Model of the Stubble Replacement Decision for Florida Sugarcane Growers." Donald R. Crane, Jr. and Thomas H. Spreen (University of Florida)
Sugarcane is a perennial plant which grows back each year after harvest. A number of factors combine to cause yield to decline as the stubble ages. The stubble can be viewed as an asset with declining productivity. Asset replacement theory is reviewed and a series of three optimization models are proposed to quantify the replacement decision.

"Agronomics and Economics of Alternative Saginaw Valley Cropping Systems." Roy Black, Roger Hoskin, Larry Connor, Don Christenson, Zane Helsel,

Vern Meints, Fran Wolak, and Tom Burkhardt (Michigan State University)
Sixteen cropping sequences from Michigan's Saginaw Valley are ranked according to profitability. Crops include corn, soybeans, navy beans, wheat, sugar beets, and alfalfa. The evaluation is completed from a whole farm perspective, where yields reflect explicit consideration of synergistic relationships among crops. Also, sequence specific machinery complements are generated.

"Economics of Grafting as Adjustment to Wine Price Changes in California's San Joaquin Valley." Nick K. Dokoozlian and Carl L. Pherson (California State University-Fresno)
The comparison of discounted cash flows indicated that grafting white varietals to red varietal vineyards was superior to establishing new white varietal vineyards. Both options were superior to maintaining red varietal production under current price trends.

Food Policies and Programs (Paul A. Gessaman, University of Nebraska, Chairperson)

"The Impact of the Food Stamp Program on Household Food Purchases." Larry E. Salathe (USDA)
A theoretical model indicates the marginal impact of an increase in bonus on food purchases varies with household income. Previous studies have ignored this varying effect, probably resulting in inaccurate estimates. Existing survey data do not contain the information needed to measure more accurately the impact of the Food Stamp Program.

"Food Expenditures and the Food Stamp Program: Some Recent Evidence from the Consumer Expenditure Survey." Donald A. West (Washington State University)
Food expenditure patterns of households are examined using the BLS Consumer Expenditure Diary Survey data. Comparison of allocations of food-at-home expenditures among individual food items shows Food Stamp Program participants buy lower cost foods. Regression analysis indicates that income, home ownership, and food stamps directly affect food expenditures.

"The Nutritional Effectiveness of Three Federal Child Nutrition Programs: United States 1971–74." G. William Hoagland (U.S. Congressional Budget Office)
Data from the National Health and Nutrition Examination Survey (HANES) were analyzed to determine the nutritional effectiveness of three federal child nutrition programs. Breakfast program participants significantly improved their overall nutritional status relative to the control population. School lunch and school milk participants did not show a significant increase in their overall nutritional status.

"Economic Formula Pricing of Milk." Art Smith and Ronald D. Knutson (Texas A&M University)
Economic formulas have been proposed as a means of moving the minimum Class I prices in the Federal Milk Marketing Order system. Developed in this study is a theoretically sound procedure through which economic formulas can be determined that embody equilibrium conditions. Formula evaluation techniques, implementation, and policy implications are discussed.

"Distribution of Social Benefits with Optimal Control of U.S. Wheat Stocks." Won W. Koo and Oscar R. Burt (Montana State University)
A stochastic dynamic programming model was used to develop an economic decision rule on U.S. wheat exports and to evaluate distribution of social benefits. The U.S. wheat storage program gives most benefits to domestic producers, leaving domestic and foreign consumers worse off. An efficiency frontier curve is developed to show a trade-off between price stability and social benefits. It indicates that opportunity cost of price stability is larger than that of social benefits.

Environmental Quality (Stephen D. Reiling, University of Maine, Chairperson)

"Space and the Demand for Environmental Amenities." James Hite (Clemson University)
The amount of space over which an environmental amenity of a given quantity is available can serve as a measure of the quantity of that amenity for purposes of demand analysis. A simple paradigm incorporating that idea is developed and discussed.

"Economic Impact of Coastal Erosion on Shoreland Property and Structures." Waldon R. Kerns (Virginia Polytechnic Institute and State University)
Marginal values for tidal shoreline erosion induced losses to adjacent property and structure values were estimated by relating (*a*) historical erosion rates for individual parcels of property to value of that property and (*b*) changes in distance between structure and shoreline to value of those structures.

"A Low Cost Strategy for Reducing Agricultural Nonpoint Pollution in Lake Erie." D. Lynn Forster (Ohio State University)
A model is developed to simulate changes in net farm income in the Lake Erie Basin under alternative crop management practices. Results indicate that adoption of reduced tillage technologies on appropriate soil series causes little change in net farm income while nearly halving Basin soil loss.

"A Stochastic Methodology for Estimating the Value of Wetlands in Controlling Agricultural Nonpoint Pollution." William M. Park and Sandra S. Batie (Virginia Polytechnic Institute and State University)
Wetlands appear to buffer the effect on nonpoint pollution, smoothing out the time pattern of loading

to receiving waters. A stochastic methodology is required to value appropriately this function where high rates of pollutant loading in short periods of time pose a significant problem.

"Methodological Considerations in Estimating the Economic Value of Marsh and Estuarine Areas to Marine Production Processes." Gary D. Lynne and Patricia Conroy (University of Florida)
A methodology is developed and tested pertaining to a means to measure the economic value of these areas in the production of marketed marine species. The methodology draws heavily on the fish population dynamics modeling efforts. Declines in marsh acreage on Florida's Gulf Coast have caused declines in the marginal and average productivity of fishing effort in the blue crab fishery. The real impact, in a quantitative sense, however, has been small.

Community and Rural Development (C. Edwin Young, ESCS, Chairperson)

"Export Orientation of Nonmanufacturing Businesses in Nonmetropolitan Communities." Stephen M. Smith (University of Idaho)
Community characteristics—distance from nearest SMSA; size of local economic base—were most important in determining export orientation of nonmanufacturing businesses. Export level was also directly related to total firm expenditures, percentage of total spent nonlocally, and percentage of nonlocal ownership. Firm organization and business type were further distinguishing factors.

"The Effect of Intergovernmental Grants on Local Government Spending and Production Decisions: A Preliminary Econometric Model." John F. Savage and Bruce A. Weber (Oregon State University)
OLS regression results from a theoretically based model of county spending indicate that mental health (MH) grants stimulate MH spending. 3 SLS regression estimates of a simultaneous MH wage-labor-output model indicate that grants stimulate MH employment, wages are not endogenous, and production relationships need better specification.

"An Operational Extension of the Leontief Dynamic Input-Output Model." Thomas G. Johnson and Frederick W. Obermiller (Oregon State University)
Although conceptually superior to its static counterpart, the dynamic input-output model has failed to achieve popularity due to its virtual inoperability. Key extensions to the Leontief dynamic model facilitate specification using numerical and simulation techniques. The extended model's operability and capabilities are demonstrated using county-level data.

"Local Government Employment Trends: Some Perspectives on Growth and Tax Revolts." Leon B. Perkinson (ESCS, North Carolina State University)
Between 1957 and 1977, local government employment expanded rapidly relative to population but increased only slightly faster than real personal income. Since individual consumption of public services does not affect the individual's tax bill, decreasing consumption in response to falling real income does not directly reduce tax bills. This might lead to tax "revolts."

"Unemployment Insurance and Agricultural Labor Supply." Robert D. Emerson and Gustavo J. Arcia (University of Florida)
Long-run adjustments in labor supply resulting from the recent inclusion of farm workers under the Unemployment Insurance program are estimated in this paper. The adjustments to the revised work incentives are done on the basis of income and substitution effects evaluated from an estimated labor supply equation. The estimated adjustments are substantial, resulting in a 25% reduction in labor supply, *ceteris paribus*.

Inflation and Prices (Hal W. Everett, University of Illinois, Chairperson)

"Inflation Control through Commodity Supply Regulation." R. McFall Lamm, Jr. (ESCS)
The basic purpose of agricultural policy has been to redistribute income to producers and to stabilize farm prices. This paper suggests that agricultural policy also be used to control food price inflation. The results would be internal consistency between macroeconomic and agricultural policies and a decrease in total welfare loss.

"Inflation and U.S. Agriculture: A General Equilibrium Analysis of the Events of 1973." Shun-Yi Shei (Academia Sinica, Nankang, Taipei, Republic of China) and Robert L. Thompson (Purdue University)
An open general equilibrium econometric model of the U.S. economy, including a monetary sector, is used to decompose observed 1973 sectoral and aggregate price increases. In decreasing order the major causes found were U.S. monetary expansion, the Soviet grain deal, dollar devaluation, and the world crop failure.

"Macroeconomic Impacts of the 1979 Feed Grain Set-Aside Program." Joseph M. Roop (ESCS), Thomas M. Bell (University of Illinois), and Lloyd D. Teigen (Michigan State University)
The acreage response to the 1979 feed grain set-aside program is translated into prices and quantities for the major commodities via impact multipliers derived from USDA's Cross-Commodity Forecasting System. The prices and quantities are then translated into measures of agricultural aggregates such as cash receipts, farm income, and retail food prices.

"The Interrelationship of a Pesticide Regulation to Target Prices: A Multiple Policy Approach to Pest

Management." Reuben Weisz, Mike Lancaster, and Bill Quinby (ESCS)
Federal pesticide policies contradict and compliment other agricultural policies in ways that need to be explicitly recognized if a comprehensive evaluation of a pesticide policy is to be conducted. This paper presents a first attempt at this type of analysis.

"The Sensitivity of U.S. Wheat and Coarse Grain Exports and Prices to Alternative Yield Scenarios: A Forecast to 1981." Donald O. Mitchell and David R. Armstrong (Michigan State University)
The Michigan State University Agricultural Model is used to forecast U.S. wheat and coarse grain exports, prices, and stock levels for 1979, 1980, and 1981. Trend yield levels are assumed in the base simulation. The sensitivity of this assumption is examined by imposing yield decreases in the United States and Soviet Bloc.

Editor's note:

Award-Winning Theses

Chavas, Jean-Paul. "A Quarterly Econometric Model of the U.S. Poultry and Egg Industry." Ph.D. thesis, University of Missouri, 1979.

The current world food problem and the recently experienced variability in domestic food prices have raised a number of forecasting and policy issues for the U.S. agricultural sector. One approach to the development of improved policies and forecasts involves an attempt to obtain better model representations of the agricultural sector. The present study addresses this problem by developing a model of the U.S. poultry and egg industry.

The industry-oriented objectives of the modeling exercise are to elucidate the various interrelationships that exist among major factors influencing the price determination in this subsector and to develop a quantitative procedure for generating forecasts. The more general objectives are to illustrate a modeling approach which would appear to have potential for improving the performance of large scale econometric models. The approach emphasizes the fact that the model is an approximation to the true economic system. The model specification is linear in the variables, allowing analytical investigation of its dynamic properties.

The production components of the model are structured to take advantage of technical information provided by industry specialists. As the model relies on quarterly observation, inventory fluctuations may have substantial impacts on price and consumption. The stocks equations are specified using specialized results obtained from a theoretical model emphasizing speculative and convenience motives for holding inventories. The consumption components of the model use price dependent mix-demand functions. Also, it was found that the wholesale price leads both farm and retail prices of eggs, broilers, and turkeys. For this reason, all the dynamic properties of the model rely on wholesale prices.

As the model is an approximation of a highly complex economic system, it is important to specify the model so that it can be revised continually to comply with information contained in most recent observations. For this purpose, the Kalman filter is used to update selected equations of the model. Results suggest that the Kalman filter is a potentially powerful tool for handling problems of structural change and updating in large-scale econometric models.

Mittelhammer, Ronald Carl. "The Estimation of Domestic Demand for Salad Vegetables Using A Priori Information." Ph.D. thesis, Washington State University, 1978.

The main objective of this dissertation is the econometric estimation of annual aggregate domestic demand schedules for fresh vegetables both at the retail level and at the derived farm level. A secondary objective is to examine the empirical behavior and assess the usefulness of a technique called mixed statistical estimation which allows the incorporation of linear probabilistic constraints on the parameters of an econometric model in the statistical estimation of the model.

The relations were estimated using sample information for the years 1954 through 1975 together with prior information derived from various sources including neoclassical demand theory, previous studies, and subjective beliefs.

The demands for the various salad vegetables were characterized by inelastic responses of quantities demanded to changes in vegetable prices both at the retail level and at the derived farm level. Many significant substitute and complementary relationships were identified between the various salad vegetables. The income elasticities of quantities demanded with respect to changes in disposable income were in the inelastic range at both the retail and derived farm levels. The total elasticities of price transmission representing the percentage changes in retail prices that occur due to percentage changes in farm values were all in the inelastic range.

The mixed estimation technique resulted in parameter estimates that were found to be more precise than estimates not using prior information. The estimated reductions in variances were substantial in the case of the retail demand equations, where the prior information was more precise than the sample information. The estimated reductions in variances were less substantial in the case of the margin relations, where the sample information was generally more precise than the prior information.

Sharp, Basil M. H. "The Economics of Managing Water Quality: A Multiobjective Analysis of Alternative Policies." Ph.D. thesis, University of Wisconsin, 1978.

In this thesis a methodology is developed for analyzing the economics of institutional alternatives designed to improve regional water quality. A multiperiod model was used to generate trade-offs between two noncommensurate objectives: water quality and net present value. The hierarchical structure of the model facilitated a synthesis of socioeconomic and ecological processes. In particular, the first level consisted of the following three submodels: a module that determines the level of dissolved oxygen; a pulp and paper firm

that represents a point source of pollution; and an agricultural firm that represents a nonpoint source of pollution. The institutional component of the model comprised the second level of the hierarchy and it was here that the firms' incentive structure was perturbed according to the specific abatement program invoked.

The model was used to illustrate the pivotal position that institutions occupy during the analysis, synthesis, and implementation of policy alternatives. Each pollution abatement program was made up of various combinations and levels of educational and technical assistance, cost sharing, low interest loans, and regulation. Ten alternative programs were analyzed with respect to their impact on the two criterion functions and their effect on distribution. The slope and the location of the trade-off surface, and the distribution of net present value and assimilative capacity was shown to be dependent upon the institutional arrangements used to implement policy. By recognizing the status quo, programs can be designed that are amenable to the specific economic entities involved, and at a minimum social cost.

AAEA Business

Committee Reports

Report of the President

It has been an honor and a privilege to serve as president of our Association. It has been a learning experience and a rare opportunity to become acquainted with a broad cross-section of our membership. There is a wonderful reservoir of good will toward the Association. The willingness of members to serve and assist in carrying out the work of AAEA is one of our important assets. In our efforts each year to document what has been done by the Board and the committee structure, how much we own, and how well we fared financially, we should not forget or neglect the good spirit and sense of responsibility which has been fostered among our members. Let me start this report by paying special tribute to our membership for expressing their opinions in all their diversity and for keeping their professional association vibrant and alive.

Our membership roll of individuals and library subscribers has numbered more than 6,000 for the past two years and should surpass that total again in 1979. Our membership committee, chaired by Gene Mathia is active. A new, blue brochure to solicit members has been developed by Bob Rauniker. All of us can assist by encouraging our colleagues and associates to participate in the Association through membership and volunteering to work on a committee or some activity.

There are at least three key ways a large number of members participate: (*a*) as members of Association committees, (*b*) as participants in the summer or winter meeting programs, and (*c*) as authors and reviewers of papers considered for publication in the *Journal*. My quick count indicates more than 250 members serve on AAEA committees currently with a little more than one-third of the members of these committees changing each year. I appointed more than 100 different individuals to committee assignments this year. They came from 49 states and a wide range of institutions and agencies. In addition, there are more than 300 people involved as chairmen, speakers, discussion leaders, and organizers for this year's summer meeting program. Editor Rhodes will shortly report receipt of over 300 manuscripts that were considered for publication and the involvement of almost 400 reviewers during the past year. Recognizing that there are some members who participated in more than one of these three categories, there are still enough joint authors to insure at least 1,000 different members have been involved in important ways in some aspect of AAEA activities this year. We can all take pride in this achievement and seek to insure that more of our members find ways to participate in the future.

One of the major accomplishments of 1978–79 was the publication of the *AAEA Newsletter*. The first four editions came out on schedule. Editor Rhodes has developed an interesting and readable sixteen-page format. Suggestions for content from the membership are encouraged. Jim Rhodes and his staff deserve our praise and thanks for making this new enterprise and service to members an instant success.

President Farrell appointed a special committee on management, structure, methods, and procedures in March 1977. Its chairman, W. Burt Sundquist, presented a final report to the Board in January 1979. One of its elements was a summary of a comprehensive survey concerning AAEA operations obtained from all officers and committee members who have served since 1970. This substantial effort was completed by a subcommittee chaired by Ludwig Eisgruber. In its final report the committee made the following points strongly reinforced by the survey:

(*a*) The effectiveness of AAEA operations has improved significantly in recent years, in part because specific responsibilities have been assigned to individual members of the Executive Board.

(*b*) The planning functions of the Board and the management of financial operations have been given high priority and are well received by members.

(*c*) Despite the lack of formal position descriptions and committee assignments, most office holders and committee members felt they had been given rather clear assignments and responsibilities.

(*d*) The need for strong and effective leadership by committee chairmen is recognized as the key to committee output and performance.

(*e*) There is a strong desire to keep policy decisions and Association activities retained in the hands of a broad base of Association members. Overall, the Sundquist committee found a positive response to the ways in which members have been involved in Association affairs.

The committee concluded its report, which will be published in the December *Journal*, with four major recommendations. Briefly, they are:

(*a*) the continuation and strengthening of the practice of assigning specific responsibilities to individual members of the Executive Board to design, monitor, and manage the activities of the Association;

(*b*) the establishment of a task force to develop operational position descriptions for the President-Elect, President, and Immediate Past President (a key objective is to spread their workloads more evenly over the years);

(*c*) the establishment of a small working task

force to consider and design an operational data base for use in management and programming activities of the Association;

(*d*) appointment of a task force to plan the establishment of an executive office for the Association to be operational no later than 1983 and to be located in either Washington, D.C., or Chicago.

The Board accepted the first three recommendations at its January 1979 meeting and task forces on position descriptions for the office of president and the development of an operational data base for the Association were appointed, chaired, respectively, by former presidents Jim Hildreth and Ken Farrell. The Board is proceeding more slowly on the fourth recommendation. An ad hoc committee chaired by John Stovall is collecting additional information on expected costs and benefits that might be associated with establishing an executive office for the Association and other alternative ways of carrying out the management functions of the Association. No action has been taken as yet on this recommendation. It is hoped that a limited set of alternatives will be budgeted and available for review at the December 1979 meeting of the Board. The membership will be involved in any major decision on the location and operation of our Association's office.

Much of the work of the Association is done through individual enterprises managed in part by Association committees. Good work is too often taken for granted. When things go well it takes very little of the Board's time. Members are apt to assume it all happens naturally.

The *Journal* is generally viewed as the Association's most important activity. We have been well served by our editors, past and present. The quality of the publication must be a reflection of what our members write as well as the decisions of the editors and their reviewers. Editors Rhodes, Johnson, and Stoevener have maintained high standards and a diverse, readable publication.

The Registry of Agricultural Economics is now an established enterprise operated under a memorandum of agreement with the Illinois State Employment Service. The credit for the overall success of this enterprise goes to many people. Particular mention should go to Loys Mather and Steve Harsh who have worked with this project from its inception. All of us should be sure that our names are included in the Registry. We should encourage students to use this service. Allen Johnson serves as chairman of Professional Registries and Employment Committee.

The Literature Retrieval Committee supervises the work of a joint enterprise between ESCS and AAEA, the American Agricultural Economics Documentation Center. It is located on the first floor of the building where ESCS is housed in Washington, D.C. AAEA's contribution of $17,000 a year covers about 30% of the cash costs of operating the Center. The computerized search system works well. If you have not used it you should. Someone at every location where agricultural economics literature is produced should be designated to send periodically publications to the Documentation Center. That will insure that important publications are reviewed and cited in the AGRICOLA system. If you are not familiar with the system visit Cynthia Kenyon's demonstration while you are here and discover first hand how the system works.

One of the important association activities each year culminates in the annual awards program. It involves many people both in the preparation and documentation of the nominating materials, and then the selection process itself. This program seeks to recognize excellence. One of its important components is the nomination process, which provides initial recognition for individuals and their work in their own organizations. The selection process necessarily is subjective, but good work is identified and we express our continuing thanks to the many involved, including the general awards chairman, Dan Padberg.

The annual meeting program is another major enterprise of the Association. For the past two years the Board has served as a program committee spending one full day in the fall concentrating on program topics, format, and establishing the invited paper sessions. President-elect King and I served as the selection committee to choose the organized symposia from among those proposed. The contributed paper sessions were established by a committee of seventeen members co-chaired by Lee Schrader and T. Kelley White. The papers for the twenty sessions at this meeting were selected from the 213 papers offered for review. The work of this committee deserves special commendation.

The International Committee has been particularly active in carrying out an AID-funded project, "Needs and Strategies for Improving Training of Agricultural Economists for Work in International Agricultural Development." This is a follow-up to a study conducted five years earlier by AAEA's International Committee. Darrell Fienup has taken major responsibility for the conduct of the study with the active assistance of a number of committee members. Preliminary results were discussed in a workshop in June at Michigan State University. Results will be discussed here in an organized symposium to be conducted by committee chairman, Harold Riley, and at IAAE in Canada in September.

Any brief review of Association activities during the span of a year is sure to leave out some of the important happenings. At least half of the active committees have gone unmentioned but their work is appreciated. We are especially indebted to the ad hoc committee chaired by Larry Connor which organized and conducted the member survey on whether or not AAEA should join CAST. The work of the Finance Committee is especially important both to the Board and the Association. Their continuing hard work is reflected in the results you see in our operating statement, balance sheet, and budget. John Redman's careful work is reflected in

these statements. Collectively they have served all of us very well.

In closing, I would like to pay special tribute to the outlook and atmosphere created by the Presidents of the Association during my years on the Board. Jim Nielson, Jim Bonnen, Ken Farrell, and Jim Hildreth have provided an important legacy to all who follow them. They all sought to involve a broad spectrum of the membership in Association affairs. They sought to run an open program, to insure that our members' diversity was properly represented in committees, in programs, and in Association activities. One of the reasons most of us feel good about AAEA is because these men worked so effectively to create good will and develop both cooperation and intellectual interchange.

Best wishes to Dick Crowder and Sylvia Lane, who leave the Board after three years of excellent service. They sought to instil a sense of discipline combined with good humor in our meetings and they succeeded.

The continuing challenge for all of us in the Association is to foster creativity and maintain a spirit of good will while encouraging new ways to serve member needs and interests. That requires members to ask hard questions and propose new activities while keeping our current programs lively. I am sure you will find ways to do it.

B. F. Stanton, President

Resolution

Whereas the American Agricultural Economics Association depends for its success on the selfless contributions of individuals and institutions, and

Whereas Washington State University and individuals associated with it have graciously hosted the joint annual meeting of the American Agricultural Economics Association and the Western Agricultural Economics Association;

Therefore be it resolved that the American Agricultural Economics Association express its deep appreciation to President Glenn Terrell and Vice-president Wallis Beasley of Washington State University; Ralph Loomis, Conference Coordinator; LeRoy Rogers, Chairman of the Department of Agricultural Economics; chairpersons and members of local arrangements committees; and the faculty members and families of the Department of Agricultural Economics for their hospitality and hard work which made this annual meeting a rewarding professional and social experience.

Be it further resolved that a copy of this Resolution be sent to President Terrell, Vice-president Beasley, Professors Loomis and Rogers, to each of the local arrangements committees, and to other persons as appropriate.

Report of the Secretary-Treasurer

The AAEA membership for 1978 declined slightly from the all time high of 1977 (table 1). The decline would have been greater had it not been for the policy on charging a differential registration fee for the meeting at Virginia Polytechnic Institute and State University. The decisions to charge a differential registration fee, to invite only members to serve on committees and give papers at the annual meeting, to give discounts on books, to be listed in the *Handbook-Directory*, etc., have given a big boost to the membership effort and, consequently, to the financial well-being of the Association.

Table 4. USDL Operating Statement, 31 December 1978, with Comparisons

Item	1973	1974	1975	1976	1977	1978
	($)					
Beginning balance	0	25,100	7,434	8,844	−753	−15,003
Amount received	37,500	32,000	49,500	22,000	15,000	0
Expenses	12,400	49,666	48,090	31,597	29,250	4,739
Ending balance	25,100	7,434	8,844	−753	−15,003	−19,742

activity. With this in mind, only about $50,000 can be thought of as a "normal" gain in comparison to previous years. Included in the $88,895 is a capital gain of $21,121 realized from the sale of 600 shares of stock in Clark Equipment and about $17,000 resulting from having paid for one fewer issues of the *Journal*. The royalty income tripled because of the $3,458 received from sales of the Literature Review. Subscription income increased by about $7,000, page charges by nearly $5,000, and investment income by about $4,470. The $2,000 annual meeting income was the payment of the $2,000 advance made for the annual meeting and is offset by $2,000 on the expense side. The miscellaneous income of $2,643 consisted of $43 in exchange allowances not offset by charges, a $100 gift, and a $2,500 grant from Kellogg Foundation for financing our Kellogg Lecture.

Expenses ran about as expected. We always watch and question every expenditure. Only four issues of the *Journal* (December 1977, February 1978, May 1978, and August 1978) were billed during the year. The bills for November 1978 and December 1978 issues were received and paid in 1979. The Literature Review expenses increased but were mostly offset by income. Office supplies and printing increased because the inventories had to be replenished. The annual meeting expense consisted of $3,000 in advances to Virginia Polytechnic Institute and State University and Washington State University. The miscellaneous item included $11,500 for our word processor, $500 for refunds already recorded as income, $1,087 for exchange charges, $46 for copyright fees, and $250 for dues for the statistics users group.

The cost of secretarial assistance came out better than I really anticipated. During the year, I had considerable secretarial problems which meant that at times I had three people and at times only one. This also meant that I had to do more of the routine work personally.

The National Registry project funded by a USDL grant increased the year end deficit to $19,742 as we received no additional payment during the year and spent $4,739 (table 4). However, we did receive $15,000 in 1979, and the balance will be forthcoming upon completion of the final report. When completed, this project should close with zero balance and any additional funding will be a part of the regular budget.

Net worth (at cost)	127,644	105,415	90,159	107,509	156,126	245,021
Net worth (at market value)	207,979	139,296	146,917	207,447	229,616	290,348
Total liabilities (at market value)	291,091	209,100	235,746	267,415	288,161	359,900
Total liabilities	210,757	175,219	178,988	167,477	214,671	314,573

In accordance with the policy established in 1973, the income-expense statement for editorial support as provided by the Editor is incorporated as a part of this report (table 5). It showed a deficit of $1,241.

The balance sheet for AAEA showed again considerable improvement (table 6). Our assets are carried on the books at cost. However, in previous balance sheets I showed the market value of the assets at the end of the year, so one could calculate the net worth at market value if desired. This time at the request of the Finance Committee, I included such calculations in the table. One must be more careful now in selecting the addends to arrive at the total desired. One additional comment on the balance sheet is that we are getting increasing amounts of prepaid dues and subscriptions.

In summary, the Association continues to be healthy and active. Inflation will continue to be a problem for sometime to come but the increasing pressure to provide more and more service from my office is the most immediate problem.

John C. Redman, secretary-treasurer

Investment Report

The portfolio, which went through considerable change during 1978, produced an income of $16,778. All assets carried on the books at cost of $290,212 had a market value of $335,539 at the end of the year (table 1). However, a large part consisted of near cash amounting to $111,214. We sold Clark Equipment at a nice gain over cost and purchased additional shares in American Cyanamid and Borden (table 2). We added CIT Financial and Santa Fe Industries. Also, we entered the bond market (table 3). The Finance Committee felt that debt issues, because of high interest rates, should have an important place in the AAEA portfolio. Presently, we are using our broker's ready asset account heavily to earn a high rate of return on funds not invested or not needed for immediate bills.

The portfolio subcommittee, consisting of Mike Boehlje, John Brake, and myself, has been rather active in trying to manage the portfolio well. Much gratitude is due Mike for his contributions, as he remained on the committee an extra year.

John C. Redman

Comm. Credit Corp. 8⅞% 86 RG[b]	10,165	444	0	9,192
Federal Land Bank 7.3% 82[c]	19,838	730	0	18,500
Total	49,632	1,937	0	46,092

[a] Purchased 20,000 @ $96 + $428.61 = $19,628.61 on 8-23-78.
[b] Purchased 10,000 @ $101.5 + $14.79 = $10,164.79 on 3-07-78.
[c] Purchased 10,000 @ $96.5 + $251.44 = $9,901.44 on 8-24-78; purchased 10,000 @ $96.875 + $249.42 = $9,936.92 on 8-23-78.

Report of Tellers Committee

Ballots received from the secretary-treasurer of the AAEA were counted in accordance with the bylaws of the Association to preserve secrecy. Candidates receiving the largest number of votes were: Luther Tweeten for President-elect, Neil E. Harl and Carleton C. Dennis for directors.

Lynn W. Robbins
Joe T. Davis

Report of the Editor

A total of 307 new manuscripts were submitted 1978–79, compared to 269 the previous year. We accepted 33 articles and 61 notes, making an acceptance rate of 31%. These numbers are consistent with those of the 1970s. We expect to publish 55 Proceedings papers.

The average elapsed time between submission and publication of the articles published last year was 12.3 months. The publication process requires about four months; the remainder of the time is spent in review, author revision, and (occasionally) in a short queue prior to publication.

We have assisted in the renegotiation of the three-year printing contract and in committee deliberations concerning the new copyright law.

The Proceedings of the Economic Research Conference on U.S. Food System Regulation are being published as Part II of the November *Journal*. The editorial work and the publication costs are being provided by the Economics, Statistics, and Cooperatives Service of the USDA. Mrs. Victoria Smith and Dr. William Boehm are the special editors for that Proceedings.

Our newest venture, the *AAEA Newsletter*, has gone smoothly. We are disappointed that members have failed to take advantage of the "Viewpoints" section. We assume that use of the employment and bulletin board sections will increase as members' familiarity with them grows. AAEA committees can learn to use this communication avenue with the profession. We solicit suggestions for improvements.

We are pleased to acknowledge the extremely important assistance of many reviewers (listed below).

I would like to thank my associates for their hard work so essential to this enterprise. Stan Johnson as Associate Editor makes an immense contribution to the *Journal*. Herb Stoevener, as Book Review Editor, puts many hours into the Book Reviews. Marti Luzader, assistant editor, and Donna Taylor, secretary and recordkeeper, do all the detail work so necessary to publishing both the *Journal* and the *Newsletter*. By their efforts many authors have been rescued from convoluted sentences, dangling modifiers, and split infinitives. The people at Heffernan Press have performed their tasks efficiently and punctually. Finally, we thank the editorial council (inside front cover) for their efforts and support.

Daniel I. Padberg, chairman

Report of the AAEA Committee on Management, Structure, Methods, and Procedures

Our Committee was given an assignment by AAEA President Kenneth Farrell[1] with three principal objectives: (*a*) to review the management, structure, methods, and procedures of the Association and then to make recommendations to enhance the quality of service to members and the efficiency and operations of the Association; (*b*) to examine the feasibility of establishing an AAEA Executive Office for Program Management; and (*c*) to review the performance of the Secretary-Treasurer during the past three to five years. The latter review is in keeping with the operating procedures prescribed for the Executive Board of the Association at the Edmonton, Alberta, meetings in August 1973.

Consistent with our charge from President Farrell, we did not consider it the assignment of our committee to set priorities for activities in which the Association should be engaged, but rather to suggest procedures for improving the efficiency and management of the Association's operations. In addition to the inquiry and analysis conducted by individual committee members, a major survey of past officers and committee chairpersons of the Association was conducted under the leadership of Eisgruber. ("AAEA Survey on Management, Structure, Methods and Procedures," prepared by Ludwig M. Eisgruber, December 1978, 78 pages.)

Effectiveness of Current AAEA Operations

One perspective which came through rather clearly in response to the committee's inquiry (particularly from current and past Association officers) is that the effectiveness of AAEA operations has improved significantly in recent years. This improvement appears to be, at least in part, the result of assigning specific responsibilities to individual members of the Association's executive board. Particularly mentioned were improvements in the planning functions of the executive board and in the management of the Association's financial operations. Despite the almost complete absence of any "job descriptions" for officers of the Association, and to a major degree for committees of the Association, most Association office holders and committee members felt they had been given a rather clear charge in their assignment for the Association. As-

[1] Members appointed to this Committee on March 29, 1977, by then AAEA President Kenneth Farrell include: Wallace Barr, Richard Crowder, Ludwig Eisgruber, Olan Forker, Neil Harl, Leo Polopolus, John Stovall, and W. Burt Sundquist, Chairman. A more detailed Committee report was presented to the Executive Board of the AAEA in January 1979. That report included four detailed appendices relating to: (*a*) President Farrell's charge to the Committee and the procedures followed by the Committee in conducting its assignment, (*b*) a performance evaluation of the office of the Secretary-Treasurer, (*c*) a summary of the procedures and results from a major survey of past Association officers and committee chairpersons, and (*d*) evaluation of possible alternatives for an AAEA Executive Office.

sessment of the effectiveness with which these charges were implemented, however, varies considerably. The effectiveness of committee chairpersons in moving ahead with the committee's assignment appeared the most frequently mentioned of the key variables affecting committee performance. If the committee chairperson was well organized and aggressive, committee members were generally pleased with the ability of their committee to execute effectively their responsibilities. If the chairperson was not aggressive and effective, committee performance was less than satisfactory.

With respect to the adequacy of support provided to the Association's officers and committees, officers of the Association were generally satisfied with the financial support rendered to their activities by the Association while only a few members of committees felt that Association support was inadequate. The latter is probably not surprising, given the large number of Association committees in operation (33 in 1977).

Members of the Association appeared generally well pleased with the adequacy of membership representation on Association committees and on the executive board. Some dissatisfaction was expressed, however, relative to the adequacy of representation of "industry" members in the decision-making process and programming of the Association. Clearly, a large proportion of the Association membership is involved in Association activities including the planning and operations phases of those activities. Also, a major portion of the costs of managing and operating the Association is absorbed by the organizations and institutions who are employers of these Association members. During the period of tenure in office of the editor of the Association's *Journal,* the Association's secretary-treasurer, and the members of the Association's executive board (particularly the president), the employers of these office holders absorb heavy costs, particularly via subsidization of professional salaries.

Our inquiry indicated that much of the Association's viability is judged to rest upon an enthusiastic and active membership. Thus, a number of respondents indicated that their reaction to any change in Association organization and/or management rests importantly on the extent to which policy decisions and Association activities could still be retained in the hands of a broad base of Association members. Any significant increase in membership dues to finance an executive office for the Association was viewed with a good deal of disfavor by the majority of Association members surveyed.

Frequently mentioned by past and current Association officers was the judgment that effective operation and management of several Association activities (including membership recruitment and retention, professional employment, publication of *Handbook-Directory* materials, special professional training programs and workshops, appointments to committees and task forces, etc.) are highly dependent on an accessible up-to-date data base of Association members and new entrants to the profession together with at least some key informational items on individual members. Neither the current employment registry nor the current membership list kept by the office of the secretary-treasurer provides both the required accessibility and completeness of data base coverage. Moreover, this data base and other key information for decision making needs to be more effectively transferred than it currently is from retiring officers, Board members, and committee chairpersons to their replacements in these positions.

A final item of importance mentioned by several past presidents of the Association was that the workload currently assumed by the president of the Association during his (her) one-year term of office is excessive. The heavy workload of this office plus the current distribution of responsibilities on the executive board probably discourages and may even preclude adequate attention to important policy issues and innovative programming for the Association.

Evaluation of Secretary-Treasurer

The incumbent Association Secretary-Treasurer, Dr. John C. Redman, assumed his current office in the Association in January 1970. He has performed strongly and with a high degree of personal dedication. Clearly, the Secretary-Treasurer and his office staff have conscientiously carried a heavy workload for the Association with a high degree of cost effectiveness. Our recommendation to the executive board at the summer, 1978, Association meetings was (*a*) for renewal of an additional three-year term in office for the incumbent Secretary-Treasurer and (*b*) for an expression of appreciation for dedicated and high quality performance to the Secretary-Treasurer and his staff. In addition, we outlined several issues of the secretary-treasurer's office needing attention by the executive board. These relate to office equipment, staff benefits, needed liaison with other offices, development of more formalized position descriptions, and operating guidelines for the office.

Recommendations of the Committee

The Committee is cognizant of its advisory role. Thus, the four recommendations which follow are presented for consideration by the executive board of the Association. Further, we assume that any broad based changes in Association organization and structure, such as that outlined in the fourth recommendation (*d*), should have discussion by and approval of the Association's membership prior to implementation. With these caveats in place, and with knowledge that a task force is already working

on the development of operating guidelines for the office of the secretary-treasurer, we recommend the following:

(*a*) The continuation of and strengthening of the current practice of assigning specific responsibilities to individual members of the executive board of the Association to design, monitor, and manage the programmatic, financial, and administrative activities of the Association. Appropriate mechanisms for "accountability" should be developed and implemented for Board members and committee chairpersons.

(*b*) Immediate establishment of a task force consisting of the Association's immediate past president, and the president-elect, augmented by not more than two additional members to develop operational position descriptions for the Association's president-elect, president, and immediate past president. A key objective should be to outline a three-year sequence of responsibilities which spreads more evenly the workload of the Association's presidency and permits more effective attention to policy planning and to innovative programming. Such an allocation (or reallocation) of responsibilities may require the shifting of some part of the routine workload of program planning and management to other members of the executive board of the Association.

(*c*) Immediate establishment of a small working task force to specify an operational data base for use in management and programming activities of the Association and to plan for its operational implementation. We recommend that the Association's secretary-treasurer, membership committee chairman, and a representative of the employment registry be named as ex-officio members of this task force. Regular task force membership should include employer users of such a data base, a past president who has dealt with the committee selection task, and someone with operational computer capability. The task force should have an operational plan developed within a twelve-month period after appointment. This plan should be based on a thorough consideration of data needs for management and programming of the Association's activities and on the use of up-to-date data processing technology which insures ease of accessibility and effective maintenance of the data base. Recommendations (*a*) through (*c*) need to be put into effect and can be implemented by the executive board without deliberation by the general membership of the Association.

(*d*) Immediate appointment of a task force consisting of both current members of the Association's executive board and other Association members to plan the establishment of an executive office for the Association to be operational by no later than 1983 and to be located in either Washington, D.C., or Chicago.[2] At a minimum, this office should consolidate the current responsibilities and activities of the Association's secretary-treasurer with those of operation of a modernized data base for the Association's programming and management activities. Strong consideration should also be given to establishing effective linkages between this office and the employment related services sponsored by the Association. So as to maintain the broad policy and program-planning activities in the hands of Association members, we suggest the office be called "The Office of AAEA Program Support" and that the manager of this office be titled, "Director, Office of AAEA Program Support." Effective liaison should be established between this task force and the one specifying an operational data base.

In arriving at the fourth recommendation (*d*), we are cognizant of two somewhat conflicting interests. First, the vitality of our current Association is based heavily on the involvement in Association offices, committees, and general Association affairs of a large number of members who give generously, and with dedication, of their time and energies. We feel the need to retain this broad based interest and involvement of the membership and to avoid excessive increases in the cost of Association membership. On the other hand, we feel that some individuals and institutions must currently subsidize the Association's program and membership beyond reasonable and sustainable levels. And, certain dimensions of program planning and management probably can be upgraded only through a more centralized administrative operation. We believe that a centralized administrative office can be established to expand and improve services to Association members without prohibitive costs to individual members and with the retention of policy and program decisions by a broad base of Association members. But, the Association's membership should make the final judgment in choosing from well-defined alternatives.

Finally, we believe that transition to an executive administrative office for the Association within a time frame of 1981–83 will permit effective advance development of a computerized data base for programming and management of Association activities and a plan for consolidation of administrative services, and for phasing out existing staffing and phasing in the new staff.

W. Burt Sundquist, chairman

Report of the Ad Hoc Committee on AAEA Membership in CAST

The issue of AAEA membership in CAST has been a recurring one. In 1975, a committee consisting of

[2] This recommendation did not have the unanimous agreement of our Committee. We include it here, however, with the hope that it will provide the impetus for fleshing out a set of alternatives for effective future management of the Association's business operations.

Brandow, Castle, and Toussaint submitted a comprehensive report to the AAEA Board (*Amer. J. Agr. Econ.* 57(1975):1003–7). Their recommendation against joining CAST was accepted by the Board. The issue was again considered by an ad hoc committee consisting of Farrell and Schuh in 1978. The Board approved the recommendations that action be taken to discern from the membership whether or not it wished AAEA to join CAST. The President was directed to form a committee to develop a statement reviewing the advantages and disadvantages of joining CAST so that the members could make an informed decision.

In September 1978, President Stanton authorized an ad hoc committee to pursue this issue as "the committee deemed appropriate." The composition of the committee included AAEA members who had served on past CAST task forces, one who is on the board of directors of CAST, and another member who had had no association with CAST. The committee subsequently met to review previ-

Results of the AAEA Membership Survey on CAST

The results from the membership survey are shown in tables 1 through 4. Eight hundred and eighty-five members responded (a 20% response). More than half of the respondents were from universities, approximately one-fifth were from government, and the remainder were from industry, other occupations, or there was no categorization indicated. The results indicated that 50.4% of the respondents thought AAEA should not associate with CAST, 36.9% were in favor of association, 11.2% were undecided, and no response was indicated from 1.5% (table 1). Industrial and other occupational specialities indicated a majority as favoring associating with CAST, whereas university, government, and those who did not identify their employment category predominately were against associating (table 1). Graduate students were the only age experience category indicating a favorable response to AAEA membership in CAST (table 2).

Table 3. Rank Ordering of Reasons Cited for AAEA Joining CAST

Reasons Cited	Rank Ordering (1st or 2nd) 1	2	Not Cited
	------ (No.) ------		
A substantial number of agricultural professional societies are members of CAST.	6	13	165
A substantial number of agricultural economists have been and continue to be included on CAST task forces.	14	25	132
CAST provides an important vehicle for multidisciplinary interaction on policy issues.	169	80	18
CAST establishes a closer connection between agricultural sciences and current, public decision making.	93	120	44
CAST can respond to current policy issues more quickly than such groups as the National Academy of Sciences.	18	47	126
CAST has had an important impact on some policy issues.	6	15	183
Other.	13	2	299

Table 4. Rank Ordering of Reasons Cited for AAEA Not Joining CAST

Reasons Cited	Rank Ordering (1st or 2nd) 1	2	Not Cited
	------ (No.) ------		
AAEA should not be associated with possible implicit or explicit policy positions of CAST.	221	80	75
Industry financial support of CAST or participation on CAST task forces influences its objectivity.	55	96	184
The annual AAEA membership fee is excessive.	15	30	300
CAST membership may endanger AAEA's tax-exempt status.	8	23	304
CAST's operating procedures on task force authorization and composition, and press relationships are unsatisfactory.	37	61	248
CAST has had an insignificant impact on policy issues.	19	24	316
Other.	55	21	325

that they were still not sufficiently acquainted with CAST and its role and purposes, and 35.4% indicated that while they were sufficiently acquainted with CAST, they did not have strong feelings about AAEA membership in CAST.

Recommendations

The results of the survey indicate that a slight majority of the member respondents are opposed to joining CAST, and slightly more than a third of the member respondents are in favor of joining it. The results of the survey may be subjected to various interpretations. The committee made every effort to be objective and fair in preparing the questionnaire and materials for mailing. Nevertheless, the committee was criticized for "biasing" the survey against AAEA membership in CAST. The committee also was criticized for not being "hard enough" on CAST and explaining more of the controversies surrounding CAST. It is the judgment of the committee that the negative percentage indicated from the survey probably represents a lower bound inasmuch as CAST has come under increasing scrutiny since the mailing materials were prepared and approved by the AAEA Board in January 1979.

It is the recommendation of the committee, based on the results of the survey, that the American Agricultural Economics Association not become a society member of the Council for Agricultural Science and Technology. Currently, the President of the Association provides CAST, on request, a list of agricultural economists who might make a contribution to the efforts of a particular task force. Participation on the task force is at the discretion of the individual member. The committee recommends the continuation of this practice.

Larry J. Connor, chairman

Appendix

American Agricultural Economics Association Membership Survey—AAEA Membership in Council for Agricultural Science and Technology

1. At the cost of $1.00 per member, do you believe that the American Agricultural Economics Association should join the Council for Agricultural Science and Technology?
   ___ yes ___ no ___ undecided
   (Please check one)

2. If you checked "yes" in No. 1, please rank the following reasons (1 is most important, 2 next, etc. Rank as many as you consider important.)
   ___ a. A substantial number of agricultural professional societies are members of CAST.
   ___ b. A substantial number of agricultural economists have been and continue to be included on CAST task forces.
   ___ c. CAST provides an important vehicle for multidisciplinary interaction on policy issues.
   ___ d. CAST establishes a closer connection between agricultural sciences and current, public decision making.
   ___ e. CAST can respond to current policy issues more quickly than such groups as the National Academy of Sciences.
   ___ f. CAST has had an important impact on some policy issues.
   ___ g. Other (please specify) ________

3. If you checked "no" in No. 1, please rank the following reasons (1 is most important, 2 next, etc. Rank as many as you consider important.)
   ___ a. AAEA should not be associated with possible implicit or explicit policy positions of CAST.
   ___ b. Industry financial support of CAST or participation on CAST task forces influences its objectivity.
   ___ c. The annual AAEA membership fee is excessive.
   ___ d. CAST membership may endanger AAEA's tax-exempt status.
   ___ e. CAST's operating procedures on task force authorization and composition, and press relationships are unsatisfactory.
   ___ f. CAST has had an insignificant impact on policy issues.
   ___ g. Other (please specify) ________

4. if you checked "undecided" in No. 1, please check one of the following:
   ___ a. Still not sufficiently acquainted with CAST and its role or purposes.
   ___ b. Although sufficiently acquainted with CAST, do not have strong feelings about AAEA membership in CAST.

5. Please check the following:
   ___ a. Employer: Government ___ Industry ___ University ___
   ___ b. Professional status: Graduate Student ___ Professional < 40 years age ___ Professional ≥ 40 years age ___

Thank you for your cooperation.

Ad Hoc Committee on AAEA Joining COPAFS

In a letter to B. F. Stanton, 19 January 1979, Fred Leone of the American Statistical Association invited the AAEA to participate in a three-year pilot program to establish a "Committee of Professional Associations on Federal Statistics" (COPAFS). Acceptance of the invitation would involve AAEA designation of two members of COPAFS and a minimum contribution of $2,000 per year or $6,000 for the three-year pilot program. It also would involve the appointment of a committee on governmental statistics within AAEA (which could be a subcommittee of the Economic Statistics Committee).

President Stanton, in a letter of 5 February 1979, asked James Bonnen, Norman Coats, and Bruce Gardner to consider this issue and make a recommendation to the AAEA board.

To date (June 1979), eight associations have committed themselves to the pilot program. Six (including the American Economic Association) are contributing at the $2,000 per year minimum and two (American Statistical Association and American Sociological Association) at $3,000 per year. The pilot program would get its official go-ahead as of 31 December 1979, if funding is committed to put COPAFS near its $67,500 per year budget goal. The idea is to get about two-thirds of this from foundations, one-third from the associations. There is a commitment of a few thousand from Ford and $10,000 per year from Russell Sage, but there is still a distance to go on foundation funding—although the association funding is falling into place. (This information from Fred Leone.)

Considerations in Favor of Joining COPAFS

First, there are expected to be substantial changes in the federal data system and federal statistics in the next few years. AAEA members have a real interest in these changes—particularly in the collection and availability of good quality statistics of the most useful kinds pertaining to agriculture and to rural society. COPAFS may be influential in these changes. If AAEA is not involved, the changes have a reduced likelihood of serving rural data needs.

Second, the general decline in agriculture's political self-sufficiency leaves most rural institutions more dependent on urban society and political institutions. We no longer can rely on agricultural economists alone, or even the land grant univer-

sities or USDA as a sufficient political arm to promote the data base necessary for scientific progress in rural social science. COPAFS is a mechanism for agricultural economists to become part of a broader organizational base for improved statistics.

The preceding are the major reasons why COPAFS membership for AAEA would be beneficial to the agricultural economics profession. Some less central benefits are the following: (*a*) Regular contact of the AAEA representatives with professionals in other fields will be helpful in keeping up with events and interests of these groups in statistics. This knowledge could be useful in formulating our ideas and working for improvements in federal agricultural statistics outside COPAFS. (*b*) COPAFS is expected to contribute to the improvement of the federal statistical system, and AAEA support would contribute to the success of COPAFS. Therefore, we can expect our assistance to have some marginal effect on the overall quality of and investment in federal statistics. (*c*) AAEA would be, and would be perceived to be, a better citizen in the community of professional societies if we participated than if we did not.

Considerations Opposed to Joining COPAFS

There are two primary arguments in opposition to AAEA participation in COPAFS: (*a*) the cost $2,000 per year for three years; and (*b*) there is a chance, as in any such venture, that COPAFS could be ineffective or not fully represent AAEA interests. Thus COPAFS is a risky investment.

Two other issues have come up which we do not consider to be serious obstacles to AAEA participation in COPAFS but which have generated some concern.

First, the AAEA already participates in the Federal Statistics Users Conference (FSUC), and the question of overlap has arisen. In fact, the FSUC is one of the main supporters of COPAFS, and the two would work in cooperation. The difference is that FSUC represents general interests in federal statistics and is largely business-oriented. COPAFS is explicitly set up to be concerned with statistics as a basis for social science research. This is the topic that would seem to be of prime importance to AAEA in attempting to ensure the continued development (or prevent the further erosion) of the statistical basis for rural social science research.

Second, how the AAEA sees an outlay of time and money on COPAFS may be influenced by the outcome of the membership poll on CAST. However, the issues involving CAST are of a substantially different nature. CAST concerns public issues and taking positions on them. AAEA membership in CAST might promote better public choice, but such membership may not be of direct interest to agricultural economists themselves. COPAFS, on the other hand, involves issues of direct self-interest to the agricultural economics profession; therefore, even if the AAEA membership rejects CAST, participation in COPAFS should be given serious consideration.

Recommendation

We recommend that the AAEA join COPAFS for the period of the three-year pilot program, with careful annual review of its progress.

Bruce Gardner, chairman

Minutes

Minutes of the Executive Board Meeting, Pullman, Washington

The meeting of the Executive Board was called to order by President B. F. Stanton at 8:30 a.m., 28 July 1979.

Present: Voting Members:
Stanton, Lane, Coffey, Hopkins, Crowder, Hildreth, King, Brown, Schuh

Members ex-officio:
Redman, Rhodes, Eisgruber, Colyer, Blakley

Guests:
Tweeten, Harl, Rogers, Loomis

1. Stanton read the report of the Tellers Committee which indicated that Luther Tweeten was elected as president-elect and Neil Harl and Carleton Dennis were elected as directors.

2. Stanton reviewed the agenda and made additions.

3. Loomis as conference coordinator reported on local arrangements, indicating 770 economists had preregistered, 214 papers were scheduled, and plans were proceeding smoothly.

4. Redman presented the minutes of the January 1979 Board meeting. Lane moved the approval. Seconded. Passed.

5. Redman gave the report of the secretary-treasurer for 1978 and the report on investment activity for 1978. These will be presented at the general business session.

6. Coffey as chairman of the Finance Committee reported on the meeting held in Lexington, on 23 May. The report included a review of the 1978 operating statement and balance sheet, comparison of investment guidelines and performance, a proposed 1980 budget, and recommendations by the committee. Coffey moved that the deadline for payment of dues be moved from 1 April to 15 January and that membership shall become delinquent as of 16 January; if dues are not paid prior to that date, members will not be entitled to receive the February issue of the *Journal*. However, if dues are paid on or before 1 April, membership will be restored and the member will be entitled to vote. Back issues missed are to be supplied with an additional charge of $1.00 per issue to defray the cost of postage and handling. Seconded. Passed.

7. Coffey moved that the policy adopted at Blacksburg, Virginia, charging a $5.00 lump sum for mailing back issues of the *Journal* be rescinded and that $1.00 be charged for each issue mailed. Seconded. Passed.

8. Coffey moved that all dues and subscriptions be collected in U.S. dollars or its exchange equivalent. Seconded. Passed.

9. Coffey moved that members and nonmember subscribers of the *Journal* with addresses outside the U.S., Canada, and Mexico be assessed a surcharge of $2.00 to cover the postage differential for mailing the publication. Seconded. Passed.

10. Coffey moved that all present and future volumes of the *Literature Review* be handled and mailed direct by the University of Minnesota Press. Seconded. Passed.

11. Coffey moved that investment guidelines for the portfolio be updated and changed to read as follows:

(*a*) Choose a low risk portfolio with a buy and hold strategy;

(*b*) Achieve a minimum of 7.5% annual rate of return on market value;

(*c*) Achieve a 5% rate of growth in dividend payout.

(*d*) Hold a portfolio containing 15%–50% debt issues with remainder being in equity issues.

After considerable discussion of the adequacy of these guidelines, Coffey withdrew the motion. Crowder and Schuh agreed to develop a motion reflecting a consensus of the Board. Crowder moved the following guidelines for portfolio management:

(*a*) Maintain a diversified portfolio consisting of debt, equity, and cash or cash equivalent instruments;

(*b*) Encourage the Finance Committee to consider "nontraditional" debt issues, such as REIT's, mortgage funds, housing authority bonds, investment trust certificates, etc.;

(*c*) Achieve a moving two-year average rate of return at least equal to the rate of inflation (GNP);

(*d*) A buy and hold strategy shall be followed for debt and preferred stock issues;

(*e*) All recommendations to the Executive Board for common stock purchases will include a recommended stop-loss point. If the Executive Board approves the common stock recommendation, it will also approve or disapprove the stop-loss recommendation, including whether or not to place a stop-loss;

(*f*) Between Executive Board meetings, the Finance Committee is authorized to trade common stocks equal in value to a maximum of 15% of the value of common stocks in the portfolio. A stop-loss will be placed at a level not more than 15%

below purchase price levels of stock bought. The committee will report all stock transactions to the Board within one week of the transaction date. The committee will make a quarterly report to the Executive Board on the portfolio. Seconded. Passed.

12. Coffey moved that selected target prices be used in combination with selected stop losses on stock we wish to eliminate from the portfolio rather than a blanket stop loss on all stocks, and that the portfolio be monitored on a quarterly basis to select stock to be eliminated from the portfolio. Seconded. Passed.

13. Coffey indicated that the Finance Committee recommended approval of a revision of reprint charges and advertising rates in the newsletter, but that a decision on this matter be delayed until the editor's report is heard.

14. Coffey moved that the dues schedule and other revenue earning rates be set and expenditures controlled so that the portfolio at market value will be maintained in the rate of .75 to 1.5 times the annual expenditures. Seconded. After much discussion on the proposal the motion was defeated by a vote of 7–1.

15. Schuh moved that by-laws and Board policies be changed to reflect the above motions. Seconded. Passed. Harl agreed to propose these and other appropriate changes in by-laws for Board action near the end of the meeting.

16. Redman presented a supplemental report from the Portfolio Investment Subcommittee recommending the following points:

(*a*) No new investments should be made now and that funds remain invested in the Ready Asset account. The committee feels that equity markets still have not built a strong enough base for recovery and that the Ready Asset account will generate a yield comparable or better than current bond yields as well as being more liquid.

(*b*) Authority should be given to buy Continental Corporation at $23–24. The committee feels this is a quality issue and would like to purchase it should the price decline from its current level (26-1/2 as of 19 July).

(*c*) The portfolio should be moved from Merrill Lynch to Bache. Bache can provide similar services in terms of investing dividends and other liquid funds. Bache seems eager to service the account, is willing to provide an independent appraisal at their expense (in addition to their own), and appears to have more timely advisory services.

(*d*) The committee is reviewing the status of Chase Manhattan stock so that a decision can be made as to whether or not to eliminate it from the portfolio. Crowder moved the approval of moving the portfolio from Merrill Lynch to Bache. Seconded. Passed. It was felt that the guidelines previously approved would permit the Investment Committee to carry out the other recommendations.

17. Rhodes as editor gave a summary of the report to be given at the general business session. He reminded the Board that a new editor is to be named soon. Schuh moved that an ad hoc committee be appointed to solicit, review, and advise the Board at the Winter Meeting on selection of an editor. Seconded. Passed. Schuh and Hopkin were appointed subsequently by Stanton to solicit and receive nominations for review at the December meeting.

18. Rhodes presented a proposed revision of the reprint price schedule as follows:

	No. of Pages			
	1–4	5–8	9–12	13–16
(*a*) First 100 copies current	$31.50	$47.25	$ 56.25	$ 63.00
proposed	60.00	90.00	120.00	150.00
(*b*) Add'l 100 copies current	12.50	19.50	23.75	30.75
proposed	20.00	30.00	40.00	50.00

Those paying page charges would pay the lower rates for any additional copies because they are provided 100 copies at no additional cost while those not paying the page charge must buy the 100 copies first before being eligible to buy additional copies at the lower rate. At present, all purchasers must purchase the first hundred copies. Lane moved that the new schedule be adopted. Seconded. Passed.

19. Rhodes reported that the preparation and publishing of the *AAEA Newsletter* had gone smoothly and expressed confidence that it will become more useful as committees and members learn to use it. Rhodes proposed that the advertising rate in the newsletter be revised from the *Journal* rates of $210 full-page, $115 half-page, $70 quarter-page, and $50 for a short position open ad to the following, which would be more workable:

(*a*) Continue the rate of $50 for employment ads of 85 words or less;

(*b*) For other ads, including those with several positions, the rate be $15 per column inch or fraction thereof, with a $60 minimum and photo-ready full page ads set at $275. The present $50 ad would equal about $12.50 per column inch. There are 19 column inches per page and a full page ad would be

$285 when prepared by the editor. This $275 rate would provide a $10 discount if prepared by the advertiser. Hopkin moved the adoption of the recommended advertising rates. Seconded. Passed.

20. Rhodes reported on criteria for publication outlets for AAEA reports. In 1978, the Board approved the practice of publishing abstracts in the *Newsletter* instead of the full report in the *Journal*. It was recommended that the *Journal* continue to include in full (*a*) the reports of the President, Reso-

would spread the workload of these officers. The significant change from the present practice is to suggest that the president-elect serve as the invited papers program chairman for the summer meeting using the Board as the program committee. The major duties of the person moving through the three positions include:

(*a*) President-Elect: (i) prepare and deliver the presidential address; (ii) serve as invited papers program chairman for summer meeting; (iii) plan

are to sign a form that assigns the authors' and their employers' copyrights to the AAEA. Such a transfer is required for publication, except for manuscripts already in the public domain, such as those of federal employees. Sample suggested statements were provided.

Hildreth moved the report be approved and the steps be implemented. After publication of such notice of the new policy in the *Newsletter* and in the February 1980 issue of the *Journal,* all articles accepted after 1 March 1980 will be subject to the new copyright policy. Seconded. Passed.

26. Stanton presented copies of the final report by the AAEA Committee on Management, Structure, Methods, and Procedures, chaired by Sundquist. It was noted that activities had been put in motion to implement most of the committee recomendations. Further, the committee was not unanimous in its specific recommendation on establishing an executive office for AAEA. Sundquist recommended that this report be presented to the membership for "information only" and that the committee be officially dissolved. Crowder moved that the report be received and the committee be dissolved with thanks. Seconded. Passed.

27. Stovall gave a preliminary report for the ad hoc committee on establishing an office for AAEA. Four alternatives are being explored: (*a*) an office in Washington or Chicago, which would cost an estimated $78,000 more than the secretary-treasurer's office now located in Kentucky (this would amount to about $12 per member and subscriber). (*b*) Contract with another association, such as American Dairy Science Association, to provide business management services including updating of the membership list, handling receipts and disbursements, handling all business and financial aspects of the *Journal,* sending out annual dues notices and receiving and recording dues payments, preparation of income and expense statements, and handling preregistration for annual meetings. For this, the cost is currently $4.50 per member, or about $29,000 per year, and it will likely go to $5 per member. (*c*) Contract the business management function to a consultant. The committee does not have any estimate of cost of such service. (*d*) Continue the secretary-treasurer's office on a part-time basis at a university. It is quite likely that individuals and institutions will be more reluctant than in the past to subsidize the Association in this manner. No action was taken, but a general consensus of the Board was that moving the office to Washington or Chicago was not a viable option. The committee planned to meet again while at Pullman and will report again to the Board in December 1979.

28. Stanton presented a brief preliminary report from Farrell, chairman of the task force on an operational data based for AAEA activities. Initial staff work has been done, which consisted of systematic identification of key decisions made on a recurring basis by the Board and the secretary-treasurer, data required for such decisions, and the availability and location of such data. No decisions were made. The committee planned to meet while at Pullman and expects to have specific proposals for action within twelve months.

29. Padberg reported for the Awards Committee. It was the consensus of the Board that contestants receiving "honorable mention" should receive a letter of congratulations and a copy of the awards program from the chairman of the awards committee.

Lane presented some suggested changes in Article 5, Sections 3 and 4, to identify more clearly in the by-laws that the awards are for outstanding master's thesis and outstanding doctoral thesis and not for programs as such. Lane moved that the by-laws be amended to reflect the changes. Seconded. Passed. These changes will be presented at the end of the Board meeting and published in the updated version of the by-laws.

30. Hildreth reported on the meeting of International Association of Agricultural Economists meeting in Banff, 3–12 September 1979, indicating that ten AAEA members received travel grants from the $2,500 provided by the Association and matched from other IAAE sources.

31. A Report of the Membership Committee, chaired by Mathia, was received. It was noted that Raunikar of Georgia designed and produced a membership brochure and his work was commended. The report provided plans for continuous recruitment of members in individual state locations as well as regionally.

32. Extension Affairs Committee, chaired by Wood, sent a report defining some issues and reflecting the chairman's views regarding the committee and its activities. He requested more definitive direction from the Board for the committee.

33. Schrader reported for the Contributed Papers Committee. Coffey suggested that a more appropriate name be sought for the contributed papers. Because they are screened, they should have more prestige than commonly given them. Coffey moved that the name be changed from "contributed papers" to "selected papers" and to seek methods of publication. Seconded. Motion lost. After continuation of discussion, Lane moved that the name be changed from "contributed papers" to "selected papers." Seconded. Passed.

34. Johnson reported for the Professional Registries and Employment Committee, indicating that 2,480 persons were now listed in the Registry. During the year, the Illinois State Employment Service, where the Registry is located, received 290 job orders and placed 248 persons as compared to 123 a year ealier.

35. Riley reported for the International Committee. It has carried out an AID-funded study entitled "Needs and Strategies for Improving Training of Agricultural Economists for Work in International Agricultural Development." Fienup will present a paper at the IAAE meeting in Banff on the study. Preliminary results have been given at other meet-

ings as well as two symposia at Pullman. Other activities include suggestions to the AAEA Employment Registry Committee on ways to make the registry more useful to prospective employers in the international development area, and a request for arrangements that will expedite AAEA mailings to members residing in foreign countries.

Schuh moved that AAEA express appreciation to the International Committee for a good performance and excellent leadership. Seconded. Passed.

Hildreth moved that if there are no budgetary demands, the AAEA sponsor the publication planned by the International Committee summarizing the AID-funded study. Seconded. Passed.

Schuh moved that the President of AAEA write a letter to AID expressing its support for the type of activity currently done by the Research Training Network (RTN) of the Agricultural Development Council. Seconded. Passed.

36. Rasmussen reported for the Literature Retrieval Committee, indicating that the American Agricultural Economics Documentation Center now provides a range of bibliographic services. A publication is placed in the search system within six weeks after receipt. There has been a marked increase in requests for searches with turn-around time of twenty-four hours for a preliminary search and three days for a comprehensive bibliography.

Rasmussen presented a budget requesting that financial support be increased from $15,000 to $19,000. A question was raised on the extent of use outside the ESCS. The request for increase in funds was delayed until the overall budget is considered.

37. Bromley reported for the Professional Activities Committee which has been concerned with two issues: (*a*) The AAEA sponsorship of conferences, symposial etc. and the criteria for judging the propriety of AAEA sponsorship of various activities. Specific criteria were adopted by the Board at its winter meeting; (*b*) the concern for the future of AAEA which was spawned by the feeling that some important groups of potential members were being missed or that groups of current members were not being served as well as possible. While there was concern voiced about how to meet the needs of groups who viewed themselves as having minority interests, the Committee believed current actions on program and committee membership had helped to meet some of these needs. No action was taken.

38. Stanton presented a request from Charles W. Howe, desiring AAEA and AEA to cosponsor a symposium on the "value of weather information" with the American Meterological Society, with no financial involvement from AAEA. Also, he presented a request from J. L. Butt of the American Society of Agricultural Engineers to cosponsor a National Energy Symposium with no financial involvement.

Schuh moved that the chairman of the Professional Activities Committee and the President designate a person to explore the feasibility of joint sponsorship of a symposium on the value of weather information with the American Meteorological Society and to report to PAC by 1 December 1979 so a recommendation can be made to the Board at the winter meeting. Seconded. Passed.

Lane moved that the previous motion be applied also to the request to cosponsor a National Energy Symposium. Seconded. Passed.

39. O'Connor reported for the Resident Instruction Committee that fifteen papers have been accepted to be presented at the "special undergraduate contributed papers session." A symposium has been planned which has gone to the Professional Activities Committee for evaluation. The AAEA brochure has been approved and turned over to Redman for typesetting, photography, and printing. The by-laws pertaining to student activities are being updated and the Committee will present a revision for Board action in December 1979.

It was the consensus of the Board based on evaluation by the Professional Activities Committee that the idea behind the proposal for the symposium was good but it needed further work before implementation. It was also suggested that the President appoint a person to assist Redman in final preparation of the brochure.

40. Eckert reported on his role as the AAEA liaison person with the American Society of Agronomy and encouraged further interaction on programs.

41. Schuh reported as chairman of the Committee on Nominations for Fellows. The main function of the committee is to provide assistance to the executive board to assure that people deserving to be named as Fellows are considered and nominated. The procedures now followed were outlined. This year, a non-North American was named Fellow for the second time in the history of the Association.

42. Schuh reported as the AAEA representative to the National Bureau of Economic Research. The NBER has made substantial progress in resolving its financial and organizational problems, placing its own program development on a firmer base. Their headquarters were moved from New York to Cambridge, Massachusetts, and their publisher was changed from Ballinger to the University of Chicago Press.

43. Tweeten reported for the Census Advisory Committee on plans underway for the 1982 Census of Agriculture. The committee recommended, in view of budget limitations, that detailed census tabulation be retained and expanded where possible and costs be offset by publishing less detail. The detailed tabulations would be made available through microfilm user tapes, and special reproductions of data on request by users.

44. The Industry Affairs Committee report was circulated. The committee's suggestions for the summer program sessions were so close to what already had been developed, they decided to lend

support and not sponsor separate sessions. The committee is undertaking a project to establish a working list of industry economists and take a survey once the list has been developed to find who they are, what they do, provide a list of speakers and contacts for field trips, determine career path possibilities, and provide information for academic program planning.

45. Gardner reported for the Economic Statistics Committee. He reported on the follow-up activities on the outlook information survey as well as the activities of the task force on productivity measurement issues and on the economic value of statistical information. He discussed the advantages and disadvantages of the invitation for AAEA to participate in a Committee of Professional Associations' on Federal Statistics (COPAFS). It will involve a contribution of $2,000 per year for a period of three years to participate in a three-year pilot program. A staff would be established in Washington which could keep apprised of developments in federal statistics and facilitiate meetings and information exchange among COPAFS members. It was felt that expected changes in federal data systems and statistics in the next few years may affect the quality and usefulness of data pertaining to agriculture and rural society, and COPAFS members are expected to contribute to the improvement of the federal statistical system. The pilot program would get its official go-ahead as of 31 December 1979, if funding is committed to put COPAFS near its $67,500 per year budget goal. The decision to join COPAFS was delayed until the AAEA budget was considered.

46. Martin, as chairman of the Postwar Literature Review Committee, reported on the status of volumes 3 and 4 of the series. He recommended that AAEA authorize negotiations with the University of Minnesota Press on publishing the remaining manuscripts in two separate volumes. He also recommended that AAEA seek financial support from agencies interested in international agriculture for volume 4, which is proposed to consist primarily of a review of economic work in agricultural development in less developed countries.

Lane moved that the literature review publications committee negotiate with the University of Minnesota Press to publish volumes 3 and 4 and be authorized to make and implement the specific decisions involved. Seconded. Passed.

47. Herr reported for the Committee on Non-Land Grant Member Services and endorsed the proposal by the Resident Instruction Committee to sponsor an instructional workshop. He also suggested that this committee be discontinued.

48. Coffey presented a proposed budget.

Hopkin moved that AAEA join COPAFS and contribute $2,000 per year for three years. Seconded. Passed.

Hildreth moved that AAEA discuss the future of the Documentation Center for 1981 and beyond with ESCS, including assessing user charges and evaluation of use of the center. Seconded. Passed. A sum of $17,000 was budgeted.

Coffey moved that a contingency fund of $15,000 be established to cover expected expenses in the future, such as the *Handbook-Directory*. Seconded. Passed. A sum of $8,000 was included in the budget for the publication of volume 4 of the Literature Review.

Other specific adjustments were made which were relatively minor in the proposed budget.

Lane moved the adoption of the 1980 budget with a negative balance of $12,550. Seconded. Passed with one negative vote.

49. Stanton presented a letter discussing research priorities and raised questions about how AAEA should respond in the future to requests for AAEA comments and inputs.

Schuh moved that the Professional Activities Committee be asked to address the question of research priorities with their activities to be divided into two parts: (*a*) a short-term input into the federal budget process and ways to respond to it; (*b*) a longer-term consideration of agricultural economics research, teaching and extension at a variety of levels. Moreover, the outgoing president should participate with the PAC in this effort, and that the PAC in conjunction with the president create a subcommittee to deal with this set of issues. Seconded. Passed.

50. Future meeting sites for 1983 were discussed. Invitations were presented from (*a*) New Orleans, supported by Louisiana State University (*b*) Hot Springs, Arkansas, supported by University of Arkansas; (*c*) Louisville, Kentucky; and (*d*) Purdue University. Hopkin moved that the invitation from Purdue University be accepted. Seconded. Passed.

51. Harl presented a list of amendments to the by-laws required because of the various actions of the Board during the past two days. Hildreth moved the approval of the by-law ammendments and changes in Board policies as follows:

ARTICLE III, Section 1, first sentence amended to read:

> Each member shall pay Association's dues in United States dollars or equivalent for each year from 1 January to 31 December following, payable on or before 1 January of each year in advance.

The following sentences be added at the end of the section:

> Members of the Association and nonmember subscribers to the official *Journal* of the Association shall be charged an additional $2 per year to cover the cost of mailing the *Journal* to locations outside the United States, Canada and Mexico. The Executive Board may from time to time establish surcharges for expedited mailing of other items on an individual or subscription basis.

ARTICLE III, Section 2, the date be changed to 16 January.

ARTICLE V, Section 3, be amended to read as follows:

Outstanding Master's Thesis Award. The Outstanding Master's Thesis awards have as their objective development of professional excellence by individuals writing Master's theses in agricultural, natural resource, or rural economics. Three awards are offered. A cash supplement of $250 accompanies each award.

Nominations may be made from any department in which students write Master's theses in the areas of agricultural, natural resource, or rural economics.

(*a*) An entry must be submitted by the head or chair of the department where the degree is earned.

(*b*) A department may submit one nomination for each fifteen Master's theses or fraction thereof presented to a graduate school faculty in the calendar year preceding the year of recognition. In determining the number of eligible theses departments should limit consideration to theses in the areas of agricultural, natural resource, or rural economics.

(*c*) Nominations should include thesis or other comparable documentation.

(*d*) Selection will be made from documentation approved in final form by the student's advisory committee. The thesis will be eligible for the competition in the calendar year following the one in which the thesis was accepted by the graduate school or division of the degree-granting institution.

(*e*) A published thesis may be entered in both the published research and Master's thesis classes but is eligible for only one award. Although a published thesis is acceptable, a copy of the thesis as submitted to the graduate faculty should be sent whenever possible.

(*f*) Three copies of a thesis (or comparable document) must be sent to the subcommittee chair. All copies are returned after they have been read by the judges.

ARTICLE V, Section 4, be amended to read as follows:

Outstanding Doctoral Thesis Award. The Outstanding Doctoral Thesis awards are given in recognition of development of professional excellence by persons writing doctoral dissertations in agricultural, natural resource, or rural economics. Three awards are given accompanied by a cash supplement of $250 each.

An entry must be submitted by the head or chair of the department where the thesis or comparable document was presented in partial fulfillment of requirements for a degree.

(*a*) A department may submit one nomination for each twelve doctoral theses or fraction thereof presented in agricultural, natural resource, or rural economics to a graduate school faculty in the calendar year preceding the year of recognition. In determining the number of eligible nominations, departments should limit consideration to theses in the areas of agricultural, natural resource, or rural economics.

(*b*) Selection will be made from documentation approved in final form by the student's advisory committee. The thesis will be eligible for the competition in the calendar year following the one in which the thesis was accepted by the graduate school or division of the degree-granting institution.

(*c*) A published thesis may be entered in both the published research and thesis categories but is eligible for only one award. Although a published thesis is acceptable, a copy of the thesis as submitted to the graduate faculty should be sent whenever possible.

(*d*) Three copies of a thesis must be sent to the subcommittee chair. All copies are returned after they have been read by the judges.

Seconded. Passed.

52. Schuh moved that the Board express its appreciation to the outgoing members (Lane, Crowder, and Hildreth). Seconded. Passed.

53. Meeting adjourned 5:30 p.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Minutes of the Annual Business Meeting, Pullman, Washington

The 68th annual meeting was called to order by President B. F. Stanton on 31 July 1979, at 8:30 a.m.

1. Stanton presented for approval the minutes of the annual business meeting held at Blacksburg, Virginia, on 8 August 1978, as published in the "Proceedings" issue of the *Journal*. Motion was duly made to approve the minutes. Seconded. Passed.

2. Stanton announced officially the results of the election of officers. Luther Tweeten was elected president-elect, and Neil Harl and Carleton Dennis were elected as directors.

3. Stanton reviewed and commented on some aspects of AAEA activities during the year. (*a*) Membership has been maintained at a high level for the past two years largely due to not only the activity of the Membership Committee but due to the large number of members being involved in AAEA activities (*b*) The publication of the *AAEA Newsletter* was initiated in 1978. (*c*) The report of the special committee on management structure, methods, and procedures of AAEA activities was completed. (*d*) The Registry of Agricultural Economics is now an established enterprise, operated under a memorandum of agreement with the Illinois State Employment Service. (*e*) The AAEA contributes $17,000 per year, which is about 30% of the cash costs of operating the American Agricultural Economics Documentation Center, a joint enterprise with ESCS. (*f*) The annual meeting program, another major activity of AAEA, is the product of the Executive Board serving as program committee, the President, and President-Elect, who select the symposia, and the committee of seventeen who select the papers for twenty sessions from 213 pa-

pers contributed. And (*g*) the International Committee has been busy carrying out and AID-funded project on "Needs and Strategies for Improving Training of Agricultural Economists for Work in International Agricultural Development." Also, President Stanton (*a*) reminded the members that good work of committees and individuals too often are taken for granted and need member support; (*b*) expressed appreciation for the work of all the committees, especially the Ad Hoc Committee on CAST and the Finance Committee; (*c*) paid tribute to Presidents Nielson, Bonnen, Farrell, and Hildreth, who served during the years on the Board, and who created the wholesome outlook and atmosphere, providing a legacy to all who follow; (*d*) Extended best wishes to Crowder and Lane who leave the Board after three years of excellent service; and (*e*) extended a challenge to all to continue to foster creativity, to maintain the spirit of good will, and to discover new ways for the Association to serve the member needs and interests.

4. Redman presented the Secretary-Treasurer's Report for fiscal year 1 January 1978 through 31 December 1978. Redman also presented a report on AAEA investments for 1978. Motion was made to accept the reports. Seconded. Passed. The reports will be published in the "Proceedings" issue of the *Journal*.

5. Stanton presented the report of the certified public accountant on the financial condition of AAEA and announced that a copy would be on file for anyone desiring to examine it. Motion was made to accept the report. Seconded. Passed.

6. Coffey reported for informational purposes on some budgetary items for 1980, especially the major changes in estimated income and expenses.

7. Rhodes reported as editor of the *Journal*. His report was accepted and will be published in the "Proceedings" issue.

8. Connor reported on the survey conducted to determine if AAEA should join CAST. The recommendation based on the survey was that AAEA should not join CAST as a professional association member. Stanton reported that the Board had voted to accept the recommendation and asked the membership to affirm the action of the Board. Motion was made to accept the recommendation and to affirm the action of the Board. Seconded. Passed.

9. No old business was noted.

10. Tweeten presented a resolution expressing appreciation and gratitude to Washington State University for hosting the meeting. An enthusiastic round of applause expressed approval. The text will be in the "Proceedings" issue.

11. Stanton turned the chair over to Richard King as the Association's new president.

12. Meeting adjourned at 9:30 a.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal.*

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.
